Proefschrift

ter verkrijging van de graad van doctor aan de Universiteit Utrecht op gezag van de rector magnificus, prof. dr. W. H. Gispen, ingevolge het besluit van het college voor promoties in het openbaar te verdedigen op maandag 17 september des middags 12.45 uur

door

Carme Huguet

geboren op 11 oktober 1976 te Barcelona, Spanje

Promotor: Prof. Dr. Ir. J. S. Sinnighe Damsté
Co-promotor: Dr. Ir. S. Schouten

This work has been financially supported by the Research Council for Earth and Life Sciences of the Netherlands Organisation for Scientific Research (NWO-ALW) and the Royal Netherlands Institute for Sea Research (NIOZ), Texel, The Netherlands.

Bressol de tots els blaus

El meu amic el mar
té la calma d'un déu adormit,
quan la meva nau busca recer
a l'illa del seu pit.

El meu amic el mar
té el coratge d'un déu exaltat,
i quan s'omple d'aire el meu velam
seguim un joc incert.

I, tanmateix, potser
el gep de l'onada acabarà
amb tot el meu somni desitjós
d'anar a aquell port d'atzars.

El meu amic el mar
és l'immens bressol de tots els blaus,
i en el seu va-i-vé de so i color
aprenc el poc que tinc.

És per això que mai
no em podré allunyar del seu batec,
i fidel viuré amarinat
fins acabar el vent.

Lluís Llach

A la meva mare

A la meva família

A la Neus

Chapter 1

Introduction

1.1 Climate change

The Earth's surface temperature has risen by $0.76 \pm 0.2^\circ\text{C}$ from 1850 to 2005 with a stronger and accentuated warming trend in the past two decades [IPCC, 2007, <http://www.ipcc.ch>]. As the CO₂ concentration rose from a pre-industrial value of about 280 parts per million by volume (ppmv) to 379 ppmv in 2005 A.D. [IPCC, 2007, <http://www.ipcc.ch>], the question arises whether most of the warming is attributable to increased concentrations of greenhouse gases caused by human activities. It is now clear that greenhouse gas forcing is becoming the dominant, though not the only process driving the warming trend [IPCC, 2007, <http://www.ipcc.ch>]. To understand the extent of the anthropogenic impact on climate, we must have accurate climatic records that can help establish the natural climatic change. The understanding of natural climate change and anthropogenic impact can help to build and test models to predict future climate trends.

Climate on earth is defined as the long-term average of weather patterns including e.g. temperature, humidity, and seasonal changes and is ultimately controlled by solar energy and its interaction with the atmosphere. However, the atmosphere and the ocean are interdependent systems and the two are linked through complex feedback loops. For example, ocean currents are related to atmospheric wind patterns and higher air temperatures will influence sea surface temperatures (SST). Conversely, the oceans have an important role in climate, for example, through heat storage and redistribution through circulation patterns [Thurman and Trujillo 1999] as well as controlling the water cycle and precipitation patterns [Henderson, 2002]. Thus, SST is an important variable in the earth's climate system and can be linked to all the climatic processes. Determination of past SST is therefore of primary importance for the reconstruction of natural climatic changes, modeling of climate and reconstruction of ocean circulation. The best way to determine SST is to have instrumental records; however, these are usually regional and relatively short, covering at best the last two centuries. These short records do not allow the precise description of long-term SST changes or the accurate evaluation of the anthropologic impact on climate. To do that we need to

extend the climate records beyond the time scale of instrumental records when there was no anthropological impact. This can be achieved by modeling or assessed with temperature proxies. While mathematical models can be very useful, they still need long climatic records to validate them and increase their reliability and thus are also dependant on proxy data. For these reasons, accurate proxy records are essential to understand and predict future climate trends.

1.2 Reconstruction of past sea surface temperatures

Several geochemical proxies for SST reconstruction have been proposed since the 1950s, and they can generally be divided between proxies based in inorganic (calcite and opal shells and skeletons) and organic remains (lipid biomarkers) (Table 1). Some of the inorganic proxies use species composition to estimate past temperature (Table 1). A using sedimented species assemblage to estimate past temperatures, calibrated through modern assemblage composition, is a common technique and can be used to determine temperature at different depths depending on the group of species chosen (Fig. 1). One of the best known examples of the use of species assemblages are the CLIMAP maps [*Climap* 1981]. There are five basic temperature proxies based on assemblage composition: the Imbrie and Kipp method [*Imbrie and Kipp* 1971], the modern analog technique [*Hutson*, 1977], the modern analog technique with a similarity index [*Pflaumann et al.*, 1996], the revised analog method [*Waelbroeck et al.*, 1998] and the artificial neural networks [*Malmgren and Nordlund*, 1997]. However, all these methods have problems related to depth habitat and seasonality of the individual species, selective dissolution and lack of modern analogs (Table 1). All this techniques rely on a constant assemblage composition being associated to a single parameter and the lack of adaptative evolution of the species composing a particular assemblage. This kind of proxies range in accuracy between ± 0.4 and ± 2.7 (Table 1).

One of the most commonly used inorganic proxies takes advantage of the temperature dependant fractionation process of oxygen that takes place in calcite and opal producing organisms. Species of foraminifera, corals and molluscs build their shells using carbonates (CO_3^{2-}) and calcium (Ca^{+2}) (Fig. 1), while diatoms build their shells from silica and water (Fig. 1).

In both cases, O^{18} is preferentially taken up instead of the lighter O^{16} during the shell building process, but the proportion of O^{18} versus O^{16} varies depending on water temperature [Urey, 1947; Epstein *et al.*, 1953]. The ratio between ^{18}O and ^{16}O , expressed as $\delta^{18}O$, translates into temperature through an empirical relationship (Table 1). The use of $\delta^{18}O$ for SST reconstruction is complicated by several uncertainties related to the formation and preservation of shells as well as the carbonate ion concentration, and the $\delta^{18}O$ and salinity of the original seawater [e.g. Spero *et al.*, 1997; Wefer *et al.*, 1999; Lea, 2003]. Dissolution of shells become especially important when the $\delta^{18}O_{\text{opal}}$ is considered as opal is more prone to dissolution. Moreover there are vital effects related to the metabolic reactions performed by the organisms during shell formation (Table 1). Despite these caveats, this isotopic technique has errors of only $\pm 1^{\circ}C$ and is one of the most widely used SST proxies.

One of the more recent inorganic proxies uses an element ratio rather than an isotope one. Usually the composition of most calcareous shells approximates that of the minerals calcite and aragonite. However, in almost all shells there is a substantial substitution of Ca by the element Mg which seems to be a temperature dependant process and thus the Mg/Ca ratio can be used to estimate temperature [Elderfield and Ganssen, 2000] (Table 1, Fig. 1). While the Mg/Ca ratio is less dependent on the composition of the original sea water, other factors like the carbonate ion concentration, species-dependent vital effects and shell dissolution as well as the residence time of Mg and Ca over geological time scales are still an issue [Wefer *et al.*, 1999; Lea, 2003] (Table 1). The Sr/Ca ratio, which is also measured in calcite (Fig. 1), is based on the same principle as the Mg/Ca ratio and it has been used in coral skeletons to reconstruct SST [Beck *et al.*, 1992]. Similar to the Mg/Ca ratio, the Sr/Ca ratio is not only affected by dissolution but also by differences in growth rate. Moreover, the residence time of Sr is only 2.5 Myr, thus limiting the application of this proxy to Quaternary climate reconstructions as on longer time scales there is a lack of knowledge about the amount of Sr in sea water [Henderson, 2002] (Table 1).

The first proxy based on organic remains was proposed in 1986 by Brassell *et al.* [1986a]. This proxy uses the ratio of $C_{37:2}$ and $C_{37:3}$ long-chain unsaturated ketones synthesized by haptophyte algae to define the $U_{37}^{K'}$ index (Table 1) [Brassell *et al.*, 1986b]. Haptophyte algae are light dependant which means they must live in the upper part of the water column and thus there is usually a good correlation between $U_{37}^{K'}$ and SST (Table 1;

[Brassell *et al.*, 1986a]). The $U_{37}^{K'}$ index is often considered more robust than the inorganic proxies discussed above, as the values are not directly controlled by sea-water chemistry and, hence, assumptions concerning this are not required. Furthermore, global surveys of surface sediments and water column particulate organic matter reveal a strong and consistent correlation between the $U_{37}^{K'}$ and SST (reviewed by Herbert, [2003]). However, the biochemical function of alkenones is still unknown and the $U_{37}^{K'}$ may be affected by changes in the species composition through time, nutrient utilization [Prah *et al.*, 2005] and also by oxic degradation [Hoefs *et al.*, 1998; Gong and Hollander, 1999]. In addition, the $U_{37}^{K'}$ may be affected by seasonality and depth habitat changes of the haptophytes. Alkenones are mainly produced by *Emiliana huxleyi* but in certain areas there are also contributions of *Gyphrocapsa oceanica* thus creating uncertainties about species variability which could affect the $U_{37}^{K'}$ ratio [Herbert, 2003]. None the less the $U_{37}^{K'}$ is one of the most accurate proxies to date with an estimated accuracy of $\pm 0.7^\circ\text{C}$ and is been used in numerous paleocenographic studies [Herbert, 2003].

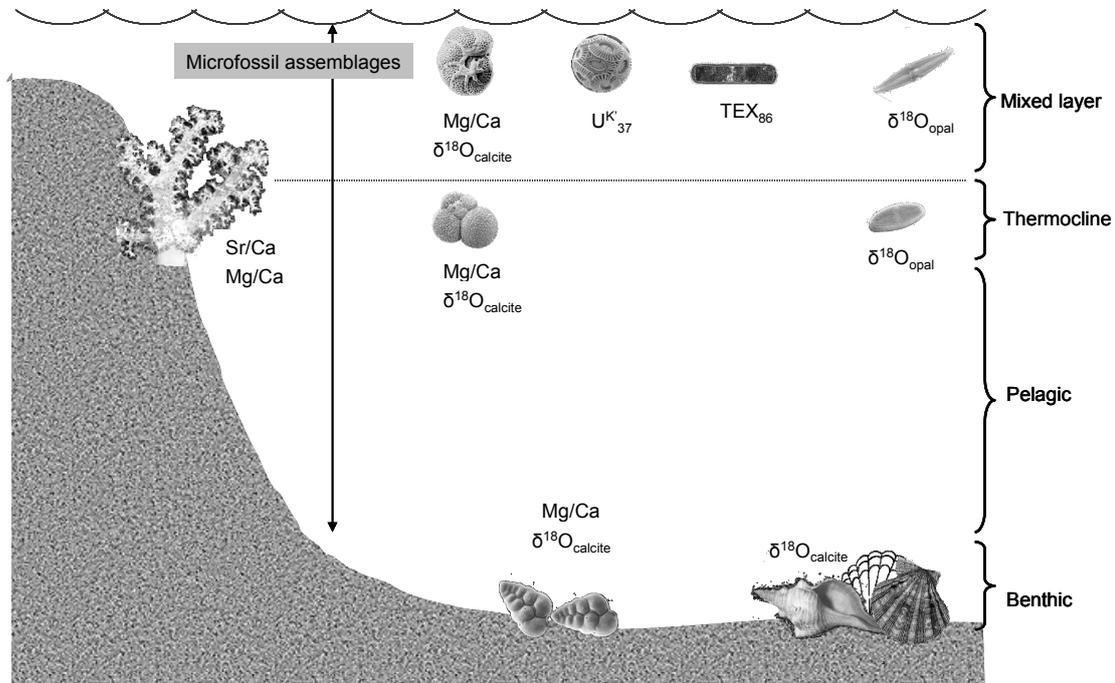

Figure 1. Schematic drawing showing the organisms from which sea surface temperature proxies are derived as well as their standard depth distribution.

In 2002, a second proxy based on organic remains was proposed by *Schouten et al.* [2002]. This proxy, the TEX₈₆, is based on the distribution of glycerol dialkyl glycerol tetraethers (GDGTs), membrane lipids of the marine Crenarchaeota Group I (Table 1), a group of micro-organisms belonging to the domain of Archaea and occurring ubiquitously in the ocean. Crenarchaeota biosynthesize isoprenoid GDGTs with a varying number of cyclopentyl moieties which has been found to change according to temperature [*Schouten et al.*, 2002; *Wuchter et al.*, 2004]. Although Crenarchaeota are distributed throughout the water column, TEX₈₆ values of particulate organic matter, sediment traps and sediment core tops are better correlated with SST (depths <100m) than with the temperature of deeper water [*Wuchter et al.*, 2006b] (Fig. 1). However, as is the case with the other temperature proxies, the TEX₈₆ proxy may be affected by seasonality and depth habitat changes of the Crenarchaeota as well as species variability through time (Table 1, and see below).

1.3 Biology and ecology of Crenarchaeota

Archaea were originally grouped within the extremophilic bacteria but genetic work by [*Woese et al.*, 1990] revealed that the Archaea form a separate domain of life (Fig. 2). Archaea synthesise unique membrane lipids that, coupled with their unique gene composition, sets them apart as a third domain of life [*Woese et al.*, 1990]. While Archaea are prokaryotes like Bacteria, they have similar replication and expression systems as the Eukarya, suggesting that they were the ancestors of both those groups and thus positions them at the base of the evolution tree [*Woese et al.*, 1990]. Archaea are further subdivided into three phyla, the Crenarchaeota, including marine Group I, the Euryarchaeota [*Woese et al.*, 1990] and the Korarchaeota [*Barns et al.*, 1996] (Fig. 2).

Marine Crenarchaeota Group I (Fig. 2) have been found in a wide variety of aquatic environments like marine settings [*Murray et al.*, 1998; *Murray et al.*, 1999b; *Teira et al.*, 2004; *Herndl et al.*, 2005], large lakes [*MacGregor et al.*, 1997; *Powers et al.*, 2005] and rivers [*Herfort et al.*, 2006; *Kim et al.*, 2006]. Crenarchaeota are distributed throughout the water column [*Massana et al.*, 1998; *Murray et al.*, 1999b; *Massana et al.*, 2000; *Karner et al.*, 2001; *Wells et al.*, 2006] though the highest abundances are usually noted in the upper hundred meters both in the Pacific [*Karner et al.*, 2001], the Atlantic [*Herndl et al.*, 2005] and

in the Black Sea [Coolen *et al.*, 2007]. However, there are known exceptions for the Santa Barbara Basin [Murray *et al.*, 1999a], and the Arabian Sea [Sinninghe Damsté *et al.*, 2002a].

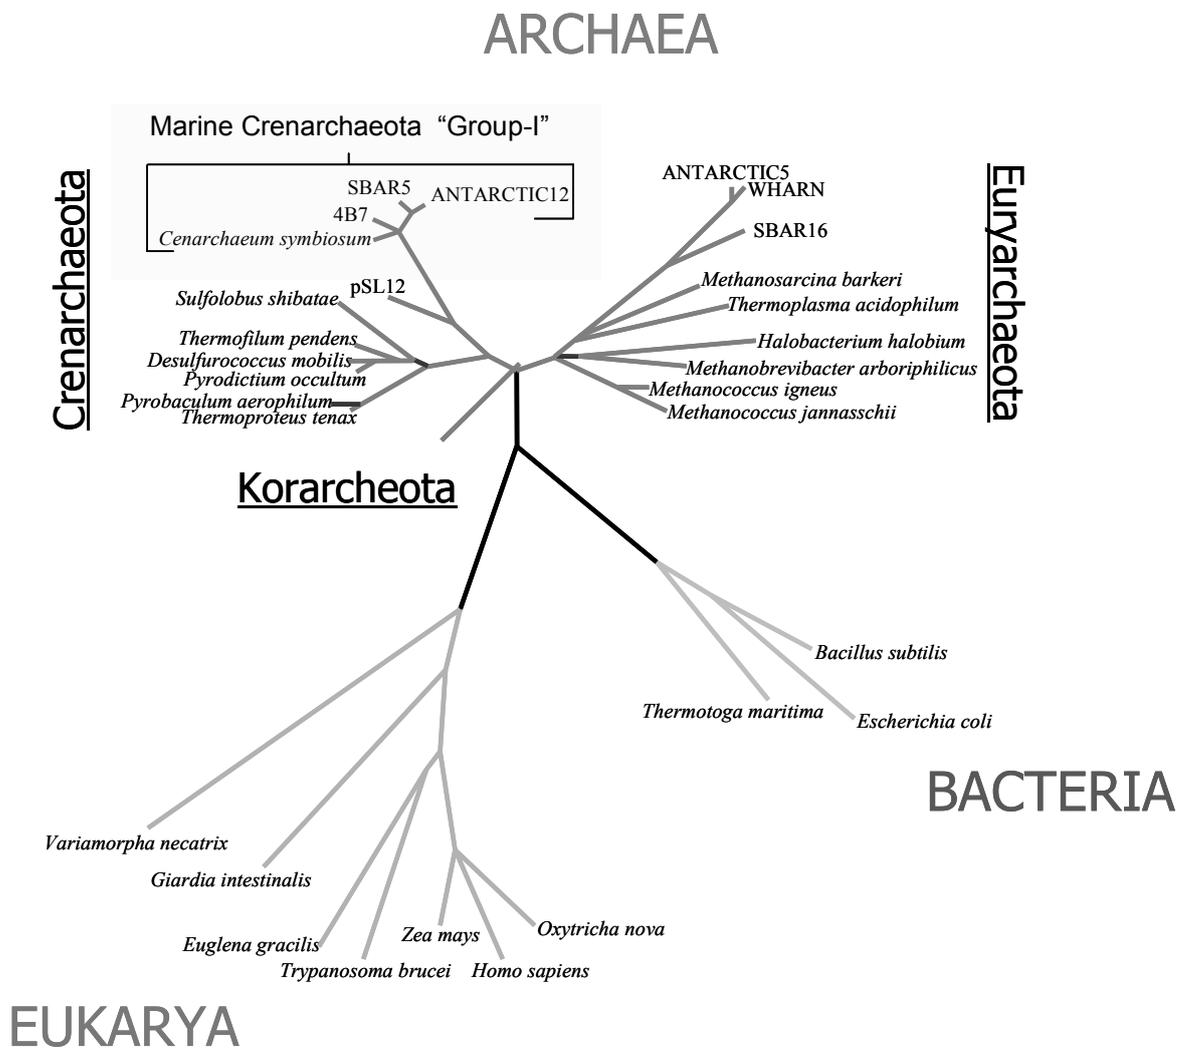

Figure 2. Tree of life based on rDNA showing the three main Domains of life. Archaea are further subdivided into three kingdoms, the Crenarchaeota, including marine Group I, the Euryarchaeota [Woese *et al.*, 1990] and the Korarchaeota [Barns *et al.*, 1996]. The Group I Crenarchaeota has been highlighted.

Crenarchaeotal abundance may also vary with season. High abundances have been reported in winter in the North Sea [Wuchter *et al.*, 2005], the Santa Barbara Basin [Murray *et al.*, 1999a] and the Pacific Ocean [Karner *et al.*, 2001]. Supposedly, in these environments Crenarchaeota thrive in winter as then they do not need to compete for ammonia with phytoplankton (see below). However, in other areas the seasonality might be different; for example, in the Antarctic Ocean Crenarchaeota bloom in spring [Massana *et al.*, 1998; Murray *et al.*, 1999b].

Crenarchaeota have been suggested to be chemoautotrophs [Hoefs *et al.*, 1997], but the physiology of the marine Crenarchaeota is still largely unknown, although recently significant progress has been made. Crenarchaeota have been reported to take up dissolved amino acids [Ouverney and Fuhrman, 2000; Teira *et al.*, 2006] and recent evidence has shown that part of them are chemoautotrophic nitrifiers [Könneke *et al.*, 2005; Wuchter *et al.*, 2006a]. They reportedly take up NH_4 and, thus, are linked to the nitrogen cycle. However, the Crenarchaeota are a diverse group with a ubiquitous distribution [DeLong *et al.*, 1994] and potentially they may have a wide range of physiologies and ecological niches.

1.4. Membrane lipids of Crenarchaeota

Living cells have a cytoplasmatic membrane that functions as a barrier between the cytoplasm and the environment [van de Vossenberg *et al.*, 1998]. Cell membranes are also essential to control the exchange between the cell and the surrounding environment. Most cell membranes of Bacteria and Eukarya are formed by fatty acyl chains ester bound to glycerol with a polar head group. These phospholipids are organised in a bi-layer structure with the polar head-groups oriented towards the aqueous phase and the hydrophobic carbon chains position in the middle [van de Vossenberg *et al.*, 1998] (Fig. 3).

The cell membranes of Archaea on the other hand, are unique and different from the bi-layered cytoplasmatic membranes of Bacteria and Eukarya [Woese *et al.*, 1990]. Archaeal membrane lipids are composed of saturated isoprene chains of different length which are ether bound to glycerols and with a polar head group [Gliozzi *et al.*, 2002]. A large number of Archaea also synthesize tetraether membrane lipids which span the whole width of the membrane and form a mono-layer [de Rosa, 1996] (Fig. 3).

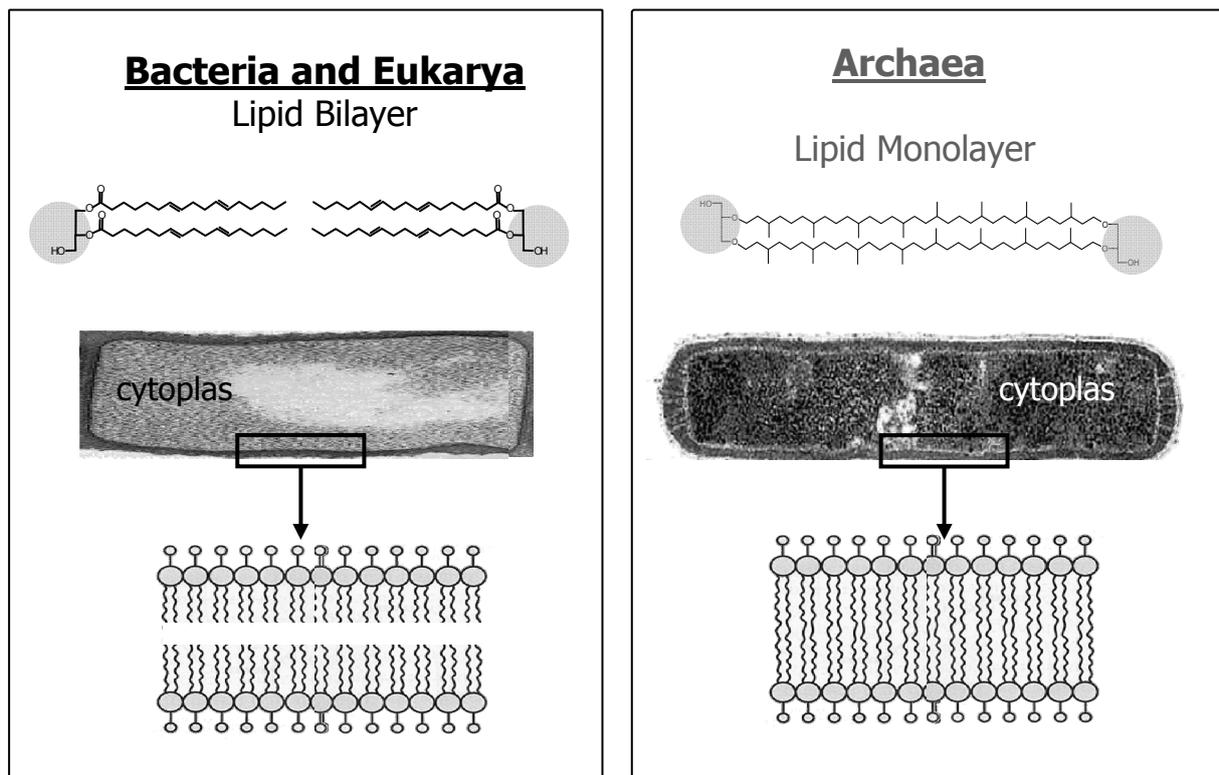

Figure 3. Membrane structure and lipids of Bacteria, Eukarya and Archaea.

Liposomes composed of archaeal tetraether lipids are more stable than bi-layer lipid ones and have extremely low proton permeability [*van de Vossenberg et al.*, 1998] which is thought to enable archaea to survive in extreme environmental conditions such as low pH, or high temperatures [*Gliozzi et al.*, 2002].

Remarkably, marine Crenarchaeota Group I also biosynthesize different types of GDGTs (Fig. 4a) despite that they do not live under extreme conditions. Their GDGTs contain 0 to 3 cyclopentane moieties (GDGT 0-3; Fig. 4a) and crenarchaeol (GDGT 4; [*Schouten et al.*, 2000a; *Sinninghe Damsté et al.*, 2002b]) which, in addition to 4 cyclopentane moieties, has a cyclohexane moiety. Crenarchaeol (GDGT 4) is thought to be a biomarker for the non-thermophilic Crenarchaeota [*Sinninghe Damsté et al.*, 2002b]. The unique presence of a cyclohexane moiety in non thermophilic Crenarchaeota compared to hyperthermophilic Crenarchaeota is thought to be the result of an adaptation of the latter group to relatively cold sea temperatures. To cope with the relatively lower temperatures in the ocean, a key step in the evolution of group I Crenarchaeota was the formation of the cyclohexane moiety which

created a three-dimensional structure that reduces the packaging of the membrane in cold conditions [Sinninghe Damsté *et al.*, 2002b]. This structural change still allows the exchange of products between the cytoplasm and the surrounding water while maintaining the integrity of the membrane. Crenarchaeota also biosynthesize small quantities of the crenarchaeol regioisomer GDGT 4' (Fig.4a).

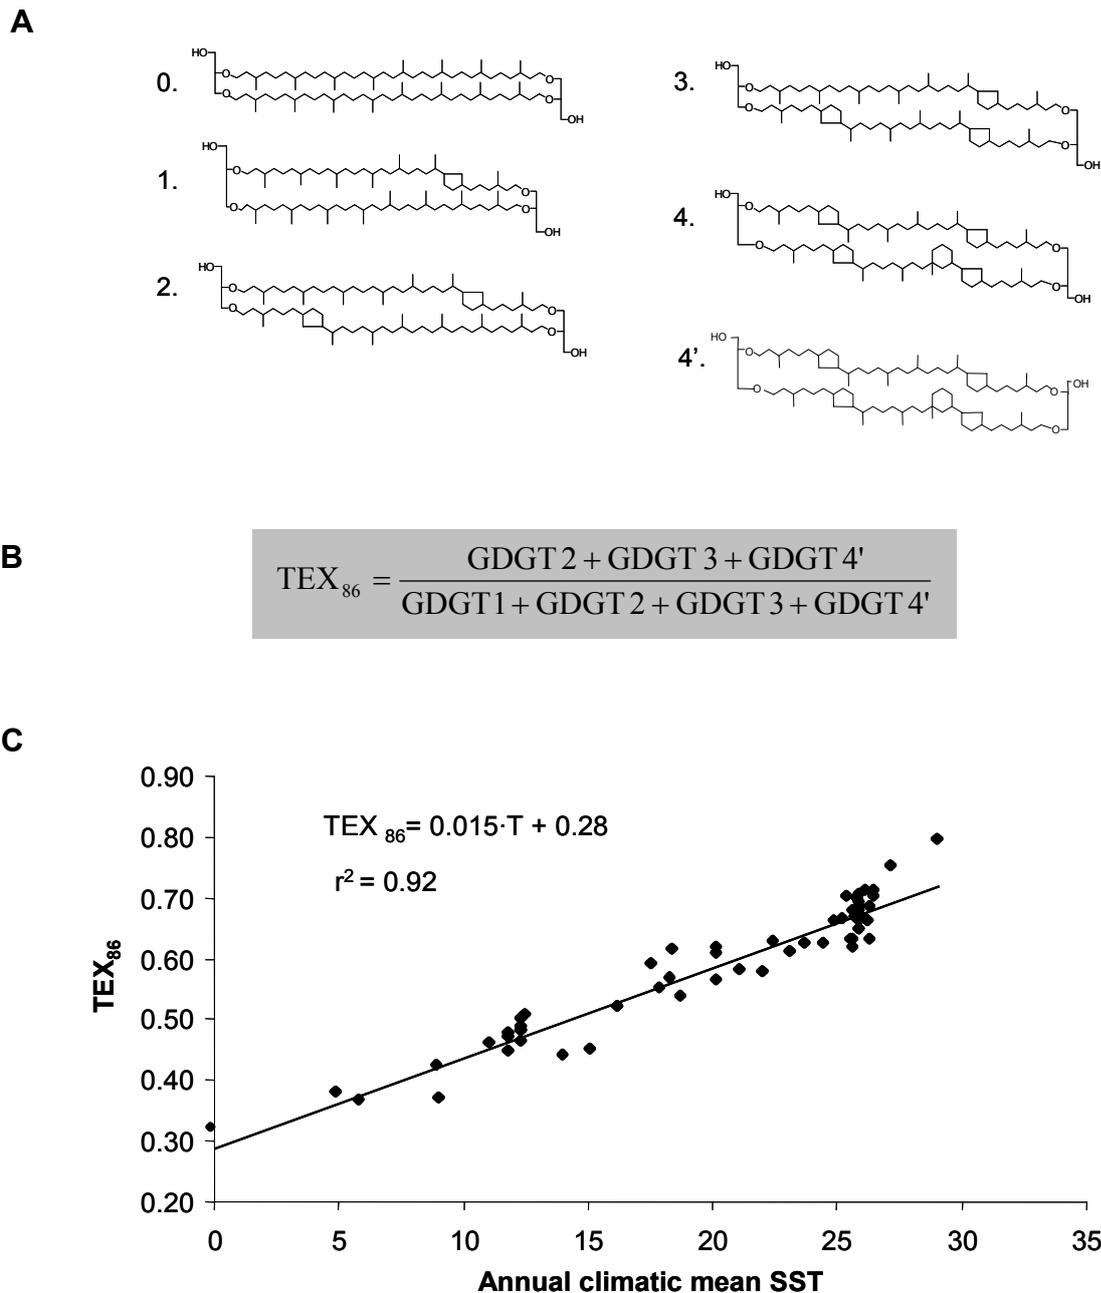

Figure 4. Definition of the TEX₈₆ proxy; a) GDGT lipids used in the TEX₈₆, b) the definition of the TEX₈₆ ratio and c) empirical correlation between TEX₈₆ values of core tops and annual mean SST [from Schouten *et al.* 2002]

Recently, it has also become clear that GDGTs such as those occurring in marine Crenarchaeota are present in lacustrine [Schouten *et al.*, 2000b; Powers *et al.*, 2004] and riverine environments [Herfort *et al.*, 2006]. Some of these crenarchaeotal GDGTs have also been found in terrestrial organic matter albeit in much lower abundances [Hopmans *et al.*, 2004; Weijers *et al.*, 2004].

1.5. Membrane lipids of Crenarchaeota as a new temperature proxy

Crenarchaeotal GDGTs are characterized by the presence of cyclopentane moieties. Previous culture studies of hyperthermophilic Archaea had already indicated that the relative number of cyclopentane moieties of GDGT membrane lipids changed with growth temperature [Gliozzi *et al.*, 1983; Sugai *et al.*, 2004], i.e. there is an increasing number of cyclopentane moieties with increasing temperature. This increase in the number of moieties is thought to provide a better packing of the membrane at higher temperatures [Gliozzi *et al.*, 2002].

This temperature adaptation has also been detected in the GDGTs of non-thermophilic Crenarchaeota and forms the basis for a new temperature proxy proposed by Schouten *et al.* in 2002. This proxy, the TEX₈₆, is based on the distribution of GDGTs (Fig. 4; Table 1); with increasing number of cyclopentane moieties in the GDGTs, the TEX₈₆ ratio also increases. This ratio was determined for a range of marine core top sediments and found to correlate well with annual mean SST [Schouten *et al.*, 2002] (Fig. 4c). However, this is merely an empirical correlation and there was no direct prove for a functional relationship between temperature and TEX₈₆. The observed correlation was confirmed by Wuchter *et al.* [2004] using a Crenarchaeota enrichment culture which was incubated under different temperatures. Their results showed that TEX₈₆ is linearly correlated with temperature and that changes in salinity and nutrients do not substantially affect the TEX₈₆ [Wuchter *et al.*, 2004]. A subsequent study of particulate organic matter (POM) from different marine settings revealed that the TEX₈₆ correlates well with surface water temperatures (depths <100m) and that the signal in the deeper water layers and surface sediments is primarily derived from these surface waters [Wuchter *et al.*, 2005].

The apparent paradox of a SST origin of the TEX₈₆ signal whereas Crenarchaeota also occur at much larger depths was explained by the GDGTs transport mechanism to the sediment floor, i.e. through consumption and re-packaging which mostly takes place in the active food web in the upper part of the water column [Wuchter *et al.*, 2006b].

The diagenetic stability of the TEX₈₆ proxy was also tested. To do this, a number of sediment samples deposited at the same time in oxic and anoxic settings in the Arabian sea were compared, and this indicated that the TEX₈₆ proxy seems to be unaffected by water redox conditions [Schouten *et al.*, 2004]. Artificial maturation of the GDGTs showed a clear effect on TEX₈₆-derived temperatures at higher maturity levels [Schouten *et al.*, 2004].

These initial results clearly showed that the TEX₈₆ is a potentially useful SST proxy. However, further validation of the TEX₈₆ proxy is clearly needed. For example, the analytical reproducibility of TEX₈₆ analysis was initially reported to be as high as 2°C [Schouten *et al.*, 2002]. In addition, this proxy had not been compared to either instrumental records or other SST proxies and was, until recently, not used in paleoceanographic studies. Thus, further research is necessary to validate the TEX₈₆ as a SST proxy and understand its use and limitations.

1.6. Scope and framework of the thesis

The main objective of this thesis was to improve, validate and apply the TEX₈₆ proxy. The thesis is divided in three parts:

- I. Analytical aspects of measuring the TEX₈₆
- II. Transport mechanisms and influence of diagenesis on the TEX₈₆ signal
- III. Application and validation of the TEX₈₆ proxy

Part I covers the analytical aspects and consists of **Chapters 2 and 3**. **Chapter 2** deals with the analytical aspects related to the work-up procedures and the methods to determine the TEX₈₆. Extraction using Soxhlet, ultrasonic, and accelerated high pressure extraction techniques did not give a significant bias in TEX₈₆. The same was true when two different HPLC/APCI-MS set-ups were used to determine the TEX₈₆. However, comparison of TEX₈₆

analysis using Single Ion Mode (SIM) and mass scanning detection, respectively, revealed that SIM is up to 2 orders of magnitude more sensitive.

The detection limit of the GDGTs was also established and shown to be 0.05 ng GDGTs injected on-column. At higher levels the TEX₈₆ could be analyzed with a reproducibility of 0.3°C.

Chapter 3 focuses on the testing of a synthetic internal standard (C₄₆ GDGT) to improve the accuracy of absolute GDGT abundance measurements. Initially, GDGT abundances were determined with an external standard curve but the introduction of an internal standard greatly improved the accuracy and reproducibility of the abundance measurements, reducing the standard deviation from 43% with the external standard curve to only 5% with the internal standard. Thus, the new internal standard technique will greatly improve the accuracy of GDGT abundance measurements, enlarging the potential of GDGTs in (paleo)ecological studies and enabling the detection of degradation patterns in studies such as the one in Chapter 6.

Part II of the thesis deals with the transport of the signal from the water column to the sediment and the effect of GDGT degradation on the TEX₈₆ signal. The origin and transport of the signal was covered in **Chapter 4**, where different transport mechanisms and possible degradation of GDGTs through incorporation in the food web was investigated by analyzing GDGTs in stomachs and intestines of crustacean decapods. Results from this study suggested that both passive (by sinking particles) and active (by organism migration) transport mechanism can explain, at least in part, the transport of GDGTs from surface waters to the sediment. GDGTs were found in most decapods' guts, suggesting they are taken up by decapods and that they are transported to the sediment by their faecal pellets. Furthermore, pigment analysis of the stomach content confirmed that the fresh GDGT signal can be transported by massive falls of organic matter after peaks in surface production. GDGT abundances are significantly lower in intestines, but TEX₈₆-derived temperatures are not significantly different between stomachs and intestines (<1°C), suggesting that TEX₈₆ values are not altered during gut transit.

In **Chapter 5** a two year sediment trap series was analyzed to understand the factors that control the production and transport of the TEX₈₆ signal in the Santa Barbara Basin (SBB). Highest fluxes of crenarchaeotal lipids in the water column were found in May-June

1996 and from October 1996 to January 1997, and in general showed a good correlation with mass fluxes.

TEX₈₆ reconstructed temperatures from the sediment trap series ranged from 8-11°C and were usually substantially lower than sea surface temperatures (SST), indicating that, unlike in previous studies, the TEX₈₆ corresponds to sub-surface temperatures, likely between 100-150 m. TEX₈₆ temperature variations observed in trap samples were not coupled to changes in SST or deep-water temperatures and only to some degree with crenarchaeotal lipid fluxes. This suggests that a complex combination of different depth origins and seasonal growth periods of Crenarchaeota contributed to the variations in TEX₈₆ signal during the annual cycle. We also analyzed a high resolution record for the last 150 years from this basin which confirmed the sub-surface origin of the TEX₈₆ signal in this particular setting. This result highlights the importance of performing calibration studies using sediment traps and core tops before applying the TEX₈₆ temperature proxy in a given study area.

In **Chapter 6** the effect of oxic degradation on the TEX₈₆ and Branched versus Isoprenoid Tetraether index (BIT) [Hopmans *et al.*, 2004], was evaluated by analyzing turbidite sediments from the Madeira Abyssal Plain (MAP). Concentrations of GDGTs were reduced by one or two orders of magnitude in the oxidized turbidite parts, suggesting substantial degradation of GDGTs. This was also the case for long-chain alkenones and to a lesser extent for organic carbon. Upon oxidation large shifts in the BIT and TEX₈₆ occurred which can be explained by a strong relative increase in soil-derived GDGTs compared to the marine-derived GDGTs. This selective preservation of soil-derived lipids which are chemically nearly identical to that of their marine counterpart strongly suggests that the mineral matrix to which soil organic matter is attached enhanced its preservation. The results show that care has to be taken when analyzing TEX₈₆ in sediments which have been exposed to oxygen for a long time.

Part III includes **Chapters 7, 8 and 9** and deals with the application of the TEX₈₆ in different settings. With a similar time span as the SBB study in Chapter 5 we analyzed two cores in the Drammensfjord, Norway in **Chapter 7**. While some of the signal could be coming from the chemocline our results suggest that TEX₈₆ indicates surface (upper 25m) temperatures. Moreover, TEX₈₆ temperature patterns seem to follow variations in the historical record of averaged spring to fall Oslo air temperature relatively closely suggesting

the signal is produced during this period. Therefore, TEX₈₆ temperature records of fjord sediment cores can potentially be a useful tool in reconstructing past variations of coastal climates.

Chapter 8 describes the behavior of the TEX₈₆ and U₃₇^{K'} during the last glacial-interglacial transition in two cores in the Arabian Sea. U₃₇^{K'} and TEX₈₆ SST records from two sites in the Arabian Sea revealed different temperature variations over the last 23 Kyr for each proxy. TEX₈₆ SST records were similar at the two study sites over the last glacial-interglacial cycle and were in phase with temperature changes recorded in Antarctica ice core records. This suggests that the TEX₈₆ records of SST in the area are mainly controlled by the southern hemisphere climate dynamics during the SW monsoon. U₃₇^{K'} SST records from the same cores are different in magnitude of change and differ also in phase, and are partly in phase with northern hemisphere climate dynamics during the NE monsoon. This is likely due to different growing seasons of the biomarker source organisms, and to a change in the upwelling dynamics and monsoon strengths between the LGM and the Holocene.

Finally, in **Chapter 9**, TEX₈₆ was applied to a sediment core spanning the Marine Isotope Stadials (MIS) 6 and 7 in the Western Mediterranean. A recent study in the Alboran Sea (Western Mediterranean, core ODP-977A) revealed that alkenone records not only show temperature trends similar to $\delta^{18}\text{O}$ records of *G. bulloides*, but also stadial-interstadial temperature changes during the penultimate climate cycle (from 244 to 130 cal. ky BP). To independently confirm these abrupt changes we have applied the TEX₈₆ proxy to reconstruct SST using the same sediment core and compared it with the previously published U₃₇^{K'} and $\delta^{18}\text{O}$ records. The TEX₈₆ indicates similar stadial-interstadial changes as detected with the U₃₇^{K'}, thus providing independent evidence for rapid temperature changes. However, the two proxies behave differently during glacial marine isotopic stage (MIS-6) and interglacial MIS-7. During MIS-7 there is very good correspondence in absolute SST estimates between the two proxies, but in MIS-6 the TEX₈₆ showed much larger temperature changes compared to the U₃₇^{K'}. We hypothesize that this may be caused by changes in the season in which the haptophytes and Crenarchaeota are blooming and/or variations in the depth habitat of Crenarchaeota. As the climate forcing differs between glacials and interglacials, a change in

seasonal patterns and/or depth habitat can be expected which could have a strong and differential effect on the TEX_{86} and U^{k}_{37} proxies.

In summary, the analytical work shown here has greatly improved the analysis of TEX_{86} as well as the determination of absolute abundances of GDGTs. Some of the possible transport mechanisms for GDGTs were confirmed and gut passage degradation of GDGTs was found to have no effect on the TEX_{86} signal. However, the degradation of GDGTs after long term exposure to oxygen was found to affect the TEX_{86} and caution should be exerted when the sediment cores are known to have been exposed to oxygen for long periods of time. Finally, the use of TEX_{86} as a paleo-proxy was validated by a number of down core applications and found to work in most of the study areas. This shows that TEX_{86} is a useful SST proxy which can provide complementary information to other SST proxies.

Chapter 2

Improved analytical methodology for TEX₈₆ paleothermometry by high performance liquid chromatography/atmospheric pressure chemical ionization-mass spectrometry

Stefan Schouten, Carme Huguet, Ellen C. Hopmans, Michiel V.M. Kienhuis

and Jaap S. Sinninghe Damsté

Published in *Analytical Chemistry* **79**, 2940-2944(2007)

Abstract

The TEX₈₆ is a recently proposed paleothermometer through which ancient sea water temperatures of up to 120 My ago can be reconstructed. It is based on the relative distribution of glycerol dibiphytanyl glycerol tetraethers as measured by high performance liquid chromatography/atmospheric pressure chemical ionization-mass spectrometry (HPLC/APCI-MS). The aim of this study was to examine and improve several analytical aspects in the determination of this important proxy in environmental matrices. Comparison of TEX₈₆ analysis using Single Ion Mode (SIM) and mass scanning (m/z 950 to 1450) detection, respectively, revealed that SIM is up to 2 orders of magnitude more sensitive and that the TEX₈₆ can be determined with a reproducibility of ± 0.004 or $\pm 0.3^\circ\text{C}$ using this method. Comparison of TEX₈₆ values obtained with two different HPLC/APCI-MS set-ups revealed no significant differences. In addition, analysis of TEX₈₆ of extracts obtained by Soxhlet, ultrasonic, and accelerated high pressure extraction techniques also showed no significant differences between the methods. Our results suggest that TEX₈₆ analysis by HPLC/APCI-MS is robust and can be determined with analytical errors comparable to those of other temperature proxies.

2.1. Introduction

Reconstruction of temperatures of ancient oceans is of crucial importance in understanding past climate changes and generally relies on the chemical analysis of ancient sediments. Several of these chemical temperature proxies are currently used to reconstruct past sea water temperatures and they can be broadly subdivided into proxies based on inorganic or organic fossil remains. Inorganic temperature proxies include, for example, $\delta^{18}\text{O}$ and Mg/Ca ratios of foraminifera and transfer functions of foraminiferal assemblages, [e.g. *Lea*, 2003]. The $U_{37}^{K'}$ ratio based on the relative distribution of di- and tri-unsaturated long-chain C_{37} alkenones derived from haptophyte algae was, until recently, the only proxy based on organic fossil remains. Originally proposed as a temperature proxy by *Brassell et al.*[1986] based on sediment core studies, it was later validated by temperature controlled culture studies of the haptophyte *Emiliana huxleyi* [*Prahl and Wakeham*, 1987]. The $U_{37}^{K'}$ is typically measured by determining the relative concentrations of long-chain alkenones using gas chromatography (GC) and a flame ionization detector and an analytical precision of $\pm 0.2^\circ\text{C}$ can be achieved [*Herbert*, 2003]. The analytical sensitivity can be further improved by using GC chemical ionization mass spectrometry [*Rosell-Melé et al.*, 1995] though this potentially also introduces analytical biases in determining this ratio [*Chaler et al.*, 2000].

Recently, a second organic sea water temperature proxy based on archaeal glycerol dibiphytanyl glycerol tetraether (GDGT) lipids, the TEX_{86} , was proposed [*Schouten et al.*, 2002]. These lipids are biosynthesized by marine Crenarchaeota which are ubiquitous in marine environments, occur throughout the water column and are one of the dominant prokaryotic groups in today's oceans [*Karner et al.*, 2001]. Marine Crenarchaeota biosynthesize different types of GDGTs, i.e. GDGTs containing 0 to 3 cyclopentyl moieties (GDGT 0-3; see structures in Fig. 1) and crenarchaeol which, in addition to 4 cyclopentyl moieties, has a cyclohexyl moiety (GDGT 4)[*Schouten et al.*, 2002; *Sinninghe Damsté et al.*, 2002]. Finally, they also biosynthesize small quantities of a crenarchaeol regio-isomer (GDGT 4'). A study of marine surface sediments showed that higher sea surface temperatures result in an increase in the relative amounts of GDGTs with two or more cyclopentyl moieties [*Schouten et al.*, 2002]. Thus, measuring the relative amounts of GDGTs present in sediments allows determination of the temperature at which the Crenarchaeota were living when they produced their membranes.

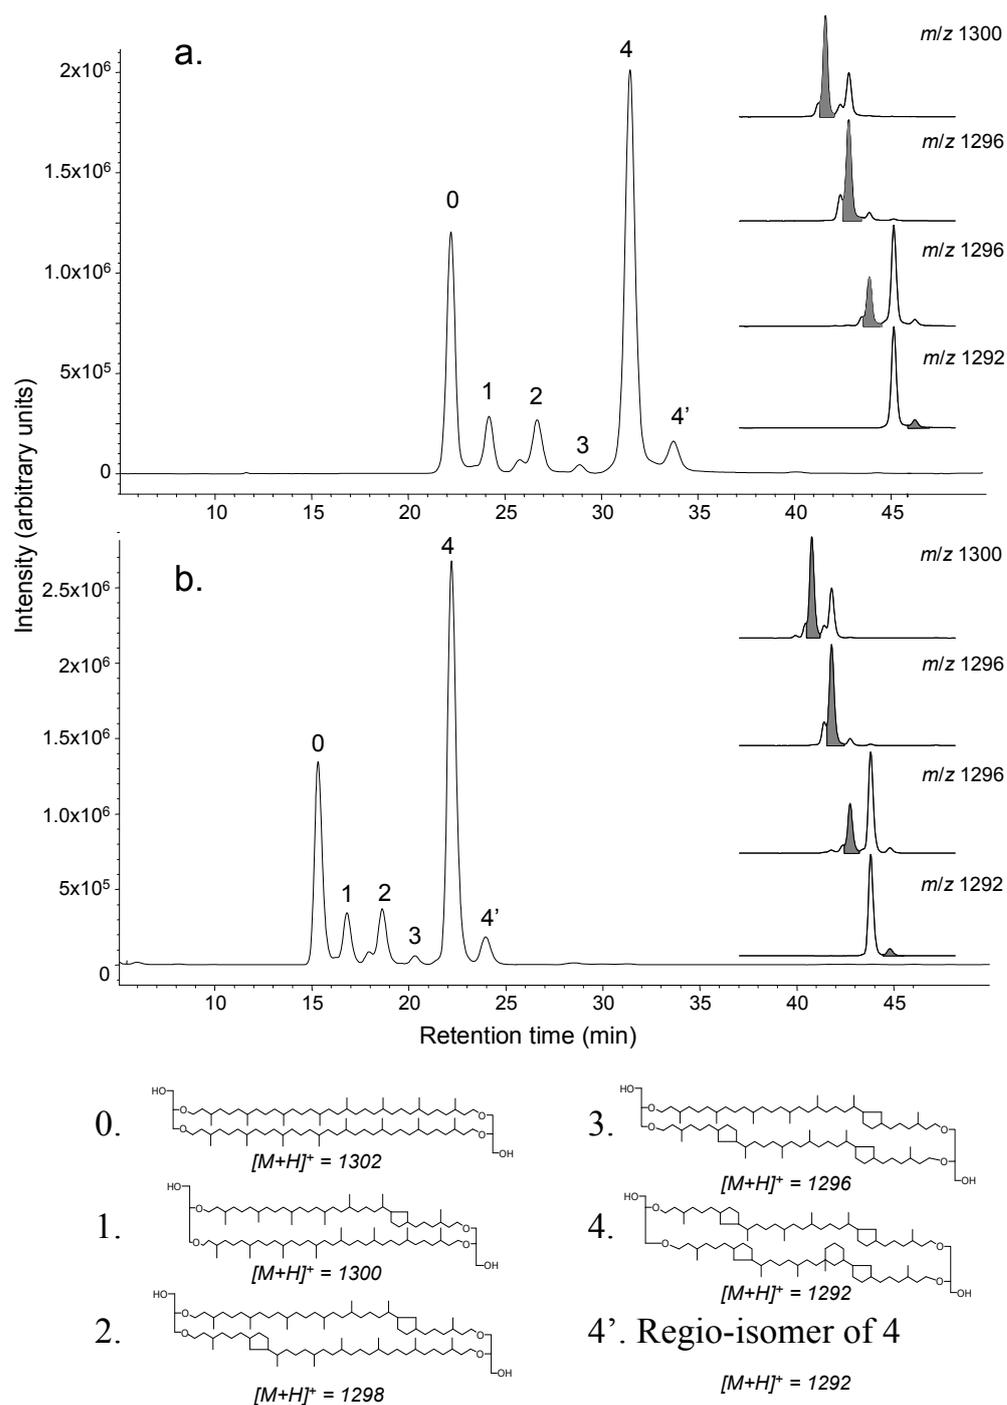

Figure 1. Base peak chromatogram of GDGTs eluting on (a) an Econosphere Amino column (4.6 x 250 mm, 5 μm) at 1 $\text{ml}\cdot\text{min}^{-1}$ flow rate and (b) a Prevail Cyano column (2.1 x 150 mm, 3 μm) at 0.2 $\text{ml}\cdot\text{min}^{-1}$. Inserts show mass chromatograms and integrated peak area's of the four GDGTs used in the determination of the TEX_{86} .

The TEX₈₆ ratio was proposed as a means to quantify the relative abundance of GDGTs (see also Fig. 1):

$$\text{TEX}_{86} = \frac{[\text{GDGT 2}] + [\text{GDGT 3}] + [\text{GDGT 4}']}{[\text{GDGT 1}] + [\text{GDGT 2}] + [\text{GDGT 3}] + [\text{GDGT 4}']} \quad [1]$$

TEX₈₆ was calibrated using over 40 sediment core-tops obtained from 15 different locations with the following resulting equation:

$$\text{TEX}_{86} = 0.015 \times T + 0.28 \quad r^2 = 0.92 \quad [2]$$

This equation allows the conversion of the calculated TEX₈₆ values into SSTs (see for details *Schouten et al.* [2002]).

This initial work has been followed by other studies which investigate the validity of the TEX₈₆ as a SST proxy. For example, mesocosm experiments confirmed that marine Crenarchaeota change their membrane composition with growth temperature [*Sinninghe Damsté et al.*, 2002] and a survey of particulate organic matter showed that TEX₈₆ values correlated well with in situ temperature at depths <100m [*Wuchter et al.*, 2005]. Furthermore, sediment trap studies revealed that the TEX₈₆ in sinking particulate matter in the Arabian Sea corresponds well with satellite-derived SST measurements [*Wuchter et al.*, 2006]. Application of the TEX₈₆ proxy in the reconstruction of glacial to Holocene SST in the Arabian Sea showed that several features in the TEX₈₆-SST record corresponded with well known global climatic temperature changes [*Huguet et al.*, 2006b].

Although these studies have now shown that the TEX₈₆ proxy is capable of reconstructing past SST, a number of issues still have to be resolved. The analytical uncertainty associated with determining TEX₈₆ from environmental matrices such as sediments is one of the most important issues. The measurement of the relative amounts of GDGTs requires the use of high performance liquid chromatography/atmospheric pressure chemical ionization-mass spectrometry (HPLC/APCI-MS) [*Hopmans et al.*, 2000], a technique not commonly used in the fields of organic geochemistry, paleoceanography and paleoclimatology.

Schouten et al., [2002] reported that the reproducibility in quantification of the TEX₈₆ was 0.022 or 2°C using HPLC/APCI-MS which is substantially less than that for alkenones (0.2°C) and they suggested that this required improvement. Here we report on a number of analytical experiments designed to improve the reproducibility and to explore the limitations of TEX₈₆ analysis in sediments.

2.2. Experimental section

2.2.1. Sediment extraction

Sediments (1-3 g dry mass) were taken at selected intervals from the NIOP 905 sediment core from the Arabian Sea [*Huguet et al.*, 2006b] and were freeze-dried and homogenized by mortar and pestle. The freeze-dried sediments were extracted by ultrasonication with methanol, methanol/dichloromethane (DCM) (1:1; v/v) and finally with DCM. The supernatants were collected and after evaporation of the solvents, the extracts were dried over a sodium sulfate column. An aliquot of the total lipid extract was fractionated into apolar and polar fractions using a small column with activated aluminum oxide and using hexane/DCM (9:1; v/v) and DCM/methanol (1:1; v/v) as eluents, respectively. Aliquots of the polar fractions were pooled into one large polar fraction for the analytical experiments described below. The resulting pooled polar fraction was condensed by rotary evaporation, dried further under a stream of nitrogen, dissolved in hexane/isopropanol (99:1; v/v), and filtered using a PTFE 0.4 µm filter prior to injection in the HPLC/MS.

Approximately 700 g of sediment of a box core taken from Drammensfjord [*Smittenberg et al.*, 2005] were freeze-dried and homogenized. To test the effect of extraction techniques the Drammensfjord sediment was extracted using three different methods: (1) by Soxhlet extraction with DCM/methanol (7:1; v/v) for 24 h, (2) by ultrasonic extraction using solvents of decreasing polarity, i.e. methanol (3 times), a DCM/methanol mixture (1:1; v/v, 3 times), and finally DCM (3 times) and (3) by accelerated solvent extraction (ASE, Dionex™) [*Richter et al.*, 1996] using a mixture of dichloromethane (DCM) and methanol (MeOH) (9:1, v/v) at 100°C and $7.6 \cdot 10^6$ Pa. The extracts were then separated by column chromatography and prepared for HPLC/MS analysis as described above.

2.2.2. HPLC/MS analysis

Most analyses were performed using an Agilent (Palo-Alto, CA, USA) 1100 series LC/MSD SL equipped with an auto-injector and Chemstation chromatography manager software. For comparison of HPLC/APCI-MS set ups, a range of sediment extracts with different TEX_{86} values were also analyzed by an Agilent 1100 HPLC coupled to a TSQ Quantum Ultra EM triple quadrupole mass spectrometer (Thermo Inc., San Jose, CA, USA) equipped with an Ion Max source with APCI probe. Separation was achieved on a Prevail Cyano column (2.1 x 150 mm, 3 μm ; Alltech, Deerfield, IL, USA), maintained at 30°C. For comparison with the original separation method of Hopmans et al. [Hopmans et al., 2000] we also used an Econosphere Amino column (4.6 x 250 mm, 5 μm ; Alltech). Injection volumes varied from 1 to 20 μl . GDGTs were eluted isocratically with 99% A and 1% B for 5 min, followed by a linear gradient to 1.8% B in 45 min, where A = hexane and B = isopropanol. Flow rate was 0.2 ml/min for the Cyano column and 1 ml/min for the Amino column. After each analysis the column was cleaned by back-flushing hexane/propanol (90:10; v/v).

Detection was achieved using positive ion APCI of the eluent. Conditions for the Agilent 1100 APCI-MS were as follows: nebulizer pressure 60 psi, vaporizer temperature 400°C, drying gas (N_2) flow 6 l/min and temperature 200°C, capillary voltage -3 kV, corona 5 μA (\sim 3.2 kV). Conditions for the TSQ Quantum Ultra positive ion APCI-MS were as follows: vaporizer temperature 375°C, discharge current 2.0 μA , sheath gas (N_2) pressure 20 (arbitrary units), auxiliary gas (N_2) pressure 4 (arbitrary units), and capillary temperature 280°C. The conditions for GDGT analysis were optimized by injection or infusion of cholesterol or by a GDGT-0 standard.

To study the effect of scanning mode vs. SIM on the TEX_{86} , GDGTs were detected with SIM of their protonated molecules $[\text{M}+\text{H}]^+$ (dwell time = 234 ms) and by mass scanning from m/z 950-1450 on the Agilent 1100 HPLC/MS. In addition, GDGTs were detected by SIM on the TSQ Quantum Ultra triple quadrupole MS to investigate the influence of a different brand of mass spectrometer on TEX_{86} measurements. In this case the triple quadrupole MS was utilized as a single quadrupole MS, using the third quadrupole only. GDGTs were quantified by integration of the peak areas using Excalibur software. TEX_{86} values were calculated according to equation [1]. Absolute amounts of GDGTs injected on column were determined by using external standard curves of a crenarchaeol standard [Huguet et al., 2006a].

2.3. Results and discussion

2.3.1. Separation of GDGTs

The original method to separate and analyze GDGT isomers by HPLC/MS involved the use of a 25 cm x 4.6mm Amino column and 5 µm particle size and using a solvent flow rate of 1 ml/min [Hopmans *et al.* 2000]. To improve speed of analysis and reduce the amount of solvent used, i.e. reducing flow rate which also improves ionization chamber stability, we tested a Cyano column with reduced column width (2.1 cm) and length (15 cm) and smaller particle size (3 µm) and reduced flow rate of 0.2 ml/min. Injection of an identical amount of polar fraction of the sediment extract from the Arabian Sea using similar MS conditions shows that the reduced column width, particle size and flow rate yielded slightly reduced peak widths at halve height (for crenarchaeol 0.64 min versus 0.49 min for Amino and Cyano columns, respectively) and thus also slightly higher peak heights (Fig 1), mainly because the GDGTs eluted much faster (25 min versus 35 min). Furthermore, separation between crenarchaeol (GDGT-4) and its regio-isomer was substantially improved (see inserts in Fig 1), an important point considering that the regio-isomer is used in the determination of the TEX₈₆ index (see introduction). Nevertheless, TEX₈₆ under these two different column conditions was nearly identical, i.e. 0.658 and 0.653 for the Amino column and Cyano column, respectively. These new column conditions, thus, substantially speed up the time of analysis for TEX₈₆ determinations and resulted in a 5-fold reduction of the amount of solvents needed.

2.3.2. Mass spectrometry techniques

The original study proposing the TEX₈₆ as an SST proxy used mass scanning from m/z 950 to 1450 to detect, identify and quantify the GDGTs required for TEX₈₆ calculations [Schouten *et al.*, 2002]. Although this technique is suitable for the detection and identification of GDGTs, i.e. through the presence of their characteristic $[M+H]^+-18$ and $[M+H]^+-74$ ions [Hopmans *et al.*, 2000], it is less suitable for quantification due to the relatively low signal-to-noise-ratio compared to, for example, Single Ion Monitoring (SIM) or Selected Reaction Monitoring techniques. Indeed, the reproducibility reported in the study by Schouten *et al.*, [2002] using mass scanning was not very high (± 0.022 or $\pm 2^\circ\text{C}$ based on duplicate analysis of various sediment samples) and required further improvement. Ions from co-eluting molecules interfering with the $[M+H]^+$ ions of GDGTs were rarely encountered using our LC separation

technique and therefore we decided to use SIM to quantify the relative GDGT abundances needed for the TEX₈₆ (Fig. 1).

The reproducibility of the SIM-MS detection technique was tested by analyzing two different sediments for the five TEX₈₆ GDGT isomers (Fig. 1). One sediment is from a Norwegian fjord, Drammensfjord [Smittenberg *et al.*, 2005] characterized by relatively low annual mean sea surface temperatures (SST) of ca. 8°C whilst the other sediment is from the Arabian Sea [Huguet *et al.*, 2006b] with an annual mean SST of ca. 26°C. HPLC/MS analysis showed that, in agreement with the above water temperatures, the TEX₈₆ value of the Drammensfjord sediment was lower, 0.42, than that of the Arabian Sea sediment, 0.66. The reproducibility of TEX₈₆ using SIM-MS detection for the Drammensfjord was 0.0043 (1σ s.d, n=6) and for the Arabian Sea 0.0035 (1σ s.d., n=6) with total GDGT amounts injected on-column ranging from 4 to 1000 ng. Using equation [2] this translates to a reproducibility of ca. 0.3°C for TEX₈₆ analysis using SIM, at least for sediments with TEX₈₆ values ranging from 0.4 to 0.7 or 8 to 28°C. The reproducibility for samples with TEX₈₆ values >0.7 is expected to be similar or even better due to the relatively high amounts of the different GDGTs used for determination of the TEX₈₆, whilst for samples with TEX₈₆ values <0.4 potentially poorer reproducibilities may be expected. The improved reproducibility using SIM is a substantial improvement, by nearly one order of magnitude, from that using mass scanning previously reported [Schouten *et al.* 2002].

We then compared the sensitivity of the SIM mode to that of the mass scanning mode. When the amount of polar fractions injected on column was decreased in several steps from 20 μg down to 0.2 ng, or from 990 to 0.02 ng total GDGTs depending on the sediment analyzed, detection of peaks in the mass scanning mode quickly became difficult, as expected. Some of the less abundant GDGTs used in the TEX₈₆ (GDGT 2, 3 and 4'; Fig 1) became non detectable in mass scanning mode when the amount of extract injected on column was reduced to 4 ng GDGTs inject on column in case of the Drammensfjord or 0.1 ng in case of the Arabian Sea (Fig. 2). This difference in sensitivity between the extracts is caused by the relatively lower abundance of GDGTs 1, 2, 3 and 4' compared to GDGT 0 and 4 in the Drammensfjord extract. However, at these concentrations, the TEX₈₆ could still be easily determined by SIM. In fact, analysis by SIM yielded, within analytical uncertainty, identical TEX₈₆ values compared to those at high (>100 ng) concentrations down to 0.05 ng of GDGTs

injected on column in case of the Arabian Sea though with decreasing reproducibility (Fig. 2). Thus, SIM yields reproducible TEX₈₆ values at two orders (Arabian Sea) and one order (Drømmensfjord) of magnitude lower concentrations than the scanning mode. At the lowest amounts of injected GDGTs where peaks could still be detected with SIM, TEX₈₆ values start to significantly deviate from those at higher concentrations suggesting that care has to be taken when analyzing TEX₈₆ close to the limit of detection of the GDGTs.

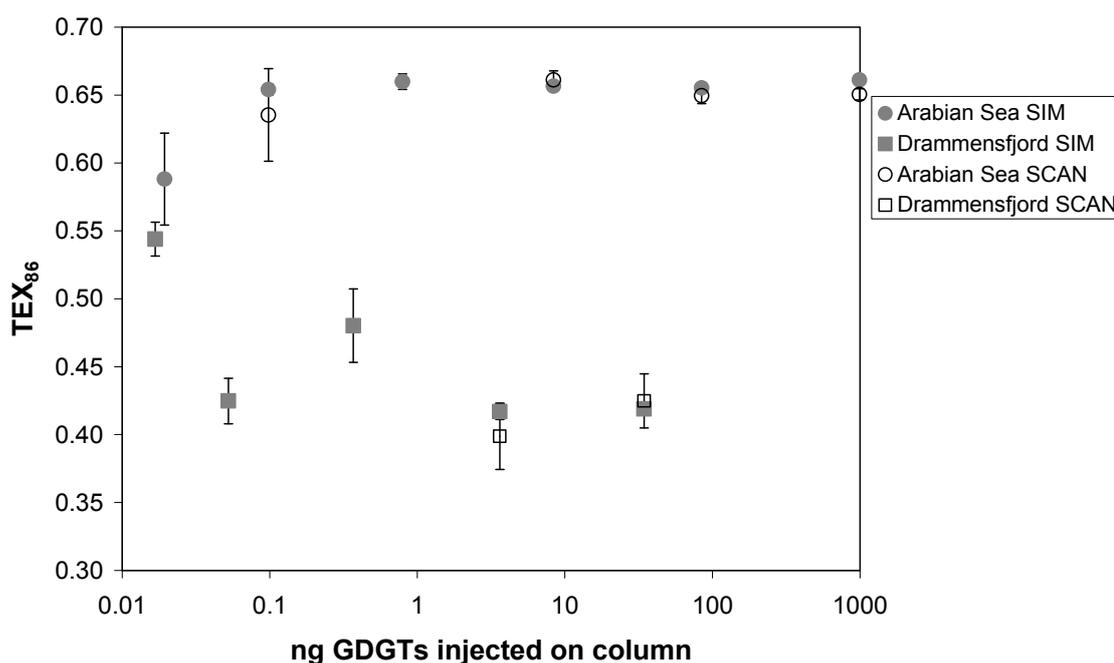

Figure 2. TEX₈₆ values as a function of total amount of GDGTs injected on column and using different mass spectrometry techniques (scanning and SIM) as analysed on an Agilent 1100 MSD SL HPLC/APCI-MS. The polar fractions are derived from pooled polar fractions of sediments from the NIOP905 core of the Arabian Sea and from extract of a composite sediment of the Drømmensfjord, respectively. Error bars indicate $\pm 1\sigma$ standard deviation of triplicate measurements.

2.3.3. Comparison of mass spectrometers

A selected set of sediment extracts, with a range of TEX₈₆ values, were analyzed by HPLC/APCI/MS in SIM mode using two different mass spectrometers, i.e. the Agilent 1100 MSD SL and the Thermo Inc. TSQ Quantum Ultra Triple Quadrupole MS.

The resulting TEX_{86} values from single analysis of similar quantities of GDGTs injected on column are cross plotted in Fig. 3 which shows that the TEX_{86} values are close to the 1:1 correlation line, suggesting little systematic instrumental biases. Thus, it seems that the TEX_{86} is not strongly dependent on APCI interface design and mass spectrometer. However, it should be noted that this method was only tested in SIM mode on a quadrupole mass spectrometer and it is unknown if the use of other mass spectrometry techniques such as ion trap mass spectrometers causes deviations. Recently, *Escala et al.*, [2007] reported the analysis of TEX_{86} with an HPLC/APCI/ion trap-MS and a reproducibility of 0.012 or 0.8°C suggesting that this index can be determined on different types of instruments.

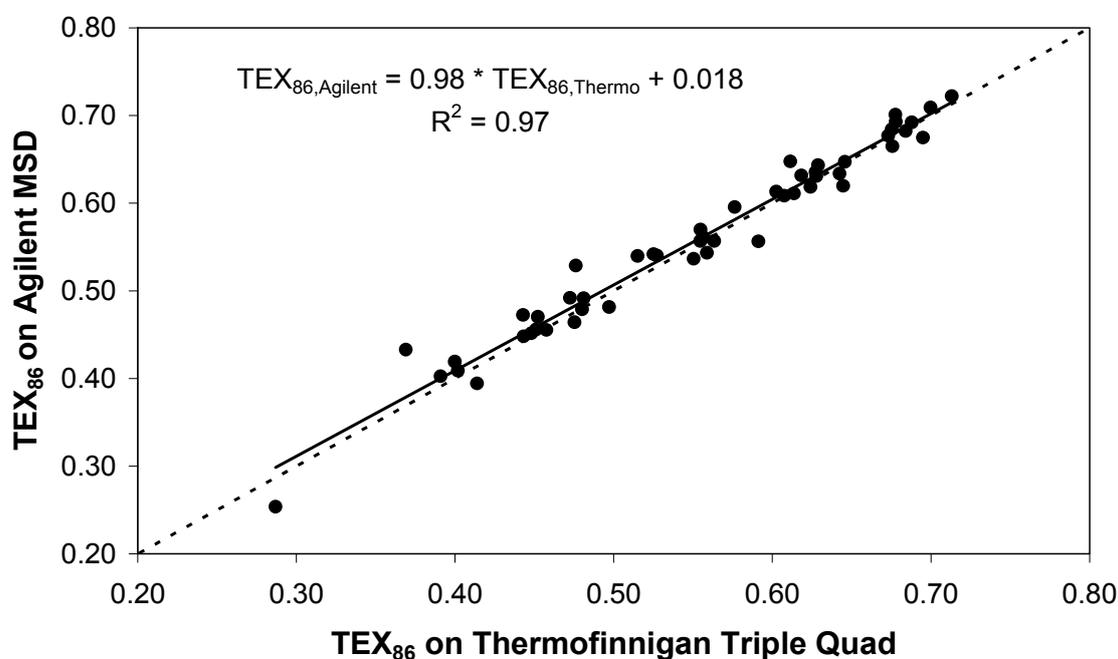

Figure 3. Cross plot of TEX_{86} values determined using the TSQ Quantum Ultra (Thermo Inc.) and an Agilent 1100 MSD HPLC/APCI-MS. Dashed line indicates the 1:1 line.

2.3.4. Effect of extraction techniques

We also investigated whether the use of different extraction techniques could potentially bias the TEX_{86} . Sediment from Drammensfjord was extracted in triplicate using ultrasonic extraction, Soxhlet extraction and accelerated solvent extraction at high pressure and temperature.

The results show that the TEX_{86} values obtained through the different techniques are identical within error (Fig. 4). The average error is 0.010 or 0.7°C which is twice as high as that of the analytical reproducibility (see above). However, this error now also includes errors due to different extraction techniques and the work up procedure (e.g. column chromatography, filtration) of the extracts. Thus, it seems that only relatively minor errors are introduced due to the work up procedures and that all these different extraction techniques can be used. Importantly, this includes accelerated solvent extraction which allows rapid extraction (<30 min.) in a highly automated fashion [Richter *et al.*, 1996] and therefore a high throughput of samples, an important prerequisite for high resolution paleoceanographic studies [Forster *et al.*, 2007].

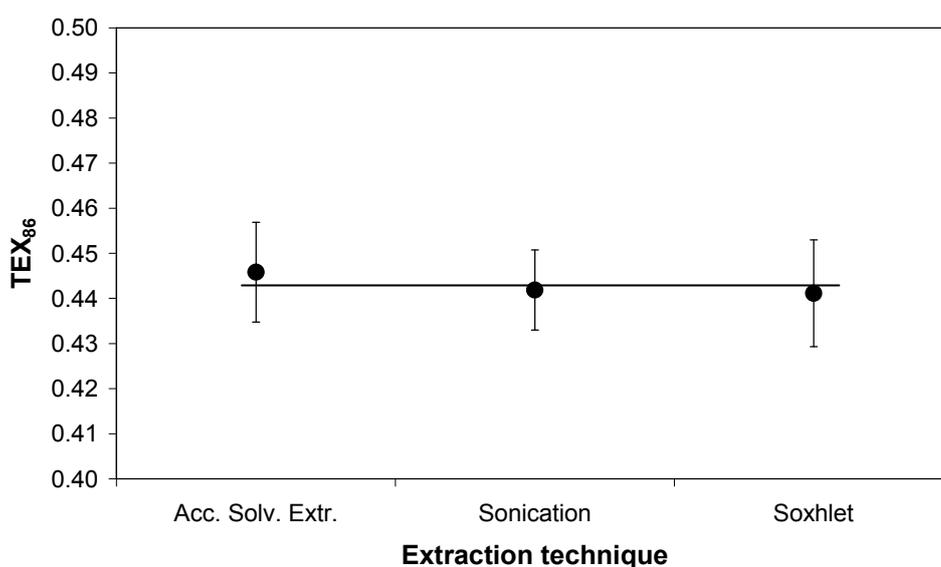

Figure 4. TEX_{86} values of composite sediment of Drammensfjord extracted using ultrasonic, Soxhlet and accelerated solvent extraction techniques. Error bars indicate $\pm 1\sigma$ standard deviation of triplicate extractions and triplicate analysis. Line represents the average TEX_{86} of all the experiments.

2.4. Conclusions

Our results show that TEX₈₆ is not biased by extraction techniques and that different HPLC/APCI-MS set ups can be used. We substantially decreased the time of analysis of TEX₈₆ compared to previous methods by using a smaller LC column and reduced flow rates. We also show that SIM is an improved technique for TEX₈₆ analysis compared to the originally used mass scanning technique and gives a reproducibility in TEX₈₆ determination of ca. ± 0.004 or ca. $\pm 0.3^\circ\text{C}$.

Abstract

Isoprenoid glycerol dialkyl glycerol tetraethers (GDGTs) are specific membrane lipids derived from archaea, one of the three domains of life. These lipids can be used as biomarkers in paleo-ecological studies. GDGTs can be analyzed by high performance liquid chromatography (HPLC)/mass spectrometry (MS). To quantify GDGTs, external standard curves were run monthly on the HPLC/MS. However, external standard curves represented a snapshot and do not adjust for changes during storage, dissolution and manipulation of samples or drifts in HPLC/MS conditions. To measure absolute GDGT abundances more accurately, we tested the use of a newly synthesized C₄₆ GDGT as an internal standard. The accuracy in the determination of GDGT concentration improved significantly when using the internal standard (5% standard deviation) compared to that obtained with the monthly external standard curve (43% standard deviation). Thus the new internal standard technique will greatly improve the accuracy of GDGT abundance measurements, enlarging the potential of GDGTs in paleo-ecological studies.

3.1. Introduction

Archaea are prokaryotes which are phylogenetically distinct from bacteria and possess different membrane lipids. While bacterial membranes are generally formed by straight-chain fatty acids ester bound to glycerol, membranes of dominant archaeal groups contain lipids with isoprenoid alkyl chains bound by ether bonds (Fig. 1). Most of the cultured members of the archaeal domain producing isoprenoid glycerol dialkyl glycerol tetraethers (GDGTs) are extremophiles, but recent investigations showed that crenarchaeota, a subgroup of archaea, are ubiquitous and abundant in seawater [Hoefs *et al.*, 1997; Massana *et al.*, 2000; Karner *et al.*, 2001] and lakes [Powers *et al.*, 2004]. GDGTs biosynthesized by these crenarchaeota are similar to those of their thermophilic ancestors, except for crenarchaeol, a unique GDGT containing one cyclohexane moiety in addition to the more common cyclopentane moieties [Sinninghe Damsté *et al.*, 2002a]. It is thought that the biosynthesis of crenarchaeol is an adaptation to the relatively cold sea water temperatures, compared to thermophilic environments such as hot springs [Kuypers *et al.*, 2002]. For this reason, crenarchaeol (Fig. 1) is a taxonomically-specific biomarker for non-thermophilic crenarchaeota.

Crenarchaeol has been used to study the abundance of crenarchaeota in the Arabian Sea [Sinninghe Damsté *et al.*, 2002b] and the Black Sea [Wakeham *et al.*, 2003]. Results of these studies are in general agreement with those of molecular biological studies which show that crenarchaeota occur throughout the water column [e.g. Karner *et al.*, 2001]. GDGTs are separated with high performance liquid chromatography (HPLC) and then identified by mass spectrometry (MS) [Hopmans *et al.*, 2000]. To quantify the GDGTs for the above studies, external standard curves were run, using a GDGT-0 standard (Fig.1) [Wakeham *et al.*, 2003]. However, this technique is likely not very accurate for calculating absolute abundances as it does not account for differences in the extraction, processing, storage of the samples and drifts in MS response. Hence, the changes observed in the relative abundances in depth profiles such as those noted in the Black Sea and the Arabian Sea may be reliable, but the calculated absolute amounts might be less precise. The best way to improve the analytical accuracy in the quantification of GDGTs is to use an internal standard that can be added at the beginning of the extraction process. This internal standard should not occur naturally and needs to be chemically similar to the GDGTs quantified. Here we tested a C₄₆ GDGT which was synthesized by Patwardhan and Thompson [1999], and compared GDGT absolute abundance

measurements using this new internal standard to those calculated with the external standard curve technique for the same set of samples.

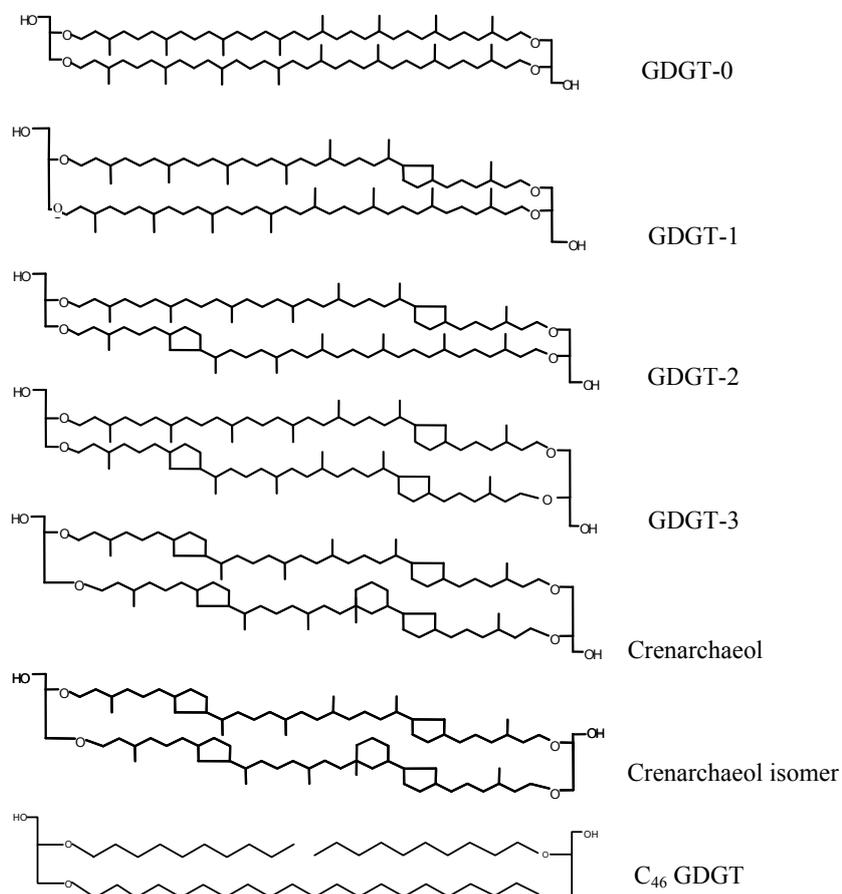

Figure 1. Molecular structures of protonated GDGT molecules and the internal standard, C₄₆ GDGT.

3.2. Experimental

As an internal standard we used a GDGT with two glycerol head groups linked by a C₂₀ alkyl chain and two C₁₀ alkyl chains (Fig. 1) which was synthesized by *Patwardhan and Thompson* [1999]. A mixture of the C₄₆ GDGT and crenarchaeol (1:1 w:w) was prepared and analyzed every week over a four month period to determine the relative response factor (RRF). To produce the external standard curves we used crenarchaeol as isolated previously [*Sinninghe Damsté et al.*, 2002b] and injected amounts ranging from 10 to 200 ng.

Both the internal and external standard quantification methods were tested by analyzing GDGTs in a sediment sample from the Drammensfjord (59°40' N 10°23' E). The sediment sample was a composite sample from a core taken in the centre of the Drammensfjord with the RV 'Pelagia' on October 29th, 1999 [Smittenberg *et al.*, 2005]. The core was freeze dried and ground to produce a homogenous sample. The freeze dried sediment sample was extracted using an Accelerated Solvent Extractor 200 (ASE 200, DIONEX) with a mixture of dichloromethane (DCM) and methanol (MeOH) (9:1 vol:vol) at 100°C and 7.6×10^6 Pa. A solution of the C₄₆ GDGT in 99% n-hexane: 1% isopropanol (0.01 mg/ml) was added to the total extract, with a proportion of 750 ng of the C₄₆ GDGT for 1 mg of total extract. The total extract was separated using a glass pipette column filled with activated alumina oxide by sequentially eluting with hexane/DCM (9:1 vol:vol) to obtain an apolar fraction and DCM/MeOH (1:1 vol:vol) to obtain a polar fraction. The polar fraction containing the GDGTs was filtered through a 0.45 µm pore size, 4 mm diameter PTFE filter prior to injection. The samples were analyzed by HPLC-atmospheric pressure positive ion chemical ionization mass spectrometry (APCI)-MS by applying conditions slightly modified from Hopmans *et al.* [2000]. Analyses were performed with an HP 1100 Series HPLC/MS equipped with an auto-injector and ChemStation chromatography manager software. Separation was achieved on a Prevail Cyano column (2.1 x 150mm, 3µm; Alltech, Deerfield, Illinois, USA), maintained at 30°C. The GDGTs were first eluted isocratically with (A) hexane and (B) propanol as follows, 99 % A: 1 % B for 5 min, then a linear gradient to 1.8 B in 45 min. Flow rate was 0.2 mL/min. After each analysis the column was cleaned by back flushing hexane/propanol (90:10, vol:vol) at 0.2 mL/min for 10 min. Conditions for APCI/MS were as follows: nebulizer pressure 60 psi, vaporizer temperature 400°C, drying gas (N₂) flow 6 L/min and temperature 200°C, capillary voltage -3.5kV, corona 5 µA (~3.2kV). Mass spectra of the C₄₆ GDGT and crenarchaeol were obtained by scanning at *m/z* 100-1000 and *m/z* 900-1400 respectively. For the standard curves and GDGT quantification Single Ion Monitoring (SIM) was used instead of mass scanning because SIM improves the signal to noise ratio and thus improves the reproducibility. SIM parameters were set to detect the protonated molecules of the 5 isoprenoid GDGTs (*m/z* 1302, 1300, 1298, 1296, 1292) as well as the protonated molecule of the C₄₆ GDGT internal standard (*m/z* 744), with a dwell time of 237 ms per ion.

3.3. Results and discussion

3.3.1 HPLC/MS analysis of the C₄₆ GDGT

Analysis of the apolar and polar fraction of the Drammensfjord sample showed that the C₄₆ GDGT eluted in the same fraction as the GDGTs, i.e. the polar fraction. The LC retention time of the C₄₆ GDGT varied between 22.5 and 23.3 minutes, eluting immediately after crenarchaeol (~21 minutes). The mass spectrum of the C₄₆ GDGT shows a predominant protonated molecule ($[M+H]^+$, Fig. 2a). There is a minor fragment due to loss of an OH group (-18 Da) but the most abundant fragment results from the loss of one of the C₁₀ chains (-140 Da) and the subsequent loss of an OH group (-158 Da). The second most abundant fragment is the loss of a C₁₀ alkyl chain and glycerol group (-232 Da) (Fig. 2a). In comparison, mass spectra of isoprenoid GDGTs are dominated by the $[M+H]^+$ protonated molecule and only show minor fragments due to losses of 18 and 74 Da, which correspond to the loss of an OH and a glycerol group, respectively [Hopmans *et al.* 2000; Fig 2b]. The difference in fragmentation pattern is due to the fact that the C₄₆ GDGT is not a macrocyclic compound in contrast to the isoprenoid GDGTs.

3.3.2 Relative response factor

The response factor of both the C₄₆ GDGT and crenarchaeol on the HPLC/MS was determined by SIM of both compounds at a range of concentrations (Fig. 3). The response factor of crenarchaeol is much higher than that of the C₄₆ GDGT, i.e. 44.8 arbitrary units per ng injected GDGT versus 6.9 arbitrary units per ng injected GDGT. This is likely due to the enhanced fragmentation of the C₄₆ GDGT compared to crenarchaeol, which results in a relatively lower abundance of the protonated molecule (Fig. 2). Depending on source conditions and calibration of the MS, differences may occur in the relative fragmentation pattern of the C₄₆ GDGT over time. This would affect the response factor as the protonated molecule then represents a changing percentage of the total ion signal over time.

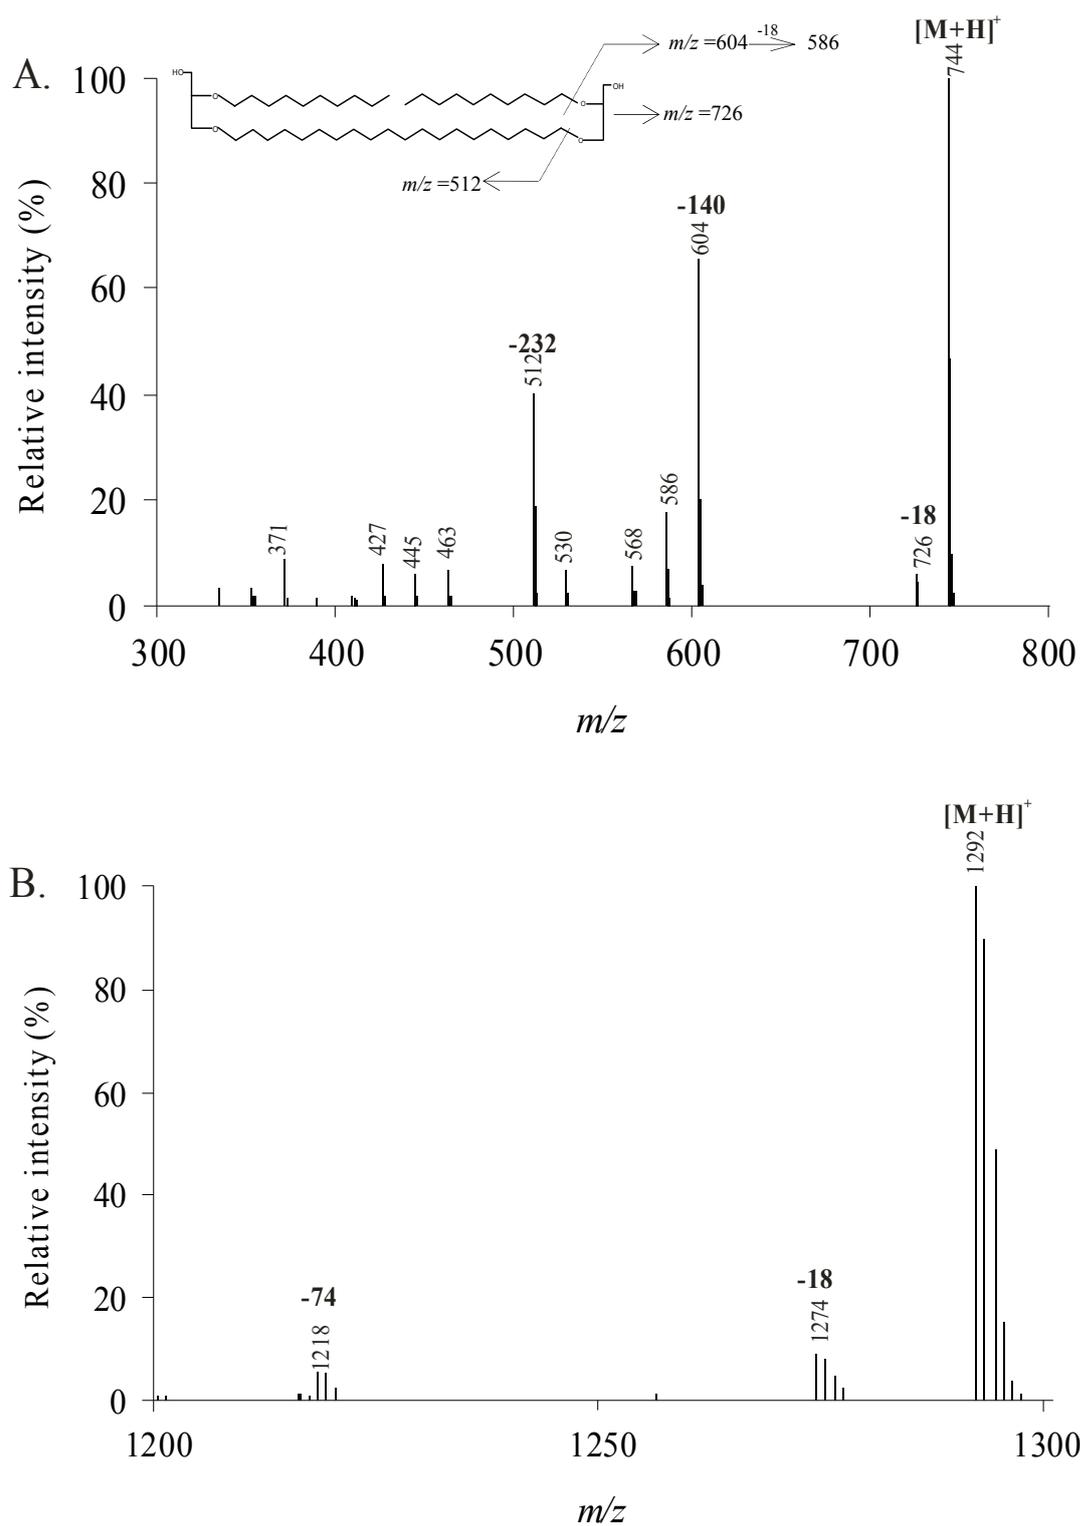

Figure 2. APCI mass spectrum of (A) C_{46} GDGT (m/z 744) and (B) crenarchaeol (m/z 1292). Mass spectra have been corrected for background.

To assess this, the difference in response factor between the C₄₆ GDGT and crenarchaeol was measured over time. For this, a standard mixture of C₄₆ GDGT and crenarchaeol (1:1 w:w) was analyzed once every week, over a four month period to determine the relative response factor (RRF). The RRF was calculated as follows:

$$\text{RRF} = \frac{(\text{Area crenarchaeol})}{(\text{Area C}_{46})} \times \frac{(\text{Weight C}_{46})}{(\text{Weight crenarchaeol})} \quad [1]$$

The RRF changed frequently, with values ranging between 2.9 and 4.8 (Fig. 4). During this study the HPLC/MS conditions regularly changed due to power cuts and re-calibration of the MS (black arrows, Fig. 4). The most marked changes in RRF occurred after the first power cut (Fig. 4a) when the ratio changed from 4.2 to 4.8 and after the MS re-calibrations when RRF values dropped from 4.7 to 3.8 and 3.8 to 2.9 respectively (Fig. 4b and d). Primary reasons for these large changes are changing conditions in the APCI source and loss of mass accuracy due to drifting of the mass axis. The first will change the relative degree of in-source fragmentation of the internal standard and the relative degree of ionization. The latter factor will induce changes in the RRF due to the large mass difference between the internal standard and the GDGTs. This shows that the RRF needs to be determined regularly and in particular after HPLC/MS conditions have changed.

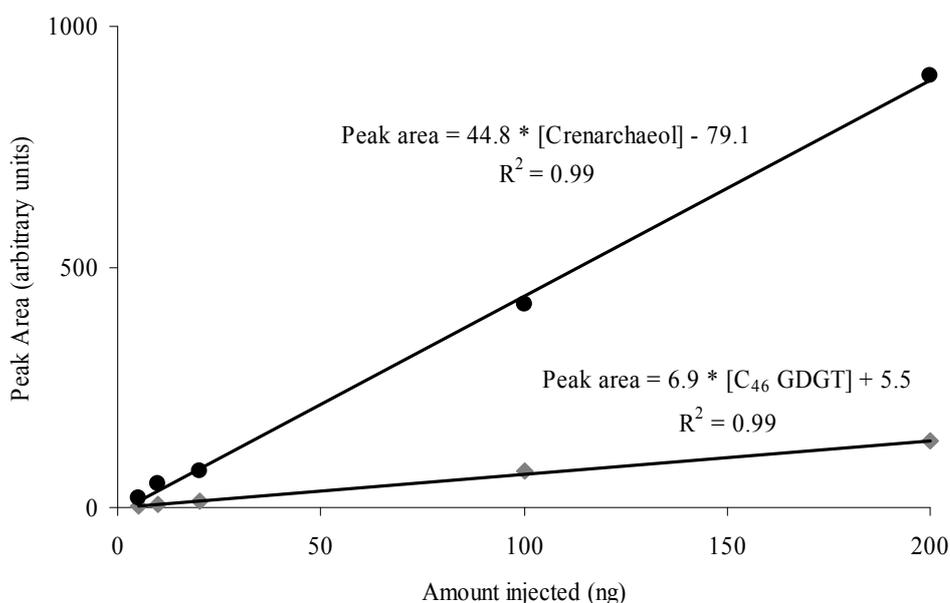

Figure 3. Standard curves of amount injected versus peak area for crenarchaeol and C₄₆ GDGT.

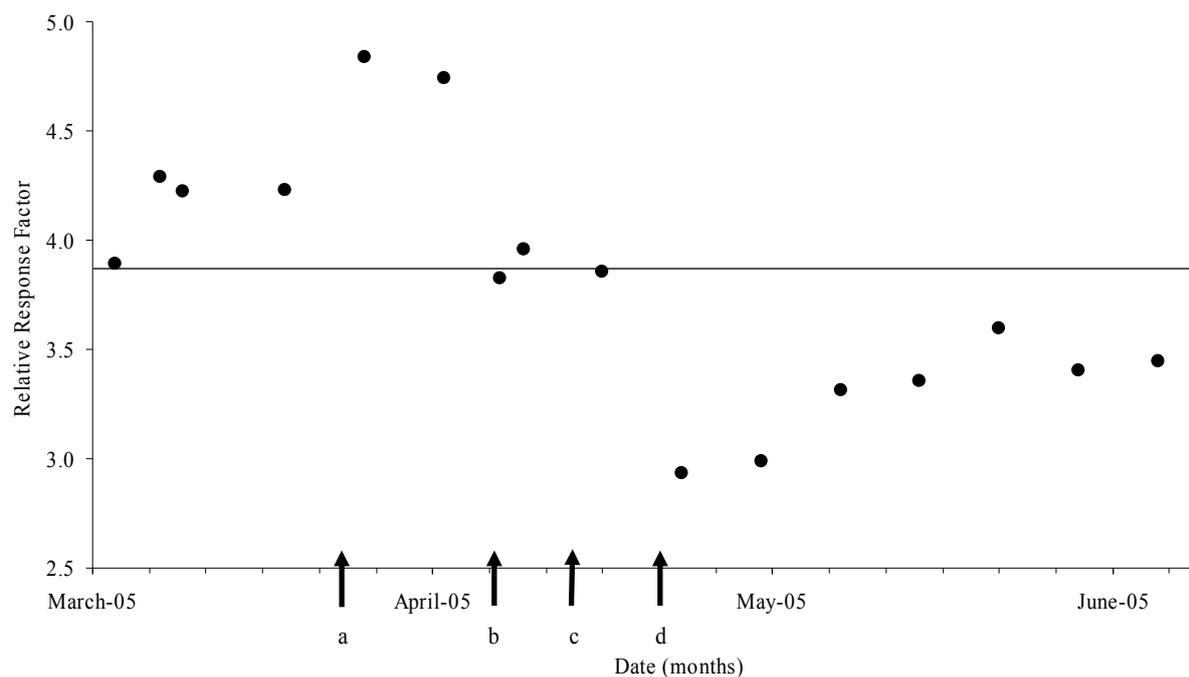

Figure 4. Variation of the relative response factor over time. The average value is indicated by the black line. Black arrows signal changes in the HPLC/MS conditions. (a) power cut, (b) re-tuning, (c) change of parts and air-conditioning restored, (d) MS re-tuning and a power cut.

3.3.3. Quantification of GDGTs using internal and external standards

Over the same period of time that the RRF stability was evaluated, we also measured GDGT abundances in a Drammensfjord sediment sample using both the internal and the external standard. These analyses were performed once every two weeks, directly after determining the RRF value. The external standard curves were determined on a monthly basis and after major alterations in the MS conditions (e.g. MS re-calibration). When calculating the absolute GDGT abundances obtained using either the internal or external standard, similar average GDGT concentrations are obtained for both methods (Fig. 5). However, the relative standard deviation is much higher when using the external standard curves (43%) than with the C₄₆ GDGT internal standard (5%). This is likely because the internal standard undergoes the same work up as that of the sedimentary GDGTs. In addition, the internal standard is measured at the same time as the sample, thus reducing errors due to drifts in HPLC/MS conditions that can not be accurately measured with an external standard. Hence, for GDGT

absolute abundance measurements the use of an internal standard will lead to improved accuracy of quantification.

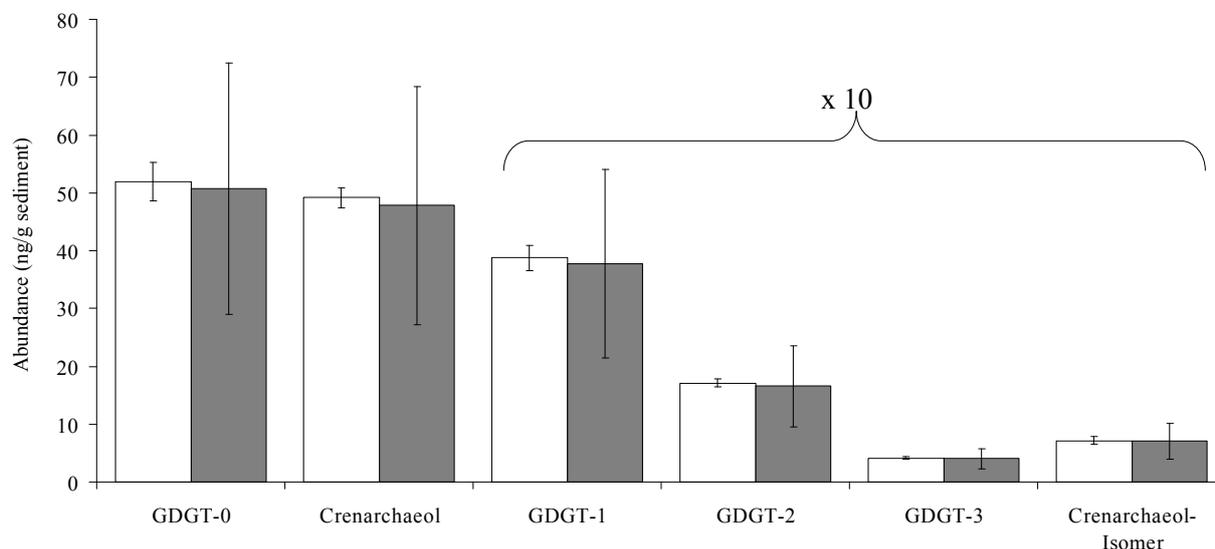

Figure 5. Abundance of GDGT molecules in Drammensfjord sediments, calculated with internal standard (open bars) and external standard (grey bars). Relative standard deviations are shown by the vertical bars. The abundance of GDGT-1, GDGT-2, GDGT-3 and the crenarchaeol isomer are multiplied by 10.

Published in *Geochemistry Geophysics Geosystems*, 7, doi:10.1029/2006GC001305 (2006)

Abstract

Pelagic Crenarchaeota produce glycerol dibiphytanyl glycerol tetraethers (GDGTs) as membrane lipids and the GDGT composition changes according to growth temperature. This forms the basis of the TEX₈₆ palaeotemperature proxy. This ratio correlates with sea surface temperature (SST) despite the fact that Crenarchaeota are distributed through the water column. Therefore, there must be mechanisms that transport the surface signal to sediments such as repackaging in faecal pellets, marine snow, mass falls after phytoplankton blooms or daily migration. To study GDGT transport, we analyzed stomachs and intestines of Atlantic and Mediterranean decapods as they are one of the major megafaunal groups, are easy to sample and occur in both pelagic and benthic environments. GDGTs were found in most decapods' guts. GDGT abundances are significantly lower in intestines, but TEX₈₆-derived temperatures are not significantly different between stomachs and intestines (<1°C), suggesting that TEX₈₆ values are not altered during gut transit. Atlantic decapods show no difference in TEX₈₆ values between benthic detritivores and pelagic predators. However, Mediterranean decapods show a substantial difference between macroplankton feeders and benthic-pelagic predators. This is probably related to the freshness of the material consumed. TEX₈₆-derived temperatures in Atlantic decapods are close to the SST around the time of sampling in agreement with stomach content analysis that shows fresh organic matter being ingested. For Mediterranean decapods, TEX₈₆ temperatures are significantly higher than SST around the time of sampling. This can be partly attributed to the large variability between decapod specimens and the low amounts of fresh material found in their stomachs.

4.1. Introduction

Sea surface temperature (SST) is one of the most important parameters associated with past climate. Since the 1950s, several temperature proxies have been developed, the most common being $\delta^{18}\text{O}$ and Mg/Ca ratios of planktic foraminifera [Chave, 1954; Emiliani, 1955; Nurnberg *et al.*, 1996] and the U_{37}^k index of long-chain unsaturated ketones synthesized by haptophyte algae [Brassell *et al.*, 1986]. A new SST proxy was recently introduced, the TetraEther index of lipids with 86 carbons (TEX_{86}) [Schouten *et al.*, 2002], which may be a useful complementary palaeotemperature tool. The TEX_{86} proxy is based on temperature-related changes that occur in the composition of archaeal membrane lipids.

Archaea were once thought to be extremophilic bacteria, but genetic studies showed that archaea constitute a different domain of life [Woese *et al.*, 1990]. Furthermore, molecular ecological studies revealed that archaea are ubiquitous and abundant in non-extreme settings such as the marine environment [Hoefs *et al.*, 1997; Massana *et al.*, 2000; Karner *et al.*, 2001]. One archaeal sub-group, the Crenarchaeota, is genetically related to (hyper)thermophilic archaea and has adapted to the relatively cold marine waters [Kuypers *et al.*, 2001]. Archaeal membranes are composed of glycerol dibiphytanyl glycerol tetraethers (GDGTs) [Sinninghe Damsté *et al.*, 2002] and changes in the relative abundance of these lipids allow them to adjust their membrane fluidity as a response to fluctuations in water temperature. The relative abundance of GDGTs is quantified with the TEX_{86} ratio [Schouten *et al.*, 2002]. An empirical correlation between TEX_{86} values of sediment core tops from a wide variety of geographical locations and annual mean SST is used to calibrate the TEX_{86} proxy [Schouten *et al.*, 2002]. Experiments with Crenarchaeota enrichment cultures and particulate organic matter studies have shown that this new proxy is strongly correlated with temperature and is not dependent on salinity or nutrient concentration [Wuchter *et al.*, 2004; 2005]. There is, however, a gap in knowledge that needs to be addressed in order to understand the origin of the TEX_{86} signal. Although several studies have established that Crenarchaeota are distributed throughout the water column [Murray *et al.*, 1999; Karner *et al.*, 2001], TEX_{86} values of particulate organic matter, sediment traps and sediment core tops are better correlated with SST (depth <100 m) than with deeper water temperatures [Schouten *et al.*, 2002; Wuchter *et al.*, 2005; 2006]. Thus, the signal in the deeper water layers and surface sediments seems to be primarily derived from the upper 100 meters of the ocean.

Crenarchaeotal cells are too small ($< 1 \mu\text{m}$; [Margot *et al.*, 2002]) to sink to the sediment after cell death and this would prevent the TEX_{86} signal from reaching the sediment surface. Thus, there have to be mechanisms that allow GDGTs to reach the sediment. Transport of organic matter to the sea floor can be a passive or an active process, though the latter pathway is usually considered to be insignificant. The active pathway requires the vertical migration of surface organisms such as macroplankton, euphausiids or decapods which are located close to the bottom during daylight periods, where they are consumed by benthopelagic and benthic species [e.g. Cartes, 1993; Cartes and Abelló, 1992]. The passive pathways include the main transport mechanisms such as marine snow, faecal pellets and massive falls of phytoplankton material after surface blooms which are believed to agglomerate water-surface particles and enable them to sink quickly to the bottom of the ocean where they fuel benthic food webs. The formation of particle aggregates is higher in surface waters, where most food webs are active, which could explain why GDGTs produced in the surface of the ocean, carrying a SST TEX_{86} signal, reach the sea floor. Further understanding of the transport mechanisms and deposition of the crenarchaeotal GDGTs is, thus, required to apply this new proxy. Once the GDGTs reach the sediment floor, benthic activity is also likely to have an effect with unknown consequences for the TEX_{86} signal.

To address these issues we investigated the presence of GDGTs in decapod guts. Decapods are a key element of most pelagic food webs. Decapod crustaceans are widely diversified in bathyal marine environments from mid and subtropical latitudes and constitute the most abundant megafaunal group in deep water environments such as the deep Mediterranean Sea [Cartes and Abelló, 1992; Maynou and Cartes, 2000]. Although they are not the main consumers of plankton in the upper 100 m or the main faecal pellet producers, they are involved at different levels of the food web and can serve as a model system for other organisms such as copepods and microzooplankton. In contrast to copepods they are more easily collected and larger amounts of biomass can be obtained. Pelagic decapods could actively or passively consume lipids and participate in the transport of GDGTs from the surface ocean to the sediment, whilst benthic species potentially could alter the TEX_{86} signal deposited in the sediment. The aim of this study was to assess if Crenarchaeota, and thus their GDGTs, are taken up by decapods and if the TEX_{86} temperature signal may be partly transported or altered through decapod feeding activity. We selected species with different

feeding habits, i.e. trophic resources both associated with bottom sediments (benthos) and/or to the water column (suprabenthos, zooplankton), and from two distinct settings, the oligotrophic Mediterranean Sea and the productive North Atlantic coast in two different seasons. Potential bias of the TEX_{86} ratio due to preferential degradation or differential retention time during passage through the gut system and possible differences caused by diverse decapod feeding strategies were also investigated.

4.2. Material and methods

4.2.1 Study area

Samples were collected from two different areas, (i) the Mediterranean, around the Balearic island (cruise IDEA, 39°N, 2°39'E) at two sites situated northwest and southwest of Mallorca Island in February 2004 and (ii) the North Atlantic coast of Spain (off Gijon) taken 20 km off the north coast of the Iberian Peninsula in April 2004 (ECOMARG03, 44°N, 4°29'W) (Fig. 1). The two sites in the Mediterranean are rarely affected by wind mixing and a strong summer thermocline is often present. Monthly averaged SSTs varied between 28.4°C in August 2003 and 14.3°C in February 2004 around time of sampling (Table 2). The Mediterranean Sea is characterized by an almost constant water temperature of 13°C below 200 m, high salinity (37-39) and very low nutrient concentrations [Comas *et al.*, 1996]. The North Atlantic coast study area, known as Le Danois bank, is a marine mount-shape relief orientated E-W parallel to the northern coast of the Iberian Peninsula coast. SST in this area varied between 24°C in August 2003 and 11.9°C in February 2004 (Table 2), but in contrast to the Mediterranean, temperatures below 200 m in the water column decrease with increasing depth. Conductivity Temperature Depth (CTD) profile data collected in April 2004 during the ECOMARG03 indicated temperatures ~10°C below 30 m depth. The Atlantic has lower salinity values (35.7-35.8) and higher nutrient concentrations than the Mediterranean.

4.2.2. Samples

We selected five decapod species with different feeding strategies and habitats. Two species, *Aristeus antennatus* (Risso, 1816) and *Plesionika martia* (A. Milne-Edwards 1883) were collected at the Mediterranean sites in February 2004. The other three species, *Acantheephyra pelagica* (Risso, 1816), *Munida tenuimana* (Sars, 1872) and *Parapagurus*

pilosimanus (Smith, 1879) were recovered in the North Atlantic (off Gijón) in April 2004 (Fig. 1).

| Species | <i>n</i> | Time | Location | Sampling depth (m) | Depth interval (m) | Habitat | Diet |
|--------------------------------|----------|------------|---------------------------------|--------------------|--------------------|---------------|--|
| <i>Plesionika martia</i> | 9 | 07/02/2004 | Mediterranean (39°N, 2°39'E) | 675 | 576-749 | Necktobenthic | Macroplankton |
| <i>Aristeus antennatus</i> | 11 | 07/02/2004 | Mediterranean (39°55'N, 2°36'E) | 775 | 576-775 | Necktobenthic | Epibenthos-benthos and pelagic prey |
| <i>Munida tenuimana</i> | 12 | 20/04/2004 | Atlantic (44°N, 4°29'W) | 1024 | 540-1024 | Benthic | Scavenging-detritivor and pelagic prey Phytoplankton detritus |
| <i>Parapagurus pilosimanus</i> | 11 | 20/04/2004 | Atlantic (44°N, 4°29'W) | 1024 | 820-1024 | Benthic | Benthic prey-scavenger Phytoplankton detritus |
| <i>Acanthephyra pelagica</i> | 11 | 20/04/2004 | Atlantic (44°N, 4°29'W) | 1024 | 550-1024 | Bathypelagic | Macroplankton predator Megabenthic remains |

Table 1. Characteristics of the five species used in the study, including time of sampling, location of fishing habitat, depth of samples, depth interval inhabited by species during the IDEA and ECOMARG surveys and a summary of their main prey (diets). *n*= number of specimens analyzed.

Figure 1. Map of study area showing sample locations (circles)

Around the Balearic Islands, 11 specimens of *A. antennatus* and 9 specimens of *P. martia* were obtained at 775 and 675 m depth, respectively (Table 1; Fig. 1). Eleven specimens of the bathypelagic shrimp *A. pelagica*, 12 of the squat lobster *M. tenuimana* and 11 of the hermit crab *P. pilosimanus* were collected in the north Atlantic at 1024 m depth (Table 1; Fig. 1). A total of 54 specimens were analyzed and their stomachs and intestines were removed under a stereomicroscope (x10, x40). Once stomachs and intestines were dissected, contents were collected with a spatula or, if they were liquid, pipetted into a tube, and subsequently freeze dried. Livers and gonads of 10 specimens from the Mediterranean were also dissected and portions were freeze dried and analyzed.

4.2.3 GDGT analysis

Freeze-dried stomach and intestine contents, and liver and gonad samples were weighed and extracted by sonication first with methanol, then a mixture (1:1; v/v) of methanol (MeOH) and dichloromethane (DCM) and lastly with pure DCM. After sonication, samples were centrifuged at 3500 rpm to remove particles. The supernatants were collected and after evaporating the solvents, the extracts were dried with a small pipette filled with anhydrous sodium sulphate. For the liver and gonad samples the total lipid extract was divided into apolar and polar fractions using a small column filled with activated alumina and using hexane/DCM (9:1; v/v) and DCM/MeOH (1:1; v/v) as eluents, respectively.

The total extracts (stomachs and intestines) and polar fractions (livers and gonads) were redissolved in hexane/propanol (99:1; v/v) and filtered through 0.45 μm PTFE filters. An HP (Palo Alto, CA, USA) 1100 series LC-MS equipped with an auto-injector and Chemstation chromatography manager software was used to analyse the samples. Separation was attained on a Prevail Cyano column (2.1 x 150 mm, 3 μm ; Alltech, Deerfield, Illinois, USA), maintained at 30°C. The GDGTs were eluted using a changing mixture of hexane and propanol. Detection was achieved using atmospheric pressure chemical ionization-mass spectrometry of the eluent [Hopmans *et al.*, 2000]. Single Ion Monitoring (SIM) was used instead of full mass scanning because SIM increases the signal to noise ratio and thus improves reproducibility. SIM was set to scan 5 $[\text{M}^+] + \text{H}$ ions of the GDGTs with a dwell time of 237 ms for each ion. Concentrations of GDGTs were used to calculate TEX_{86} values using equation [1] [Schouten *et al.* 2002]:

$$\text{TEX}_{86} = \frac{(\text{GDGT}_2 + \text{GDGT}_3 + \text{Crenarchaeol} - \text{isomer})}{(\text{GDGT}_1 + \text{GDGT}_2 + \text{GDGT}_3 + \text{Crenarchaeol} - \text{isomer})} \quad [1]$$

The numbers refer to the number of cyclopentane moieties in the GDGT molecule; the crenarchaeol-isomer has 4 cyclopentane moieties and a cyclohexane moiety. TEX_{86} temperatures were calculated with the following core top calibration [Schouten *et al.*, 2002]:

$$\text{TEX}_{86} = 0.015 \cdot T + 0.28, \text{ with } T = \text{temperature } (^\circ\text{C}) \quad [2]$$

Absolute GDGT abundances were determined by comparison with an external standard curve obtained with a range between 10 and 200 ng of GDGT_0 (GDGT with no cyclopentane moieties).

Table 2. Mean monthly sea surface temperature data from August 2003 to July 2004, corresponding to sampling sites in the Mediterranean (39°N, 2°E) and Atlantic (44°N, 4°W) from the Advanced Very High Resolution Radiometer (AVHRR) data set at <http://podaac.jpl.nasa.gov>. Annual mean SST and average stomach and intestine TEX_{86} temperatures for each decapod species are indicated. SST values at the time of sampling for Mediterranean decapods (February) and Atlantic decapods (April) are highlighted in bold.

4.3. Results

4.3.1. GDGTs in decapods

GDGTs were present in most decapod stomachs and intestines from both Atlantic and Mediterranean species (Tables 3 and 4).

| Species | n | Stomach | | n | Intestine | |

Table 3. TEX₈₆ calculated temperatures and GDGT concentrations for stomachs and intestines in Atlantic decapods. The number of measurements (n) is indicated. The standard deviations of the species-averaged temperatures and concentrations are also shown. Samples with GDGT concentrations below detection limit are labelled as *nd*.

In contrast, analysis of both gonads and livers of decapods did not reveal the presence of GDGTs. The lowest average GDGT concentration ($12 \pm 3.7 \mu\text{g}\cdot\text{g}^{-1}$ gut content) was found in *P. pilosimanus* intestines (Table 3; Fig. 2). The stomachs of *A. antennatus* contained the most GDGTs with on average $906 \pm 428 \mu\text{g}\cdot\text{g}^{-1}$ gut (Table 4; Fig. 2). Although average abundances of GDGTs were always higher in stomachs than in intestines (Fig. 2), there were large variations between individual specimens (Table 3 and 4). This resulted in substantial standard deviations for the average GDGT concentrations (Tables 3 and 4).

| Species | n | Stomach | | n | Intestine | | |

Table 4. TEX₈₆ calculated temperatures and GDGT concentrations for stomachs and intestines in Mediterranean decapods. The number of measurements (n) is indicated. The standard deviations of the measurements are also shown. Samples with GDGT concentrations below detection limit are labelled as *nd*.

However a t-test revealed that intestine concentrations are overall lower than stomach values with a 99.9 % confidence level. *P. martia* showed the largest difference, with an average of $332 \pm 465 \mu\text{g}\cdot\text{g}^{-1}$ gut content in stomachs, but only $16 \pm 9 \mu\text{g}\cdot\text{g}^{-1}$ gut content in intestines (Fig. 2). This difference may be explained because only intestines of three specimens could be analyzed (Table 4) and this may not be representative of the total population. Species in the Mediterranean revealed average GDGT concentrations in stomachs and intestines that were up to 20 times higher than those observed in Atlantic decapods (Table 4; Fig. 2).

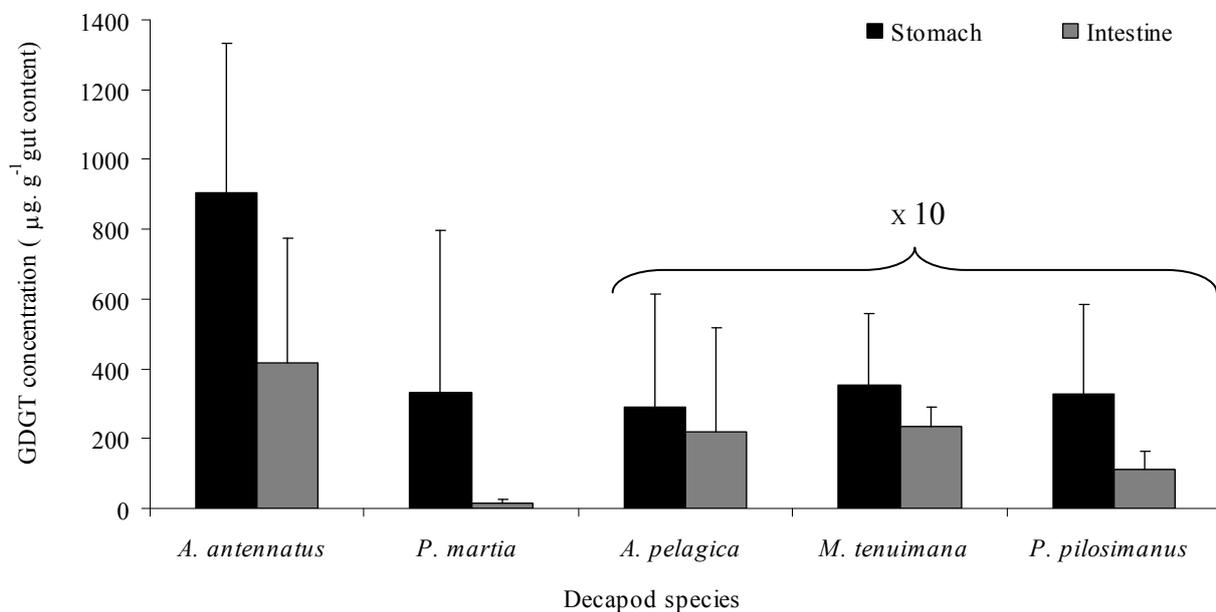

Figure. 2. Average abundance of GDGTs in stomachs (black) and intestines (grey). The abundances in the Atlantic species have been magnified by a factor of 10 to enable a better comparison.

4.3.2. TEX_{86} values

TEX_{86} values for the whole data set ranged from 0.50 to 0.63 and when converted to temperature with equation [2], these values correspond to 14.2 and 22.3°C respectively. Most decapods from the Atlantic coast were measured in triplicate (Table 3), with standard deviations ranging from 0.1 to 2.5°C for TEX_{86} -derived temperatures. Sample amounts from

Mediterranean decapods were smaller, and thus could only be measured at best in duplicate and the standard deviations ranged from 0.2 to 1.6°C (Table 4). For species-averaged TEX₈₆-derived temperature standard deviations ranged from 0.8°C for *M. tenuimana* stomachs to 5.2°C for *P. martia* intestines (Table 3 and 4; Fig. 3).

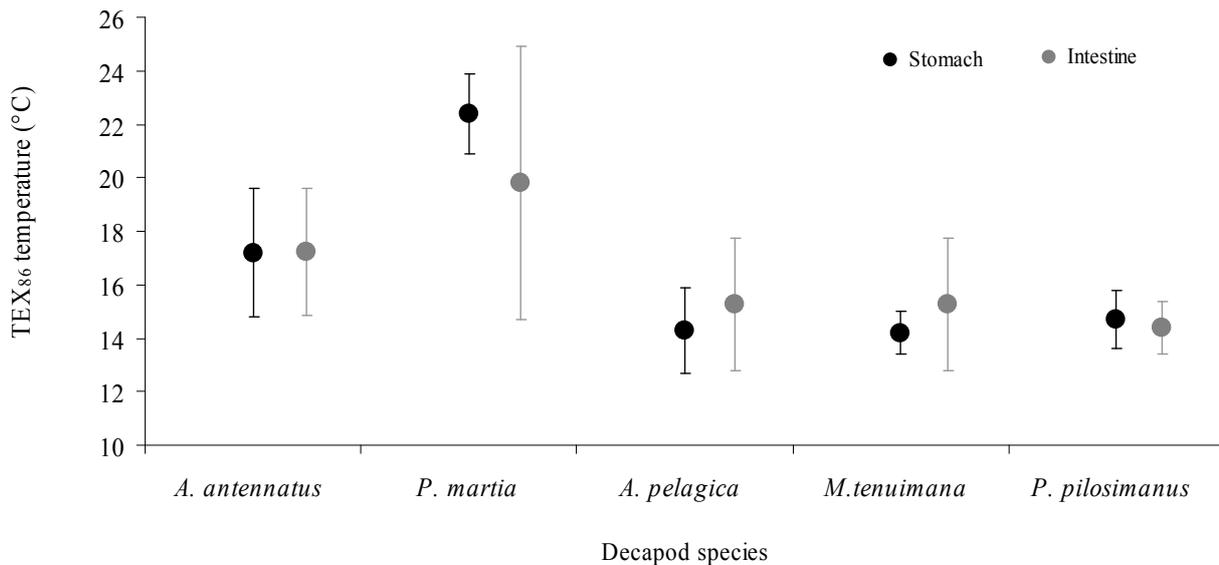

Figure 3. TEX₈₆ temperatures calculated from GDGTs present in stomachs (black) and intestines (grey).

TEX₈₆-derived temperatures in Atlantic decapods are all very similar between specimens for all species, suggesting a relatively homogenous distribution over the total population (Table 3). The Atlantic decapods showed identical values for stomach TEX₈₆ temperatures of $14.3 \pm 1.6^\circ\text{C}$ (*A. pelagica*), $14.2 \pm 0.8^\circ\text{C}$ (*M. tenuimana*) and $14.7 \pm 1.1^\circ\text{C}$ (*P. pilosimanus*) (Table 3; Fig. 3). TEX₈₆-derived temperatures for the intestine samples were also very similar ranging from 15.2 to 14.3°C (Table 3; Fig. 3). Thus, temperature values calculated with TEX₈₆ for stomachs and intestines are not significantly different in Atlantic species (Fig. 3).

TEX₈₆-derived temperatures calculated for Mediterranean decapods showed larger variability between specimens than Atlantic decapods, especially for *A. antennatus* (Table 4). Also, in contrast with Atlantic decapods, there was a significant difference between the two

Mediterranean species, i.e. stomachs of *A. antennatus* have TEX₈₆ temperatures of $17.2 \pm 2.4^\circ\text{C}$, whilst stomachs of *P. martia* have TEX₈₆ temperatures of $22.4 \pm 1.5^\circ\text{C}$ (Table 4 and Fig. 3). However, both stomach and intestines of *A. antennatus* have similar TEX₈₆ temperature values of $17.2 \pm 2.4^\circ\text{C}$. For *P. martia* this difference with TEX₈₆ temperatures is larger, i.e. $22.4 \pm 1.5^\circ\text{C}$ for stomachs and $19.8 \pm 5.2^\circ\text{C}$ for intestines. This difference is not significant considering the large standard deviation (Table 4, Fig. 3).

4.4. Discussion

4.4.1. GDGTs in decapod guts

Most stomachs and intestines analyzed in this study contain GDGTs, suggesting that Crenarchaeota may be consumed by decapods. Molecular ecological studies have previously shown the presence of marine archaea in guts of fish [Van der Maarel *et al.*, 1998] and holothurians [McInerney *et al.*, 1995], but in both cases it was not determined whether the marine archaea found in the gut were symbiotic members or had been ingested. Decapod guts are very basic structures compared to those of fish and holothurians, thus in our case the existence of gut symbionts seems unlikely. Moreover, the TEX₈₆-calculated temperatures and stomach content analysis (see below) indicate a surface origin of the GDGT signal while the decapod species were all collected below 500 m (Table 1). Lastly, some specimens did not contain GDGTs, which would contradict the idea of a symbiotic relationship. Thus, it seems likely that GDGTs are taken up in the food web and incorporated in decapod faecal pellets. Even though there is evidence of GDGT consumption by decapods, we can not discern if this is an active or a passive process. But, the scale of the mouth sorting structure of the decapod group does not allow selecting for particles of the size such as those of archaea ($<1 \mu\text{m}$; [Margot *et al.*, 2002]). Therefore, they must be accidentally ingested during feeding, either dissolved in the water, associated with food particles or already present in guts of prey organisms. Stomach content studies of decapod species showed that detritus, i.e. amorphous organic material, never represented more than 20% of the diet in weight, even in detritivores such as *Parapagurus pilosimanus* (Cartes *et al.*, unpublished results). This further indicates that an active selection of archaea as a food source by decapods is unlikely.

As the study included species with different feeding strategies (Table 1), some of the mechanisms suggested for surface water material transport to the sediments can be assessed. The passive pathway (marine snow, faecal pellets and phytoplankton massive falls) is confirmed by the presence of GDGTs in the guts of benthos feeders or scavengers-detritus feeders such as *A. antennatus*, *M. tenuimana* and *P. pagurus*. The active transport, by organism migration, is suggested by the other two decapod species feeding on migratory macroplankton (Table 1). The presence of GDGTs in decapod guts also suggests that surface organisms such as migrating macroplankton are ingesting GDGTs themselves. Thus, heterotrophic organisms such as the very abundant copepods, which are closely related to the decapods, are likely to play an important role in producing faecal pellets in surface waters that will carry GDGTs to the sediment. In addition, our results show that once the GDGTs are deposited in the sediment benthic reworking of these compounds continues.

4.4.2. *TEX₈₆ signal preservation*

The stomachs and intestines analyzed correspond to separate feeding episodes. However, most bathyal decapods feed continuously through the daily cycle without feeding peaks [Maynou and Cartes, 1998]. Thus, the stomach and intestine contents can be considered as a snapshot of the general digestion process, and no major changes in abundance or food source are expected between the two. With only a few exceptions, GDGT abundances in the intestines are consistently lower than in the stomachs in all specimens studied (Tables 3 and 4; Fig. 2) and this difference is statistically significant. The lower intestine abundances and absence of GDGTs in gonad and liver tissues suggest a partial degradation of GDGTs during stomach transit. Alternatively, the residence time for stomach contents might be higher than for intestines. However, this is unlikely as the feeding is a continuous process. Lower intestine than stomach contents can also be explained by a change of food source. However, this is unlikely as very few specimens show a higher intestine than stomach abundance (Table 3 and 4) and benthic species such as *P. pilosimanus* or *M. tenuimana*, that usually cover a small area, also show lower intestine abundances. Thus it seems that a partial degradation is the most likely explanation for the lower intestine abundance of GDGTs. This could be problematic for the *TEX₈₆* proxy if some of the GDGT isomers were degraded at different rates than others as this would alter the *TEX₈₆* ratio. However, there is no significant

difference between species averaged TEX_{86} temperatures in stomachs and intestines (Fig. 3). Thus, it seems that all the GDGT molecules are equally affected by degradation. Therefore, the TEX_{86} signal which is taken up by decapods is likely unaffected by passage through the gut and re-packaged in faecal pellets. This suggests that faecal pellets from pelagic species will help transport sea surface temperature signal to the bottom, but also that benthic decapods will not alter sedimentary signal settling or already deposited in the sediment.

4.4.3. Comparison of TEX_{86} with *in situ* temperatures

4.4.3.1. Atlantic decapods

TEX_{86} -derived temperatures are similar in all the Atlantic decapods. TEX_{86} temperatures are significantly higher than the 10°C deep-water (<30 m) signal recorded by the CTD, so we can assume a surface origin of the GDGT signal. At the time of sampling SST in the study area was 12.8°C , whilst the average TEX_{86} value for the three species is $14.4 \pm 1.3^{\circ}\text{C}$. Thus, temperatures obtained from decapod guts compare quite well with local SST, being only 1.6°C higher (Table 2). This relatively small difference may be due to several factors including uncertainties in the calibration of the TEX_{86} with temperature. Indeed, sediment trap studies in the Arabian Sea showed that TEX_{86} values may overestimate surface water temperatures by $1\text{-}3^{\circ}\text{C}$ [Wuchter *et al.* 2006]. Alternatively, the decapods may have ingested GDGTs accumulated over an annual cycle (see below), thereby increasing TEX_{86} values as annual mean SST (16.6°C) is higher than the SST around time of sampling (12.8°C).

The three Atlantic decapod species studied are known to have different feeding strategies (Table 1), i.e. *M. tenuimana* and *P. pilosimanus* are mainly benthic scavengers while *A. pelagica* is a macroplankton predator. However, we could not find any correlation between feeding mode and TEX_{86} temperatures. This is likely because all the Atlantic decapods fed on food from the same origin (i.e. the upper water column) as they were sampled right after a peak in primary production. Even though *A. pelagica* and *M. tenuimana* usually feed on macroplanktonic organisms, with important scavenging activity particularly in the last species (Table 1), this does not seem to be the case in our study. No information is available on the diet of *P. pilosimanus*, but pagurids are often considered as benthic-detritus feeders and scavengers [Lagardère, 1977]. However, in our study it seems that the Atlantic decapods' signal is derived from surface waters and is either ingested through macroplankton

predation (*A. pelagica*) or transported down by a flux of phytoplankton detritus and ingested in the benthos (*M. tenuimana* and *P. pilosimanus*). In fact, stable carbon and nitrogen isotope studies showed that marine snow can be the main food source for deep water decapods inhabiting the deep slope around the Balearic Island [Polunin *et al.* 2002]. Indeed, stomach content analysis of *M. tenuimana* and *P. pilosimanus* showed high contents of pigments derived from phytoplankton, suggesting that in this particular case these species fed on fresh phytoplanktonic detritus (Cartes *et al.*, unpublished results). Thus, the transport mechanism of the GDGTs carrying the TEX₈₆ signal may be linked to the flux of phytoplankton material after the spring bloom in the sampling area. This confirms one of the passive pathways proposed for quick transport of GDGTs from surface waters to the sediment, and it might be especially important in certain areas such as upwelling regions after periods of high primary production in the photic zone.

4.4.3.2. Mediterranean decapods

TEX₈₆ temperatures calculated for stomachs of the Mediterranean decapods studied are significantly different. *A. antennatus* indicates a temperature of ca. 17°C while *P. martia* shows significantly higher values at ca. 22°C. This difference may be partly explained by the slightly different locations where the decapod species were sampled (Fig. 1). This could explain warmer temperatures for *P. martia* as the specimens were obtained in a sheltered coastal area. However, this cannot be the only factor, as this would result in a relatively small temperature difference.

Since Mediterranean temperatures are consistently <13°C below 200 m [Comas *et al.*, 1996] and TEX₈₆ values are considerably higher, they must correspond to SST. However, average TEX₈₆ temperatures from Mediterranean decapods are also significantly higher than SST around the time of sampling (14.3°C; Table 2). The two Mediterranean species consume different prey (Table 1) and may therefore be showing a signal obtained from distinctive food sources. *A. antennatus* is basically a benthic feeder while *P. martia* has been reported as an active predator of macrozooplankton [Cartes, 1993; Fanelli and Cartes, 2004]. Thus, the feeding strategy may have affected the TEX₈₆ signal in Mediterranean decapods. As SST changes more than 14°C during the annual cycle (Table 2), the freshness of the organic matter consumed is important. We would expect a pelagic feeder like *P. martia* to ingest GDGTs

present in the guts of surface water macroplankton organisms that migrate down the water column daily, and thus, TEX₈₆ signal should be tied to recent SST. Benthic feeders, such as *A. antennatus*, could be ingesting secondary material such as an already packaged GDGT signal from marine snow and faecal pellets from the same or surrounding areas; this would probably result in a dilution of the fresh TEX₈₆ signal. Indeed, this could explain why the TEX₈₆ derived temperature in *A. antennatus* is an intermediate value between annual mean SST (20.0°C) and SST at the time of sampling. Notably, there is large variability in TEX₈₆ temperatures for individual specimens of *A. antennatus* with some values close to the SST around time of sampling and others close to annual mean SST. However, feeding strategy can not explain the large offset between TEX₈₆ inferred SST for *P. martia* and SST at the time of sampling as this organism is supposed to feed on migratory macrozooplankton and the variability between specimens is relatively small. For reasons presently unclear, the TEX₈₆-derived temperatures for *P. martia* are closer to annual mean SST, suggesting a diet of older material. In this respect it is interesting to note that, in contrast to Atlantic decapods, stomach contents of both Mediterranean decapod species contained only low abundances of pigments (Cartes et al., unpublished results), suggesting that both decapods did not have fresh phytoplankton material in their diet. This may explain the offset between TEX₈₆ temperatures in Mediterranean decapods and that of SST around time of sampling.

4.5. Conclusion

Crenarchaeota lipids have been found both in stomachs and intestines of decapods and are most likely accidentally ingested with water, organic particles or with prey organisms. Despite this uncertainty, we were able to demonstrate both passive and active transport mechanism that can explain, at least in part, the transport of GDGTs from surface waters to the sediment. Even though the GDGTs concentration decreases from stomachs to intestines we did not find evidence of incorporation of GDGTs in liver or gonad tissues of decapods. Most importantly, TEX₈₆ values do not show significant differences between stomach and intestines, and thus GDGT composition is not modified during the passage through the guts before it is transported to the sediment in faecal pellets. This holds true for both GDGTs collected from the water column or reworked in benthic settings. Furthermore, we observed that the fresh GDGT signal can be transported by massive falls of organic matter after peaks

in surface production. Different feeding modes were investigated and while no differences in TEX_{86} values were found in the Atlantic site, the Mediterranean decapods showed a significant difference probably related to the freshness of the material consumed. Finally, TEX_{86} calculated with the GDGTs taken up by decapods shows a relatively good correspondence with SST at time of sampling for Atlantic decapods but represents a mix of annual mean SST and SST at time of sampling for Mediterranean decapods. We also suggest that other heterotrophic organisms closely related to decapods, such as the abundant copepods, are likely to play an important role producing faecal pellets that will carry GDGTs from surface waters to the sediment.

Abstract

Particulate organic matter collected during a 2-year period, as part of an ongoing sediment trap study, and a high-resolution sediment record from 1850 to 1987 AD from the Santa Barbara Basin were analyzed for TEX₈₆, a temperature proxy based on marine crenarchaeotal membrane lipids. Highest fluxes of crenarchaeotal lipids in the water column were found in May-June 1996 and from October 1996 to January 1997, and in general showed a good correlation with mass fluxes. TEX₈₆ reconstructed temperatures from the sediment trap series ranged from 8-11°C and were usually substantially lower than sea surface temperatures (SST), indicating that, unlike in previous studies, the TEX₈₆ corresponds to sub-surface temperatures, likely between 100-150 m. TEX₈₆ temperature variations observed in trap samples were not coupled to changes in SST or deep-water temperatures and only to some degree with crenarchaeotal lipid fluxes. This suggests that a complex combination of different depth origins and seasonal growth periods of Crenarchaeota contributed to the variations in TEX₈₆ signal during the annual cycle. TEX₈₆ temperatures in the two sediment cores studied (8-13 °C) were also substantially lower than those of instrumental SST records (14-17.5 °C) confirming that TEX₈₆ records a sub-surface temperature signal in the SBB. This result highlights the importance of performing calibration studies using sediment traps and core tops before applying the TEX₈₆ temperature proxy in a given study area.

5.1. Introduction

A variety of sea surface temperature (SST) proxies exist for paleoceanographic applications, of which Mg/Ca ratios of planktonic foraminifera and the $U_{37}^{K'}$ index of long chain alkenones are presently the most frequently used. Five years ago, *Schouten et al.* [2002] introduced a new SST proxy, the TEX_{86} based on the relative distribution of glycerol dibiphytanyl glycerol tetraethers (GDGTs), which are membrane lipids produced by non-thermophilic Crenarchaeota. These organisms are ubiquitous and abundant in seawater [*Hoefs et al.*, 1997; *Massana et al.*, 2000; *Karner et al.*, 2001] and large lakes [*Powers et al.*, 2005]. Marine Crenarchaeota biosynthesize GDGTs with a varying number of cyclopentyl moieties, and the relative abundance of these moieties changes according to the water temperature [*Wuchter et al.*, 2004]. Therefore, by measuring the relative amounts of GDGTs present in sediments, the temperature at which Crenarchaeota were living can be reconstructed. Culture experiments showed that changes in salinity and nutrients do not substantially affect the temperature signal recorded by TEX_{86} [*Wuchter et al.*, 2004], the proxy also seems to be unaffected by water redox conditions [*Schouten et al.*, 2004].

Recent evidence has shown that part of the marine Crenarchaeota are nitrifiers [*Wuchter et al.*, 2006a; *Könneke et al.*, 2005] and thus are not depending on light for growth. Indeed, they are distributed throughout the water column though highest abundances are usually noted in the upper few hundred meters both in the Pacific [*Karner et al.*, 2001] and in the Atlantic ocean [*Herndl et al.*, 2005]. In contrast, a study of particulate organic matter (POM) at ten different locations with various oceanographic conditions (i.e. upwelling, stratification) revealed that TEX_{86} correlates well with surface water temperatures (depths <100m) and that the signal in deeper-water layers and surface sediments is primarily derived from these upper 100 meters [*Wuchter et al.*, 2005]. This apparent contrast of a surface signal obtained from organisms living within a wide depth range was explained by the GDGTs transport mechanism to the sediment floor, i.e. through consumption and re-packaging which mostly takes place in the active food web in the upper part of the water column [*Wuchter et al.*, 2005; *Huguet et al.*, 2006a].

Laminated sediments from the central Santa Barbara Basin (SBB) represent an important and frequently used archive of climate variability of the California coast [*Schimmelmann and Lange*, 1996; *Biondi et al.*, 1997; *Berger et al.*, 2004]. Sub-sill waters in

the ca. 590 m deep SBB (Fig. 1) have a low oxygen content that enhances preservation of organic matter and prevents bioturbation by macro-benthos. A high export production coupled with high sedimentation rates of several mm per year (before sediment compaction) result in the preservation of light and dark annual varve couplets [Reimers *et al.*, 1990; Thunell *et al.*, 1995] (Fig. 2). Thus, sediment cores of the SBB are excellent for high-resolution paleostudies of the climate and oceanographic conditions in the SBB area which is influenced, at different time-scales, by the El Niño Southern Oscillation (ENSO), the Pacific Decadal Oscillation (PDO), the California Current system, and the upwelling regime related to the North Pacific High as well as local factors [Weinheimer *et al.*, 1999; Berger *et al.*, 2004].

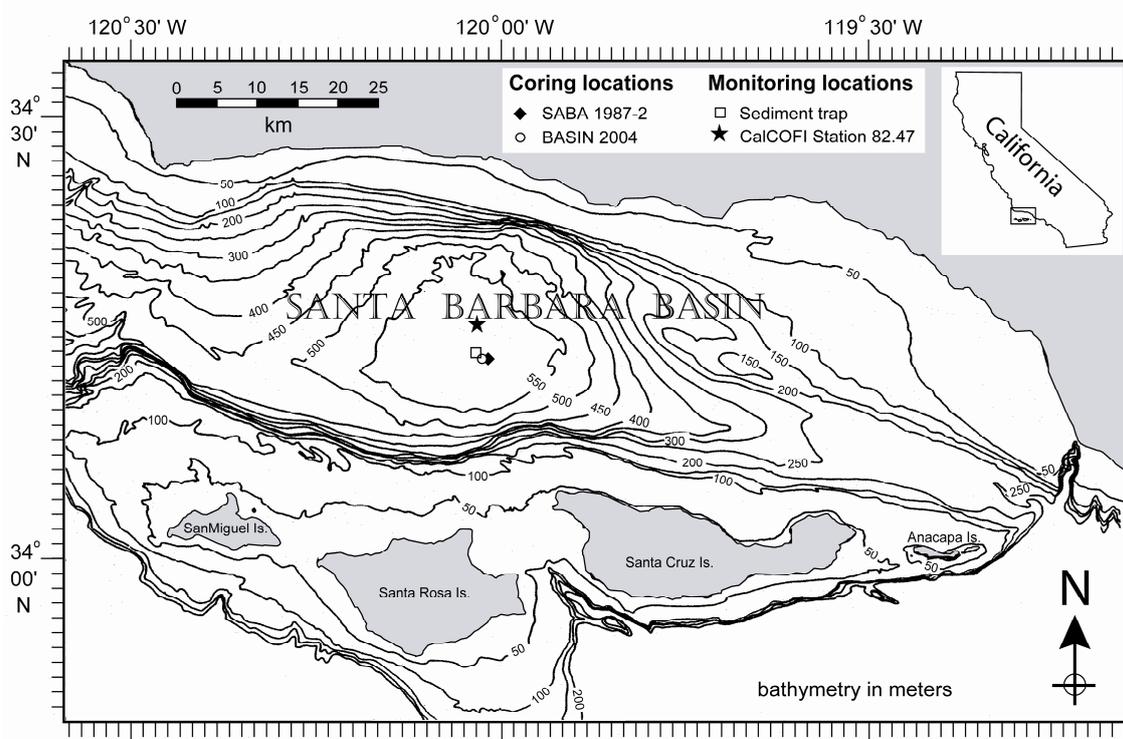

Figure 1. Map of the study area, with indication of sediment sampling locations for SABA 87-2 (34°13.5'N, 120°01.0'W), BASIN 2004 (34°13.41'N, 120°01.53'W) and the location of the sediment trap (34°14'N, 120° 02'W). CalCOFI station 82.47 is located at 34°16'N, 120° 2'W [www.calcofi.org].

A variety of proxies have been used in this area. For example, SST reconstructions using long-chain alkenones revealed occasional warming during 20th century El Niño events [Kennedy and Brassell, 1992] although the same proxy was less successful detecting ENSO in older SBB sediments [Zhao *et al.*, 2000] or even during the last century [Herbert *et al.*, 1998]. Similarly, Mg/Ca ratios of planktonic foraminifera did not record the strong increase in surface temperatures during the 1997-1998 El Niño event [Pak *et al.*, 2004]. In contrast, other studies revealed that El Niño events can be recorded by changes in foraminifera assemblages [Black *et al.*, 2001; Field *et al.*, 2006] and that $\delta^{18}\text{O}$ of planktonic foraminifera records temperature changes associated with El Niño [Thunell *et al.*, 1999]. Thus, the different proxies used in the SBB seem to yield partially contrasting information. This highlights the importance of a multiproxy approach and the need to understand the response and limitations of a proxy in the SBB area before paleoclimate studies can be performed.

Here we investigated the potential of the TEX₈₆ to reconstruct past temperatures in the SBB area by analysing sediment trap material obtained over two annual cycles (1995-1997). In addition, we analysed the TEX₈₆ in a high resolution sediment record with annual to tri-annual resolution representing the period from ~1849 to 1987 AD and compared this with an available instrumental temperature record for the SBB.

5.2. Material and Methods

5.2.1. Sample material

5.2.1.1. Sediment trap

An automated sediment trap has been deployed since 1993 in the center of the basin (34°14'N, 120°02'W) (Fig. 1) at ~490 m water depth, ~50 m from the bottom [Thunell *et al.*, 1995; Thunell, 1998]. Biweekly to monthly measurements of temperature and salinity down to 100 m depth have been made at the mooring location of the trap sample. For this study we selected 22 samples from the period between December 1995 and December 1997 which were analyzed for GDGT concentration. These samples represent collection periods ranging from 6 to 18 days. Freeze dried and homogenized sub-samples of 50-180 mg were used for this study.

5.2.1.2. Sediment core

Box cores from the depocenter of the SBB were recovered in 1987 during the cruise SABA 87-2 ($34^{\circ}13.5'N$, $120^{\circ}01.0'W$), and in 2004 during cruise BASIN 2004 ($34^{\circ}13.41'N$, $120^{\circ}01.53'W$, box core 1-MC3) (Fig. 1). Cylindrical sub-cores from box cores were sectioned in layers with approximately annual to tri-annual resolution although the resolution is higher than annual in the upper third section of each core as sediment is less compacted (Fig. 2). The sediment obtained from each section was freeze-dried and stored [Schimmelmann *et al.*, 1990]. BASIN 2004 samples dating from 1917 to 1959 AD were analyzed to cover a sampling hiatus in box core SABA 87-2. A total of 211 samples were analyzed from both cores, covering about 140 years of sedimentation from ca. 1850 to 1987 AD.

Dating of samples was performed by varve counting on sediment X-radiographs that were correlated against high-resolution porosity profiles [Schimmelmann *et al.*, 1990]. Validation of varve-counting for dating in SBB sediment had been independently achieved by ^{210}Pb geochronology, identification of specific diatom assemblages of El Niño events of 1941, 1958 and 1983 AD, and the statistical relationship of varve thickness versus precipitation on land [reviewed by Schimmelmann and Lange, 1996; Fig. 2]. The dating uncertainty for individual sediment samples is ~ 2 years below 1980 AD and about one year for younger sediments [Schimmelmann *et al.*, 1990].

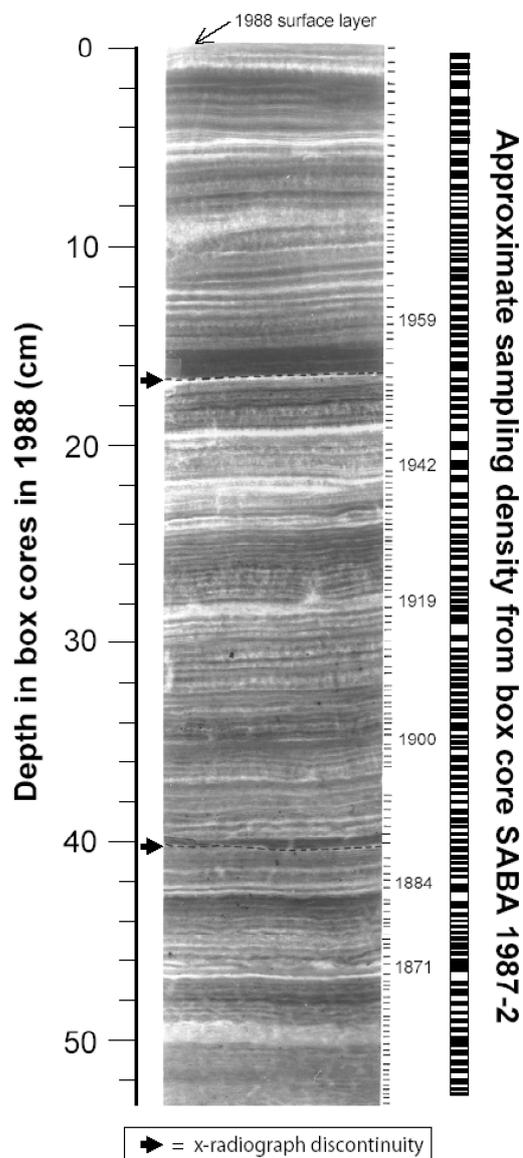

Figure 2. Composite of X-radiograph contact prints showing varves from 1840 to 1988 in the depocenter of the SBB. The black/white pattern indicates the approximate sediment sampling intervals for this study.

5.2.2. *TEX*₈₆ analysis

Freeze-dried samples between 50-180 mg were extracted using an Accelerated Solvent Extractor 200 (ASE 200, DIONEX) with a mixture of dichloromethane (DCM) and methanol (MeOH) (9:1, vol:vol) at 100°C and 7.6 10⁶ Pa. A known amount of a C₄₆ GDGT was added to the extract of the sediment trap samples as internal standard [Huguet *et al.*, 2006b]. The total extract was then divided into an apolar and a polar fraction, using a glass pipette column filled with activated alumina, and sequential elution with hexane/DCM (9:1 vol:vol) and DCM/MeOH (1:1, vol:vol), respectively. Polar fractions were analyzed for GDGTs according to the procedure described by Hopmans *et al.* [2000]. Analyses were performed in triplicate with an HP 1100 Series Liquid Chromatography-Mass Spectrometer (LC-MS) equipped with an auto-injector and ChemStation chromatography manager software. Separation was achieved on a Prevail Cyano column (2.1 x 150mm, 3µm; Alltech, Deerfield, Illinois, USA), maintained at 30°C. GDGTs were eluted isocratically first with hexane/isopropanol (99:1, vol:vol) for 5 min, then using a linear gradient up to 1.8 % vol of isopropanol over 45 min. Flow rate was 0.2 mL/min. After each analysis the column was cleaned by back flushing hexane/propanol (90:10, vol:vol) at 0.2 mL/min for 10 min. Detection was achieved using atmospheric pressure chemical ionization-mass spectrometry (APCI-MS) of the eluent using the following conditions; nebulizer pressure 4.1 10⁵ Pa, vaporizer temperature 400°C, N₂ drying gas flow 6 L/min at 200°C, capillary voltage -3kV, corona 5 µA (~3.2kV). Single Ion Monitoring (SIM) was used instead of full mass scanning because SIM increases the signal-to-noise-ratio and thus improves reproducibility. SIM was set to scan the five [M⁺]+H ions of the GDGTs with a dwell time of 237 ms for each ion. Concentrations of GDGTs in the sediment trap samples were calculated based on the added internal standard and the relative response factor of the standard versus crenarchaeol [Huguet *et al.*, 2006b]. Relative abundances of GDGTs were used to calculate *TEX*₈₆ values that relate to temperature in °C according to the following empirical relationship [Schouten *et al.*, 2002]:

$$\text{TEX}_{86} = 0.015 \cdot T + 0.28 \quad [1]$$

This equation results from the correlation of *TEX*₈₆ values from core top sediments with SST (see [Schouten *et al.*, 2002] for details).

An aliquot of an Arabian Sea sediment extract was measured every 10 samples to assess the analytical error. The resulting mean TEX_{86} value for 72 repeat analyses was 0.68 with a standard deviation of ± 0.034 , corresponding to $26.6 \pm 0.5^\circ\text{C}$ according to equation [1].

5.2.3. Time series analysis

Time series analyses were performed on (i) our 1849-1987 AD TEX_{86} record, (ii) the ENSO index Niño 3.4 of *Kaplan et al.* [1998] and *Smith and Reynolds* [2003; 2004], and (iii) the Pacific Decadal Oscillation (PDO) index of *Mantua et al.* [1997] (see <http://jisao.washington.edu/pdo/PDO.latest>). We also performed a first-order autoregressive (AR1) process to evaluate the influence of climatic red noise on the variability of all the data series. For this purpose we derived spectra directly from the unevenly spaced time series using the REDFIT program [*Schulz and Mudelsee*, 2002]. All time series were analysed with a Welch spectral window and four segments with 50% overlap ($n_{50} = 4$) [*Schulz and Mudelsee*, 2002].

5.3. Results

5.3.1. Sediment trap

The sediment trap material analyzed covers two annual cycles for the period December 1995 to December 1997. The onset of the 1997-1998 strong El Niño was in March 1997 but the effects only reached the SBB in June 1997 [*Lynn et al.* 1998] and thus our trap series covers both non-El Niño and initial El Niño conditions in the SBB area. The flux of GDGT lipids ranged from $29 \mu\text{g m}^{-2} \text{day}^{-1}$ in November 1997 to $196 \mu\text{g m}^{-2} \text{day}^{-1}$ in November 1996 (Fig. 3a). These GDGT fluxes are similar to those reported for an upwelling station near the Californian coast but higher than those reported for the Arabian Sea (up to $40 \mu\text{g m}^{-2} \text{day}^{-1}$) [*Wuchter et al.*, 2006b]. During the non-El Niño period, two clear peaks in GDGT fluxes were observed, one in May/June 1996 and the largest between October 1996 and January 1997. During the El Niño period there were no distinct maxima, and GDGT fluxes remained fairly constant oscillating between 25 and $100 \mu\text{g m}^{-2} \text{day}^{-1}$ (Fig. 3a).

TEX_{86} -derived temperatures range from 7.5°C in November 1996 to 11.4°C in March 1997 (Fig. 3a). The average flux-weighted TEX_{86} temperature over the time series is 9.6°C , with average values of 9.3°C in 1996 and 9.9°C in 1997, respectively. The average flux-weighted TEX_{86} temperatures were 9.6°C for the non-El Niño time period (December 1995-

June 1997) and 9.7°C for the El Niño period (June 1997-December 1997) (Fig 3). Both years follow a similar pattern showing a decrease in temperature in late spring, an increase towards summer, and a second decrease in autumn followed by an increase in winter. Peak TEX₈₆ temperatures are found during spring 1996 and 1997, while minima in TEX₈₆ temperatures occur during October/November and June/July of both years (Fig. 3a).

5.3.2. Sediment core record

Samples from two partially overlapping sediment cores were analyzed to determine the historical record of TEX₈₆-derived temperatures. The main core analyzed, SABA 87-2 (in black; Fig. 4a), covered the period from 1849 to 1987 AD, but no material was available for the interval 1923 to 1942 AD. We covered this gap with samples from core 1-MC3 from the BASIN 2004 cruise, by analyzing samples dating from 1917 to 1959 AD (in green; Fig. 4a). Overall, TEX₈₆ temperatures of the combined cores range between 8.4° C and 13.7°C (Fig 4a). Although the TEX₈₆ values in 1-MC 3 are consistently lower than in SABA 87-2, the general trend and interannual variability are similar for the two cores (Fig. 4a). Although with slightly lower temperatures for the BASIN 1-MC3 core, the overlap intervals show good correspondence in terms of temperature ranges and trends (Fig. 4a), especially when the analytical error and the ~ 2 year dating error are taken into account. Average temperatures for the 1942-1959 overlap interval are 10.9°C for SABA 87-2 and 10.4°C for BASIN 1-MC3, a difference which falls within the 0.5°C analytical error for TEX₈₆. For the 1917-1923 AD overlap we also find a 0.5°C difference with average SABA 87-2 and BASIN 1-MC3 values of 10.5°C and 10.0°C, respectively. The interannual variability shows similar trends with most of the differences having overlapping error limits.

5.4. Discussion

5.4.1. Glycerol dibiphytanyl glycerol tetraether fluxes in the SBB

There are two distinct maxima in the GDGT fluxes during the non-El Niño period (Fig. 3a). The first peak at the end of spring coincides with a general increase in sedimentation flux (Fig. 3a) and is associated with upwelling and high phytoplankton productivity in the SBB area in spring [Thunell *et al.*, 1999]. Similar results were reported for a sediment trap study of GDGT fluxes in the Arabian Sea which showed that the highest fluxes in GDGTs are associated with the general increase in fluxes during upwelling [Wuchter *et al.*, 2006b]. This

was attributed to increased primary production and subsequent increased food web turnover leading to enhanced transport of GDGTs to the sediment by settling particles rather than increased production of GDGTs [Wuchter *et al.*, 2005; Huguet *et al.*, 2006a]. A similar explanation can thus be invoked for the first maximum in GDGT fluxes in the SBB. However, this is not the case for the second maximum in GDGT flux observed during winter 1996/1997 as sediment fluxes remained generally low. Reported molecular ecological data revealed that Crenarchaeota in the SBB area occur in higher abundance during winter [Murray *et al.*, 1999], suggesting that the higher flux of GDGTs during the winter months could be a reflection of higher Crenarchaeota production. Alternatively, the second maximum could be caused by a previously reported inshore meander of the California current at this time [Schwing *et al.*, 1997]. This inshore meander caused an unusual increase in chlorophyll concentrations [Schwing *et al.*, 1997] and foraminiferal flux [Black *et al.*, 2001], and may also have substantially increased Crenarchaeota production. Analysis of GDGT fluxes over longer time series should make clear which of these factors played a decisive role.

For the El Niño period there are no distinct maxima in GDGT fluxes during either spring/summer or early winter of 1997, even though there are increases in sediment fluxes at these times (Fig. 3a). This suggests that the El Niño of 1997-1998 strongly reduced Crenarchaeota production during this period. El Niño does not only affect physical parameters such as temperature but also has an impact on nutrient availability and productivity [Mantua *et al.*, 1997; Chavez *et al.*, 2002]. During 1997, temperatures were higher than normal (Fig. 3b) and the upwelling was greatly reduced [Thunell *et al.*, 1999], leading to a reduction in primary production [Black *et al.*, 2001] which usually results in reduced secondary production [Simpson, 1992]. Recent evidence suggests that part of the Crenarchaeota are nitrifiers [Könneke *et al.*, 2005; Wuchter *et al.*, 2006a] and use ammonia, produced by decay of phytoplankton and zooplankton, as an energy source. As phytoplankton productivity was greatly reduced during El Niño this could have led to a severe decrease in ammonia availability and thus lower Crenarchaeota productivity.

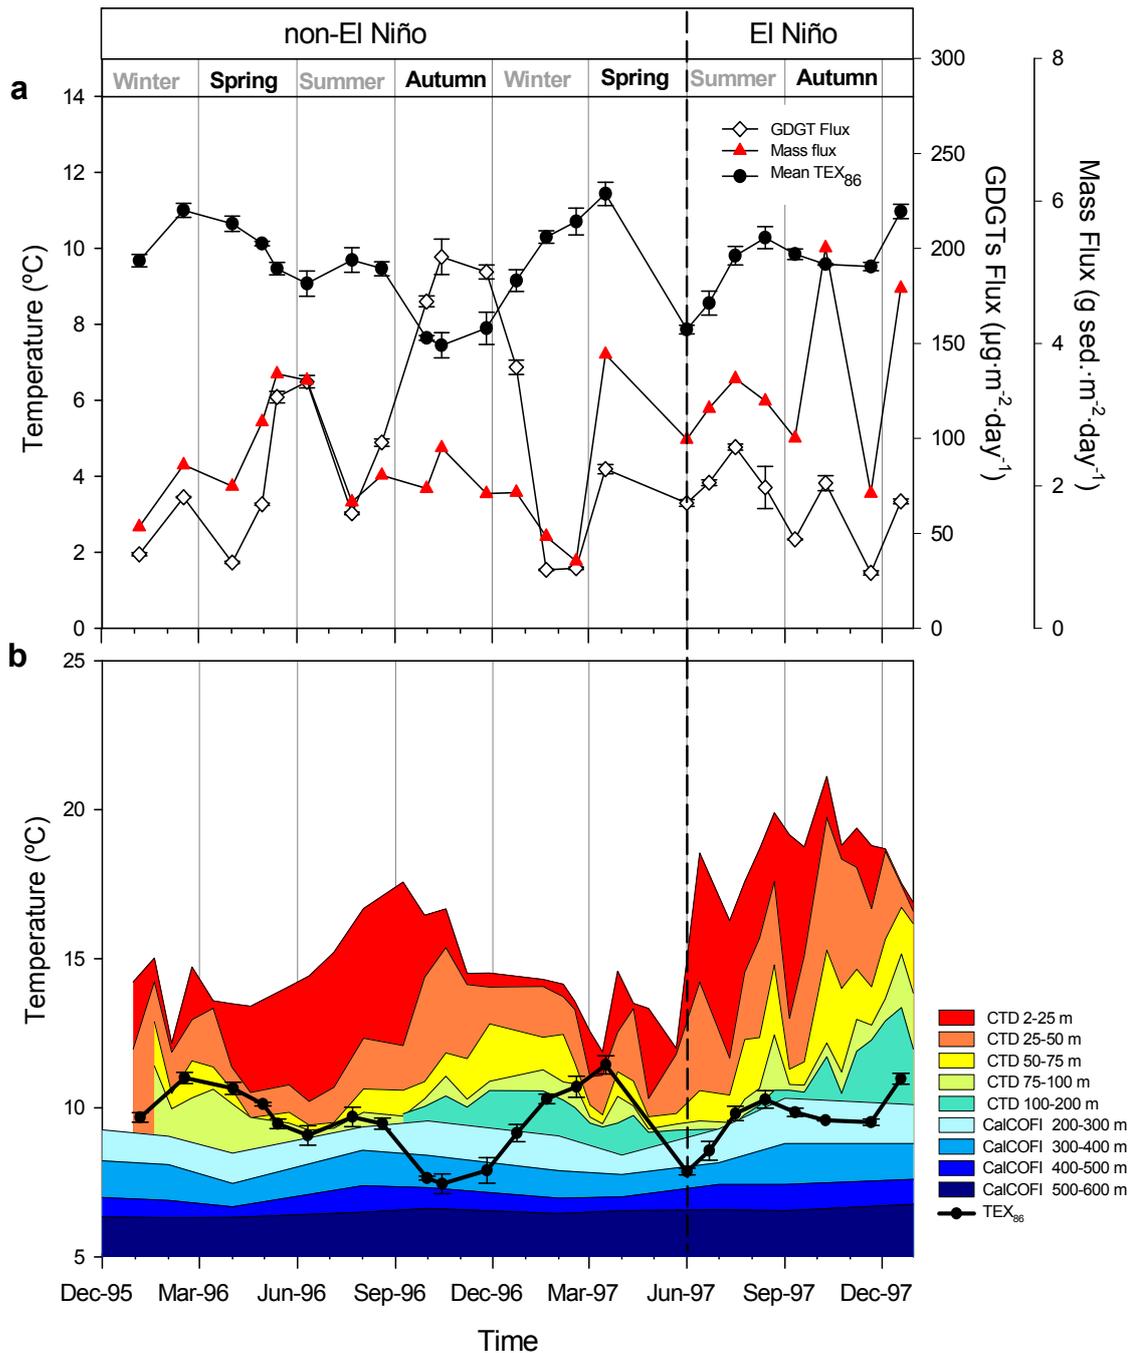

Figure 3. Flux and temperature data for the Santa Barbara Basin between December 1995 and December 1997. (a) Trap sample results for TEX_{86} -derived temperatures (\bullet), GDGT fluxes (\diamond) and mass fluxes (\blacktriangle). (b) Comparison of TEX_{86} -derived temperatures (\bullet) with in situ temperatures from 0 to 100 m (CTD data, [Thunnel, 1998]) and from 200-500 m (from the California Cooperative Oceanic Fisheries Investigations (CalCOFI, at www.calcofi.org). Error bars indicate analytical error of triplicate measurements.

5.4.2. Origin of the TEX_{86} temperature signal

Comparison of the TEX_{86} temperature signal with instrumental records, obtained by monthly CTD casts (0-100 m) and quarterly shipboard measurements (200-500 m) (Fig. 3b), revealed that the TEX_{86} temperatures, which range from 7.5 to 11.4°C, are always lower than SST values which range between 12 to 21°C. TEX_{86} -derived temperatures seem, in general, to correspond better to temperatures below 75 m, suggesting that in the SBB area TEX_{86} represents a sub-surface temperature signal, rather than SST (Fig. 3b). This is in contrast to previous sediment trap results from the Arabian Sea where TEX_{86} temperatures were slightly higher than in-situ surface temperatures [Wuchter *et al.*, 2006b]. Molecular ecological studies in the Santa Barbara Channel have shown that Crenarchaeota are most abundant below 75 m depth [Murray *et al.*, 1999] and a depth profile of GDGT concentrations in the water column of the Santa Monica Basin (SMB) [Wuchter *et al.*, 2005] also shows the highest abundance of Crenarchaeota lipids between 100-150 m depth. Furthermore, $\Delta^{14}C$ analysis of crenarchaeotal GDGTs in surface sediments of SBB and SMB showed a large ^{14}C -depletion and a lack of bomb-derived ^{14}C , and thus a deep-water origin for the GDGTs was suggested [Pearson *et al.*, 2001]. Hence, several lines of evidence suggest that crenarchaeotal GDGTs in the SBB are mostly derived from waters well below 75 m. TEX_{86} -derived temperatures for the sediment trap samples do not consistently reflect temperature at any particular depth through the annual cycle (Fig. 3b), suggesting that other factors besides deep-water temperature changes must contribute to the changes in TEX_{86} signal. Closer examination of the seasonal variation in TEX_{86} temperatures reveals that, in general, they correspond to temperatures between 100-300 m but that relatively much higher values are found in spring when TEX_{86} -calculated temperatures are only 1-3°C lower than SST (Fig. 3b). These relatively warm temperatures correspond to times of upwelling and thus lower SSTs. The relatively high TEX_{86} values could be caused by an increase in surface phytoplankton production during upwelling which in turn would have increased the amount of marine snow and fecal-pellet production in the surface during this period. GDGTs present in surface waters would then have been preferentially packaged and associated with sinking particles [Wuchter *et al.*, 2005; Huguet *et al.*, 2006a]. This would increase the relative contribution of the surface (0-100 m) versus deeper-water (below 100 m) signal. However, this should also be reflected in an increased flux in GDGTs which is not the case (Fig. 3a). Alternatively, the deep-water Crenarchaeota could be carried upwards with the upwelled and nutrient-rich waters thereby

experiencing much higher temperatures before dying and sinking to the sediment, although this is not consistent with previously observed Crenarchaeota seasonality, as they are usually more abundant at times of low phytoplankton productivity [Wuchter *et al.* 2005]. However, this is supported by molecular studies in the Santa Barbara Channel which showed that Crenarchaeota were only detected in surface waters during times of upwelling [Murray *et al.*, 1999]. This may also explain why the strong warming of surface waters during El Niño is not reflected in our TEX₈₆ record, i.e. the reduced upwelling will have left the Crenarchaeota to thrive in deeper waters and prevented their upward transport to surface waters.

Our results thus suggest that the seasonal variation in TEX₈₆ is likely determined by the varying contributions of shallow versus deep-water signals. The behavior of the TEX₈₆ proxy is quite different from that of other temperature proxies determined in SBB sediment trap studies. For example, the U₃₇^K [Hardee and Thunell, 2006] and planktonic foraminiferal δ¹⁸O [Thunell *et al.*, 1999] signals from SBB sediment trap samples show a good correspondence with SST. Mg/Ca ratios of planktonic foraminifera from sediment traps in the SBB area also show a generally good correspondence with upper water column temperatures although some variation in depth habitat of the foraminifera was noted and the Mg/Ca ratio did not reflect the warming of surface waters during El Niño [e.g. Pak *et al.*, 2004].

5.4.3. Past variation in TEX₈₆ temperatures

Our results from the SBB sediment cores show that the TEX₈₆ paleothermometer most likely records temperatures below 100 m, as the TEX₈₆ temperatures are all well below the COADS instrumental mean annual SST at 31-33° N, 119-121°W (COADS <http://www.ncdc.noaa.gov/oa/climate/coads/>) (Fig. 4b), in good agreement with results from our sediment trap study. However, TEX₈₆ temperatures do not consistently reflect sub-surface temperatures at a particular depth, as temperatures below the thermocline in the SBB have varied in general by less than 0.5°C over the last 50 years [Field and Baumgartner, 2000], while our TEX₈₆ temperatures vary by more than 4°C. Thus, it is unlikely that changes in sub-surface temperature alone caused the TEX₈₆ variation observed in the sediment cores (Fig. 4). Instead, changes in depth of origin of the GDGT signal and/or changes in seasonality of GDGT production may be responsible for much of the observed variation.

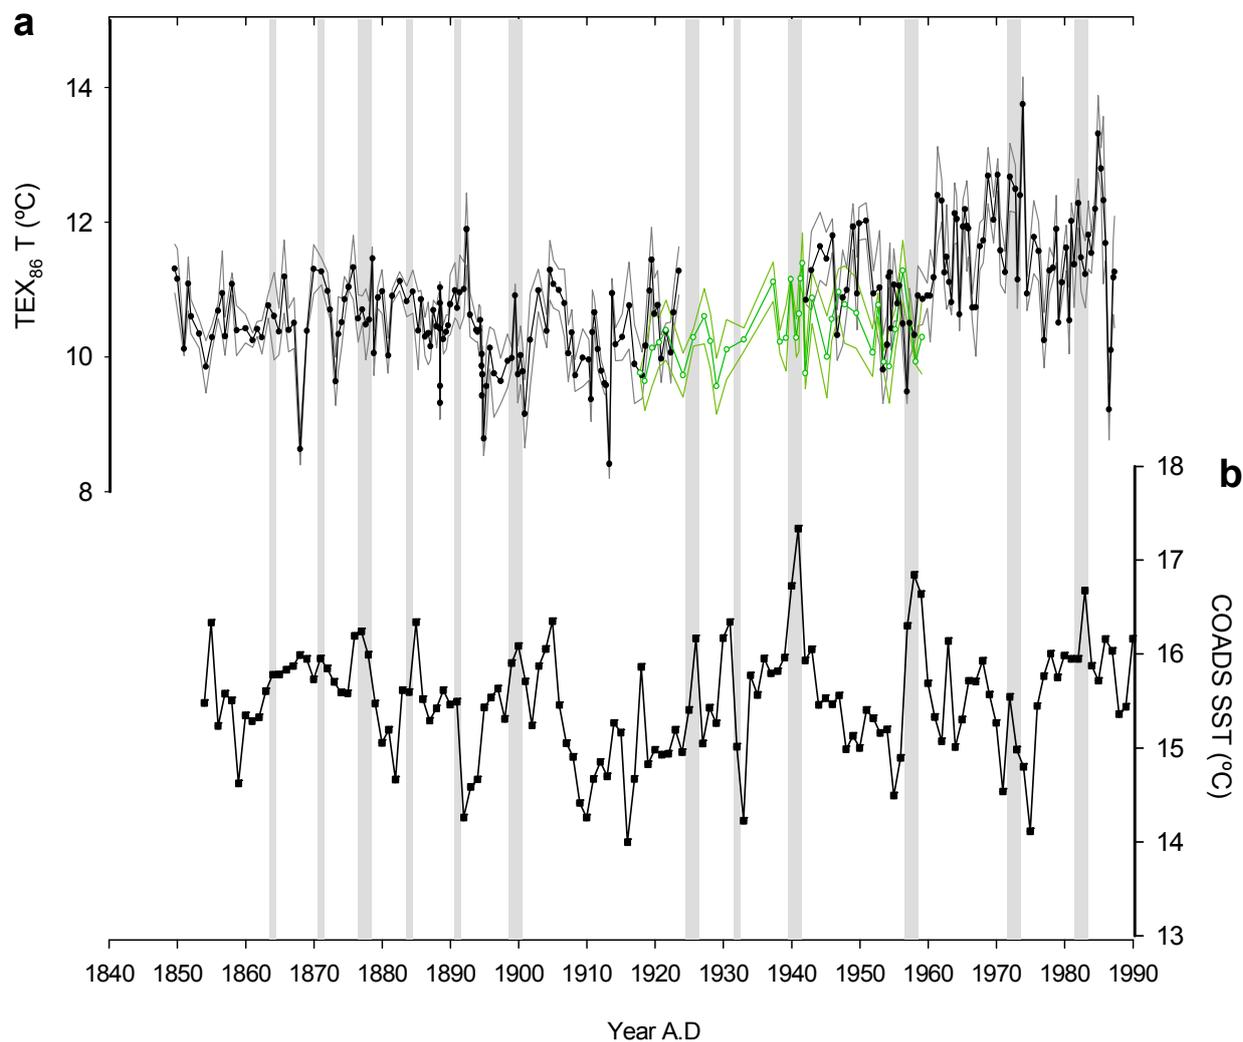

Figure 4. Temperature time series from the Santa Barbara Basin. (a) TEX_{86} -based temperature reconstruction from SABA 87-2 box core sediment (in black with \bullet) and from BASIN 2004 box core sediment (in green with \circ); temperatures were calculated using the standard TEX_{86} equation according to *Schouten et al.* [2002], with standard deviation indicated by grey lines. (b) Mean annual SST ($31-33^{\circ}$ N, $119-121^{\circ}$ W) from the Comprehensive Ocean-Climate Data Set project (COADS; <http://www.ncdc.noaa.gov/oa/climate/coads/>). Vertical grey bars indicate the timing of historic El Niño events with strengths 4, 5 and 6 according to the compilation by *Quinn* [1999]

The large increase in SST in the SBB during some El Niño events is reflected in a number of temperature proxies preserved in SBB sedimentary records [Kennedy and Brassell, 1992; Field *et al.*, 2006]. However, comparison of the TEX₈₆ temperature record with SST anomalies caused by El Niño (strengths 4, 5 and 6 according to the compilation by Quinn [1999]; indicated by vertical grey bars in Fig. 4) reveals no obvious correlation and generally no elevated TEX₈₆ temperatures coinciding with strong El Niño events (Fig. 4a), although El Niño-related SST spikes are apparent in the instrumental SST record (Fig. 4b). This is in agreement with sediment trap data where a strong El Niño warming of surface waters after June 1997 was not recorded by TEX₈₆, i.e. the flux-weighted average TEX₈₆ temperature of 9.6°C for the non-El Niño period was similar to the 9.7°C for the El Niño period.

We performed frequency analysis to investigate other possible controlling factors in past variations of TEX₈₆-derived temperatures. The results were compared to those from frequency analyses of both ENSO and PDO as the latter have been reported to influence temperatures, the structure of the water column, upwelling dynamics in the SBB, and thus also nutrient availability and primary production [Mantua *et al.*, 1997; Chavez *et al.*, 2002]. Frequency analyses of the Niño 3.4 (1856-2006 AD) and PDO (1900-2005 AD) indices revealed both highly significant (>99%- χ^2 false-alarm level) periods at 5.6-5.8 years. A ~5.7 yr cycle has been reported in various other records and seems to be rooted in ENSO forcing [Felis *et al.*, 2000], it is evidently widespread in polar to tropical areas [Felis *et al.*, 2000; Jevrejeva *et al.*, 2004; Felis *et al.*, 2004; Cronin *et al.*, 2002] and may influence atmospheric indices such as the North Atlantic Oscillation (NAO) [Felis *et al.*, 2000]. A 5.7 yr cycle is also present in our 1849-1987 AD sedimentary TEX₈₆ record, although its amplitude does not exceed the 80%- χ^2 false-alarm level. The lack of any highly significant cycles in the sedimentary TEX₈₆ record of the SBB is most likely due to the strong decoupling between TEX₈₆ and the temperature at any fixed depth interval.

The TEX₈₆ signal in the SBB sedimentary record might also be complicated by fluctuating strengths of the California and Davidson currents, changing wind patterns, intermittent upwelling, and the tidal regime. The sedimentary input received by the SBB depocenter may include allochthonous material that is transported from nearby areas by currents, as well as tidally re-suspended sediment [Berger *et al.*, 2004]. However, the reported multi-annual tidal variability is dominated by the lunar nodal cycle of 18.3 years, a cycle which we do not find in our TEX₈₆ record. In addition, our frequency analysis shows no

cycles that can be associated with those found for varve thickness or TOC records [Zhao *et al.*, 2000; Berger *et al.*, 2004], although all records use spatially compatible data from the same or similar sediment cores. This suggests that the variations observed in our *TEX₈₆* record are likely not caused by tidally-induced resuspension but by a complex array of varying depths of GDGT production and environmental factors such as upwelling.

5.5. Conclusions

TEX₈₆ analyses of sediment trap samples reveal that temperatures inferred from this proxy do not reflect SST but predominantly sub-surface temperatures (below 100 m) in the SBB. They also indicate that either the Crenarchaeota change depth habitat or that the relative contributions of surface and deep-water signals change during times of upwelling when *TEX₈₆* reflects shallower water temperatures. Analyses of *TEX₈₆* from a time series of varved sediment intervals from the depocenter of the SBB also show lower than expected *TEX₈₆* values, suggesting a sub-surface signal over the last 150 yrs from varying water depths with time. Like in the sediment traps, these changes are likely caused by changes in Crenarchaeota depth habitat or varying depth origin of the *TEX₈₆* signal as influenced by environmental factors. Thus, in contrast to *TEX₈₆* signals from other marine areas, *TEX₈₆* in the SBB cannot be used to trace changes in surface temperature. Therefore, care must be exercised when applying *TEX₈₆* in regions where environmental conditions lead to a crenarchaeotal GDGT signal that is derived from various depths rather than predominantly from the upper part (<100) of the water column.

Acknowledgements

We thank Gesine Mollenhauer and David Field for helpful comments, and Norel Rimbu and Wolf Berger for assistance with the interpretation of the 5.7 year cycle. David Valentine and Alex Sessions granted access to BASIN 2004 box cores. This project was supported by NWO-ALW (Project no. 152911), by EU project 6C (Contract no. EVK2-2001-00179 - 6C), and by National Science Foundation grants OCE 9807745 to A.S and OCE 0315234 to R.T.

Manuscript in preparation

Abstract

Burial of organic carbon (OC) in marine sediments is one of the major sinks for carbon and most of this burial takes place on the continental margins. Terrestrial organic matter (OM) is selectively preserved in (sub)oxic environments compared to marine OM but it is unclear if this is due to intrinsic chemical resilience of the terrestrial OM, or because the mineral matrix protects it from degradation. To test this we analyzed bulk organic carbon (OC), long-chain alkenones and glycerol dialkyl glycerol tetraethers (GDGTs) of oxidized and un-oxidized layers of a selection of organic-rich turbidites deposited at the Madeira Abyssal Plain (MAP). These distal, fine-grained, turbidites contain OM that first accumulated on the shelf and subsequently was redeposited in the abyssal plain. These turbidites are relatively homogenous and when exposed to bottom water oxygen this leads to an oxidation front progressing downward until the next turbidite unit is deposited. As a consequence of this oxidation, concentrations of OC, GDGTs and alkenones were reduced by one or two orders of magnitude in the oxidized upper parts of the turbidites compared to the un-oxidized lower parts, indicating substantial degradation. We also evaluated the effect of oxic degradation on two GDGTs proxies, the TEX₈₆ and the BIT index. The TEX₈₆ values remained unchanged upon oxidation in some turbidites but in other turbidites showed substantial changes with either increasing or decreasing values in the oxidized parts. In contrast, BIT indices were always substantially higher in the oxidized parts versus un-oxidized parts of the turbidites. The shifts in BIT and TEX₈₆ indices can be explained by a strong relative increase in soil-derived GDGTs compared to the marine-derived GDGTs as a result of oxic degradation. This selective preservation of soil-derived lipids with chemical structures that are nearly identical to those of their marine counterpart suggests that the mineral matrix to which soil organic matter is attached enhanced its preservation.

6.1. Introduction

Burial of organic carbon (OC) in marine sediments is one of the major sinks for carbon on geological time with important effects on the global carbon cycle and atmospheric CO₂ levels. A large part of the OC burial takes place on continental margins [Hedges and Keil, 1995]. At these locations both marine and terrestrial OC, the latter mainly transported by rivers, are deposited. During deposition, this OC is substantially degraded, especially under oxic or sub-oxic conditions. However, terrestrial OC is, in general, better preserved compared to marine organic matter [e.g. Cowie *et al.*, 1998; Hoefs *et al.*, 1998a; Burdige, 2005]. For example, studies on turbidite sediments from the Madeira abyssal plain (MAP) reported that only 40% of the terrestrial OC was degraded while as much as 90% of the marine OC was degraded [Prahel *et al.*, 1997].

Different hypotheses have been suggested to explain the differential degradation between marine and terrestrial forms of organic carbon. Compared to marine organic compounds, certain terrestrial organic molecules such as plant waxes and lignins are relatively difficult to degrade by microbes and thus have a greater preservation potential [e.g. de Leeuw and Largeau, 1993]. Also, terrestrial OC is subjected to extensive oxic degradation before reaching the continental margins and therefore the terrestrial OC finally deposited would be intrinsically more resilient to degradation than marine OC (see Hedges and Keil, [1995] for review). Alternatively, the physicochemical packaging within the sedimentary matrix could be different for the terrestrial and marine OC [Keil *et al.*, 1994] and make the OC less accessible for microbial degradation (bio-availability). In marine sediments, much of the preserved OC is either absorbed to mineral surfaces or enclosed in particle aggregates [Keil *et al.*, 1994; Hedges and Oades, 1997] and more than 90% of the total organic matter in marine sediments can not be physically separated from its mineral matrix [Hedges and Keil, 1995]. The so-called sorptive preservation is related to the mineral surface area, with clay-size particles having a relatively higher percentage of OC [Hedges and Keil, 1995]. A combination of both intrinsic resilience and matrix protection has also been suggested as leading to enhanced preservation of terrestrial OC [Prahel *et al.*, 1997].

Besides having a general impact on OC preservation, oxic degradation may also affect the relative distribution of biomarker lipids. Studies of sediments deposited in the MAP [Hoefs *et al.*, 2002] and in the Arabian Sea [Sinninghe Damsté *et al.*, 2002] showed that post

depositional oxic degradation not only decreased the concentration of lipid biomarkers by several orders of magnitude, but also that the extent of the degradation was different for different compounds and thus may cause a severe bias in the biomarker distribution. An important effect of this bias is the impact it may have on organic paleoceanographic proxies such as U_{37}^K , TEX_{86} and BIT. While some studies showed an effect of oxic degradation on alkenones and the U_{37}^K [Hoefs *et al.*, 1998a; Gong and Hollander, 1999] others only reported a decrease in alkenone abundances but no effect on the U_{37}^K ratio [Prahl *et al.*, 1989; Prahl *et al.*, 2003a]. On the other hand, a previous study comparing oxidized and un-oxidized cores in the Arabian Sea showed no significant differences in TEX_{86} [Schouten *et al.*, 2004]. However, the exposure time to oxygen in the latter study was relatively short compared to those in the MAP.

The MAP turbidites are an ideal site to study the effect of oxygen on OC and proxy biases as the organic matter in the sediment is relatively homogenous and oxygen diffusion into the sediment has created “oxidation fronts” which are easily identifiable [e.g. *de Lange*, 1998; *Cowie et al.*, 1998; *Hoefs et al.*, 1998a]. The MAP turbidite sediments were originally deposited on the anoxic African shelf and due to slope instability subsequently transported to the abyssal plain in a turbidity current and deposited as well mixed OC-rich turbidites in the oxic deep sea [Cowie *et al.*, 1995; *de Lange*, 1998; *Cowie et al.*, 1998; *Hoefs et al.*, 1998a]. The contact with the oxic bottom waters causes a “burn down” effect where the organic matter in the upper part of the turbidite is degraded by downward-diffusing oxygen while the lower part is left unaltered [*de Lange*, 1998]. This allows the study of the effect of oxygen degradation on the composition of OC. For example, it has been shown that oxic degradation is selective, with preferential preservation of terrestrial OC in the kerogen fraction [Hoefs *et al.*, 1998a]. Furthermore, as discussed above it has severe effects on the biomarker composition [Hoefs *et al.*, 1998b]. Thus, MAP turbidites are ideal material to study the long term mineralization processes that affect organic matter and proxies in both oxic and anoxic conditions [*de Lange*, 1998].

The aim of this study was to understand the effect that long term exposure of oxic degradation has on the abundance and composition of glycerol dialkyl glycerol tetraethers (GDGTs) and the GDGT-based proxies TEX_{86} and BIT index.

We compared the degree of degradation of GDGTs with those of OC and of long-chain alkenones and assessed the effects of oxic exposure on GDGT-based proxies.

6.2. Material and methods

6.2.1. Turbidite sediments

The Madeira Abyssal Plain has an average of 5400 m depth and covers an area of ~80000 km² at the bottom of the Canary Islands shelf [Cowie *et al.*, 1998]. The records in this area present meter-thick distal turbidites intercalated by cm-thin organic-matter poor marls [Cowie *et al.*, 1998]. The Pleistocene F-turbidite samples (see Table 1) are from core 90P22, which was recovered at 32°N 03.0', 24°W12.1' during the 1990 R/V Tyro cruise. The Pliocene/Miocene samples for this study (see Table 2) were collected on board the R/V JOIDES Resolution cruise, ODP Leg 157. The samples were stored in geochemical bags and were kept and transported dark and frozen from the ship to the laboratory [de Lange, 1998]. The five organic-rich turbidites used for this study are from different times of deposition: The F-turbidite emplacement took place ~127 Ka, whereas turbidites T2, T6, T10 and T13 (see table 2 for ODP codes) have emplacement times of up to 14 Ma. The F-turbidite was sampled in higher resolution (8 samples) while 3 or 4 samples were taken from turbidites T2, T6, T10 and T13.

6.2.2. TOC and $\delta^{13}C$ TOC

Total organic carbon content (TOC) and its stable isotope composition $\delta^{13}C_{org}$ were done on freeze-dried samples using Fisons 3100 Elemental analyzer coupled to an isotope ratio mass spectrometer (see de Lange, [1998] for details).

6.2.3. Lipid extraction

Freeze-dried sediment samples were extracted using an Accelerated Solvent Extractor 200 (ASE 200, DIONEX) with a mixture of dichloromethane (DCM) and methanol (MeOH) (9:1, vol:vol) at 100°C and $7.6 \cdot 10^6$ Pa. A known amount (1-2 μ g) of C₄₆ GDGT internal standard was added to the total extract to measure absolute GDGT abundances as described in [Huguet *et al.*, 2006]. An aliquot of each total extract was separated into an alkenone and a polar fraction, using a glass pipette column filled with activated alumina, and sequentially

eluting with hexane/DCM (1:1 vol:vol) and DCM/MeOH (1:1, vol:vol) yielding the alkenone and polar fraction, respectively.

6.2.4. *Alkenone analysis*

For quantification, an internal standard, a deuterated ante-iso C₂₂ alkane, was added to the alkenone fraction. The alkenone fraction was saponified with 1 N KOH in 96:4 MeOH/H₂O for 1 h at 100°C. After saponification, the neutral fraction containing alkenones was obtained by partitioning into DCM and analyzed by capillary gas chromatography (GC) using an Agilent Technologies 6890 equipped with an auto injector and a flame ionisation detector (FID). A fused silica capillary column (50 m × 0.32 mm) coated with CP Sil 5 (film thickness 0.12 µm) was used with helium as carrier gas. The samples were dissolved in ethyl acetate and injected at 70°C. The oven was programmed to heat to 130°C at 20 °C/min and then at 4°C/min to 320°C at which it was held for 25 min. Alkenone analyses were performed at least three times. Peak areas of C_{37:2} and C_{37:3} alkenones were determined using the Atlas program.

6.2.5. *GDGT analysis*

The polar fraction was analyzed for GDGTs according to the procedure described by *Hopmans et al.* [2000]. GDGT abundances were calculated using the internal standard method as described by *Huguet et al.* [2006]. Analyses were performed in triplicate with an HP 1100 Series Liquid Chromatography-Mass Spectrometer (LC-MS) equipped with an auto-injector and ChemStation chromatography manager software. Separation was achieved on a Prevail Cyano column (2.1 × 150mm, 3µm; Alltech, Deerfield, Illinois, USA), maintained at 30°C. GDGTs were eluted isocratically first with hexane/isopropanol (99:1 %; vol:vol) for 5 min, then using a linear gradient up to 1.8 % vol of isopropanol over 45 min. Flow rate was 0.2 mL/min. After each analysis the column was cleaned by back flushing hexane/isopropanol (90:10; vol:vol) at 0.2 mL/min for 10 min. Detection was achieved using atmospheric pressure chemical ionization-mass spectrometry (APCI-MS) of the eluent using the following conditions; nebulizer pressure 60 psi, vaporizer temperature 400°C, N₂ drying gas flow 6 L/min at 200°C, capillary voltage -3kV, corona 5 µA (~3.2kV).

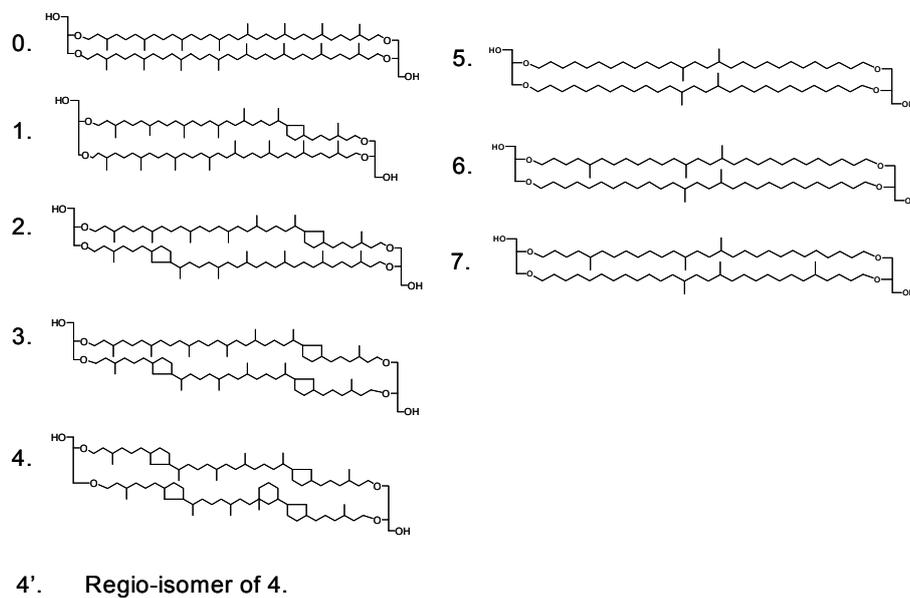

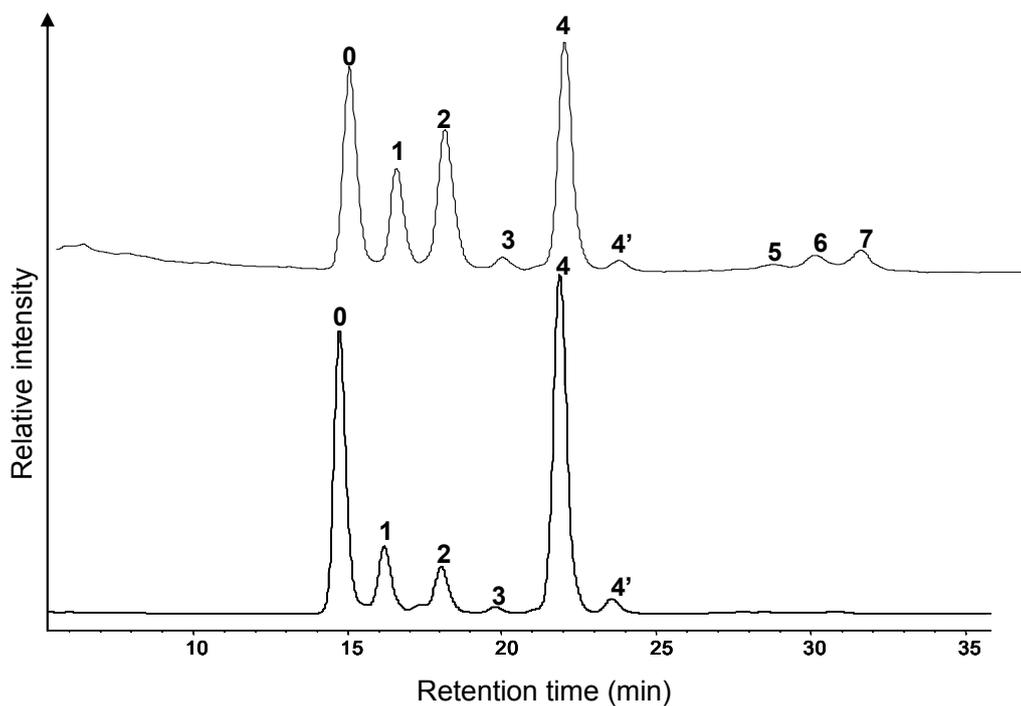

Figure 1. HPLC/MS base peak chromatograms of the F-turbidite oxidized sample at 1071 cm (upper panel) and un-oxidized sample at 1154 cm (lower panel). The numbers refer to structures of GDGTs shown below. The GDGTs on the left hand side (from 0-4') are isoprenoid GDGTs while branched GDGTs (5, 6 and 7) are in the right hand side.

Single Ion Monitoring (SIM) was used instead of full mass scanning because SIM increases the signal-to-noise-ratio and thus improves reproducibility [Schouten *et al* 2007]. SIM was set to scan the five $[M+H]^+$ ions of the GDGTs and the three $[M+H]^+$ ions of the branched tetraethers with a dwell time of 237 ms for each ion.

The TEX₈₆ ratio was calculated based on the relative abundance of GDGTs as follows [Schouten *et al.*, 2002]:

$$\text{TEX}_{86} = \frac{\text{GDGT 2} + \text{GDGT 3} + \text{GDGT 4}'}{\text{GDGT 1} + \text{GDGT 2} + \text{GDGT 3} + \text{GDGT 4}'} \quad [1]$$

The numbers correspond to structures in Fig. 1. The TEX₈₆ values relate to temperature according to the following empirical relationship [Schouten *et al.*, 2002]:

$$\text{TEX}_{86} = 0.015 \cdot T + 0.28 \quad [2]$$

The relative abundance of branched tetraethers (GDGT 5, 6 and 7) and crenarchaeol, GDGT 4, (Fig.1) were used to calculate the BIT index as follows [Hopmans *et al.*, 2004]:

$$\text{BIT} = \frac{[\text{GDGT 5} + \text{GDGT 6} + \text{GDGT 7}]}{[\text{GDGT 5} + \text{GDGT 6} + \text{GDGT 7} + \text{GDGT 4}]} \quad [3]$$

6.3. Results

6.3.1. TOC and $\delta^{13}\text{C}_{\text{TOC}}$

The division between the oxidized and un-oxidized part of the turbidites was initially established visually and then confirmed by the large changes in TOC and $\delta^{13}\text{C}_{\text{TOC}}$ [Prah *et al.*, 1989; de Lange, 1992; de Lange, 1998] (Figs. 2 and 3). In the F-turbidite the TOC ranges from 0.2 to 0.9 wt % (Fig. 2a, Table 1) and shows similar values for the un-oxidized portion (0.9±0.04 wt %) while the TOC decreases sharply in the oxidized area (grey area in Fig. 2) in agreement with previous observations. The $\delta^{13}\text{C}_{\text{TOC}}$ shows a shift towards more negative values, from -20.3 ‰ in the un-oxidized part to ca. -23 ‰ in the oxidized part (Fig. 2b).

In the T2, T6, T10 and T13 turbidites the TOC content ranges from 0.16 to 1.6 wt % (Fig. 3a, Table 2), showing consistently higher values for the un-oxidized part and lower values for the oxidized upper part (grey area in Fig. 3) in agreement with the F-turbidite results. The $\delta^{13}\text{C}_{\text{TOC}}$ shows a shift towards more negative values, and ranges from -19 ‰ in the un-oxidized part to -22 ‰ in the oxidized part (Fig. 3b).

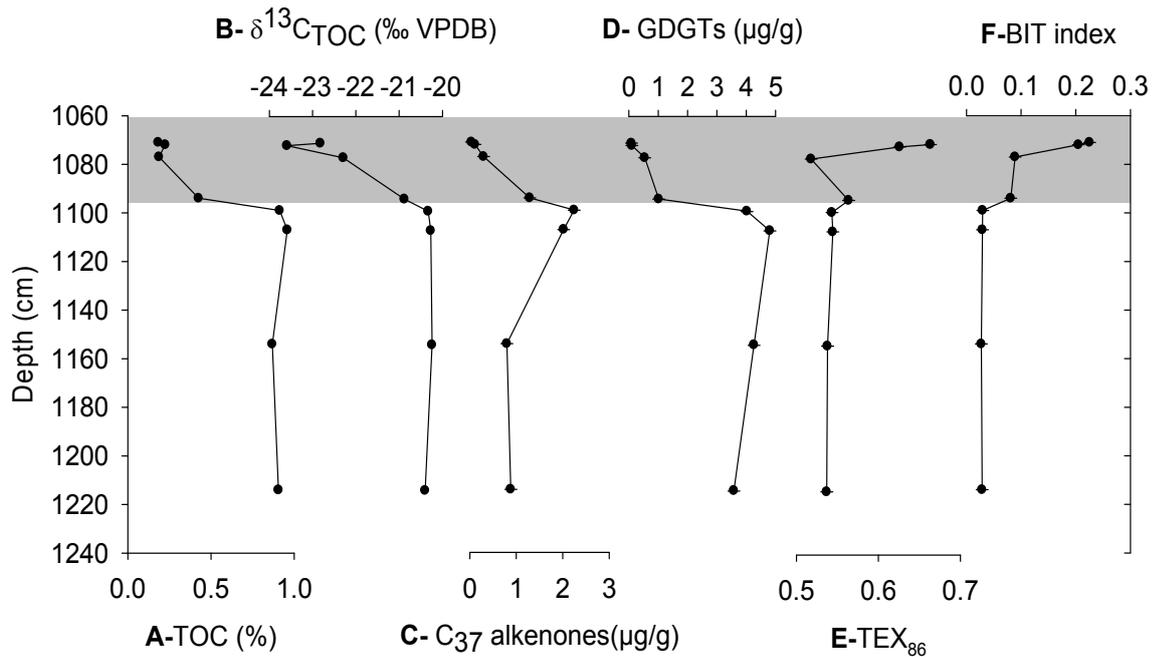

Figure 2. Profiles of A) TOC, B) $\delta^{13}\text{C}_{\text{TOC}}$, C) C_{37} alkenones abundance, D) GDGTs abundance, E) TEX_{86} and F) BIT index across the oxidation front in the F-turbidite. The oxidized part of the turbidite is indicated by the grey area.

| Core code | Depth (cm) | Interval (cm) | TOC (wt%) | GDGTs ($\mu\text{g/g}$) | C_{37} alkenone ($\mu\text{g/g}$) |
|-----------|------------|---------------|-----------|---------------------------|--|
| 90P22-2 | 1071 | 0.5 | 0.18 | 0.09 | 0.04 |
| 90P22-2 | 1072 | 0.7 | 0.23 | 0.10 | 0.11 |

| 90P22-2 | 1214 | 1 | 0.91 | 3.58 | 0.88 |

Table 1. Percentage of TOC (wt %) and concentrations of GDGTs and C_{37} alkenones in the F-turbidite with depth. Grey rows indicate oxidized samples.

6.3.2. Long-chain alkenones

In general, concentrations of C_{37} alkenones decrease sharply from the un-oxidized to the oxidized parts in the turbidites (Figs. 2 and 3). For the F-turbidite C_{37} alkenone abundances range between 0.04 and 2.3 $\mu\text{g/g}$ with the highest value at 1100 cm depth (Fig. 2c, Table 1) and lowest values in the upper-most portion of the oxidized part (1071 cm depth). For turbidites T2, T6, T10 and T13 the C_{37} alkenone abundances range between 0.09 and 7.3 $\mu\text{g/g}$ with the lowest concentrations in the oxidized part (Fig. 3c, Table 2).

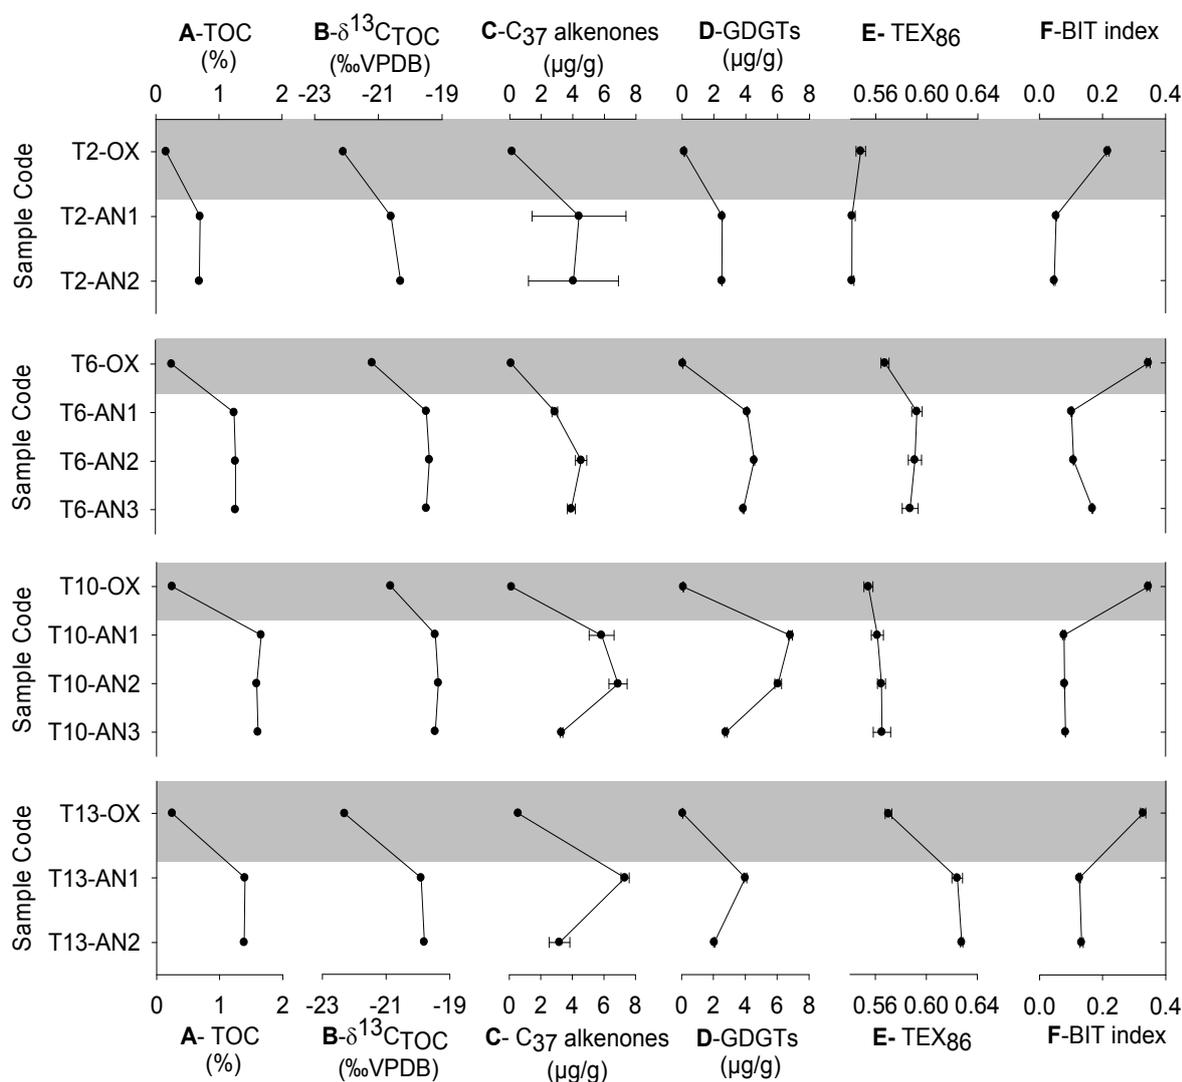

Figure 3. Profiles of A) TOC, B) $\delta^{13}\text{C}_{\text{TOC}}$, C) C_{37} alkenones abundance, D) GDGTs abundance, E) TEX_{86} and F) BIT index across the oxidation front in the T2, T6, T10 and T13 turbidites. The oxidized parts of the turbidites are indicated by the grey areas.

Table 2. Percentage of TOC (wt %) and concentrations of GDGTs and C₃₇ alkenones in the T2, T6, T10 and T13 turbidites with depth. Grey rows indicate oxidized samples.

6.3.3. GDGTs

The total GDGT abundances in the F-turbidite substantially decrease from ca. 5 $\mu\text{g/g}$ in the un-oxidized part to 0.1 $\mu\text{g/g}$ in the upper oxidized part (Fig. 2d, Table 1). The other four turbidites show similar trends with total GDGT abundances ranging between ca. 7 and 0.05 $\mu\text{g/g}$ with the lowest values always corresponding to the oxidized part of the turbidite (Fig. 3d, Table 2). Significant changes in TEX₈₆ are observed in some turbidites. The largest difference is found in the F-turbidite where the lowest TEX₈₆ value is 0.54 ± 0.004 in the un-oxidized part and is up to a 0.66 ± 0.001 in the oxidized part (Fig. 2e). The other four turbidites have different patterns with T2 and T10 turbidites showing no significant differences in TEX₈₆ values whilst the T6 and especially the T13 turbidite show a significant change from higher TEX₈₆ in the un-oxidized part of 0.59 ± 0.005 and 0.63 ± 0.003 , respectively, to lower TEX₈₆ in the oxidized part of 0.57 ± 0.003 , in both cases (Fig. 3e). These changes in TEX₈₆ values correspond in case of the F-turbidite to an increase in reconstructed SST of ca. 10°C and in the case of the T6 and T13 turbidites to a decrease of ca. 6°C when using equation [2].

The BIT index showed in all instances an increase from the un-oxidized to the oxidized part of the turbidites. In the F-turbidite, BIT values change from 0.03 in the un-oxidized to 0.23 in the oxidized part (Fig. 2f). T2, T6 T10 and T13 turbidites also show strong changes with values in the un-oxidized area as low as 0.05 increasing up to 0.35 in the oxidized parts (Fig. 3f).

| Depth (cm) | TOC (%) | C ₃₇ alkenone (%) | Total GDGTs (%) | GDGT-0 (%) | GDGT-1 (%) | GDGT-2 (%) | GDGT-3 (%) | GDGT-4 (%) | GDGT-4' (%) | GDGT-5 (%) | GDGT-6 (%) | GDGT-7 (%) |
|------------|---------|------------------------------|-----------------|------------|------------|------------|------------|------------|-------------|------------|------------|------------|
| 1071 | 20 | 2 | 2 | 2 | 3 | 7 | 5 | 2 | 2 | 7 | 29 | 24 |
| 1072 | 25 | 7 | 2 | 2 | 3 | 5 | 4 | 2 | 2 | 10 | 25 | 27 |
| 1077 | 21 | 20 | 13 | 14 | 13 | 13 | 11 | 12 | 9 | 19 | 70 | 58 |
| 1094 | 47 | 87 | 24 | 23 | 23 | 25 | 26 | 24 | 28 | 65 | 70 | 90 |

Table 3. Preservation factor of TOC, C₃₇ alkenones and total GDGTs as well as different GDGT isomers in the F-turbidite with depth. The preservation factor for each turbidite was calculated as the relative percentage normalized on the average concentration of that compound in the un-oxidized part of the turbidite.

| Sample Code | TOC (%) | C ₃₇ alkenones (%) | Total GDGTs (%) | GDGT-0 (%) | GDGT-1 (%) | GDGT-2 (%) | GDGT-3 (%) | GDGT-4 (%) | GDGT-4' (%) | GDGT-5 (%) | GDGT-6 (%) | GDGT-7 (%) |
|-------------|---------|-------------------------------|-----------------|------------|------------|------------|------------|------------|-------------|------------|------------|------------|
| T2-OX | 23 | 4 | 6 | 5.3 | 5.2 | 5.2 | 5.8 | 4.9 | 5.7 | 24.5 | 21.0 | 33.0 |
| T6-OX | 21 | 2 | 1 | 1.0 | 1.1 | 0.8 | 0.9 | 0.8 | 2.4 | 3.0 | 4.3 | 3.9 |
| T10-OX | 15 | 2 | 2 | 1.5 | 1.5 | 1.5 | 1.3 | 1.2 | 1.4 | 6.3 | 6.4 | 8.9 |
| T13-OX | 18 | 8 | 2 | 3.4 | 2.4 | 2.5 | 1.4 | 1.7 | 1.2 | 7.2 | 4.4 | 5.4 |

Table 4. Preservation factor of TOC, C₃₇ alkenones and total GDGTs as well as different GDGT isomers in the T2, T6, T10 and T13. The preservation factor for each turbidite was calculated as the relative percentage normalized on the average concentration of that compound in the un-oxidized part of the turbidite.

6.4. Discussion

6.4.1. Selective degradation of OC

It is clear from our results that both GDGTs and C₃₇ alkenones show a strong decline in concentration in the oxidized part of the turbidites and are thus severely degraded upon long-term exposure to oxygen. This is in agreement with previous studies that showed that both alkenones [Prahl *et al.*, 1989; Hoefs *et al.*, 1998a; Hoefs *et al.*, 1998b; Gong and Hollander, 1999; Prahl *et al.*, 2003b] and GDGTs [Sinninghe Damsté *et al.*, 2002; Schouten *et al.*, 2004] are degraded under (sub)oxic conditions. We calculated a preservation factor to establish the relative degree of preservation of the different compounds in the oxidized part of the turbidites (Tables, 3 and 4). The preservation factor for each compound in the oxidized samples was calculated as a relative percentage of the average compound concentration in the unoxidized part [cf. Hoefs *et al.*, 2002]. The degree of degradation of both GDGTs and C₃₇ alkenones is more extensive than the general OC decline as, e.g., 20% of the original TOC is still present in the upper sample of the oxidized part of the F-turbidite whereas only 2% of the GDGTs and C₃₇ alkenones are still present in that sample (Tables 3). In the case of the T2, T6, T10 and T13 turbidites the TOC declines down to 15-23% while the GDGTs and C₃₇ alkenones preservation range from 1 to 8% (Table 4). In general there seems to be no large difference between the relative preservation of total GDGTs and C₃₇ alkenones (Table 4), suggesting that GDGTs and C₃₇ alkenones are degraded to a similar extent. It should be noted that, unlike the TOC profiles, GDGTs and C₃₇ alkenone concentrations vary to some extent in the un-oxidized part (Table 1 and 2) of the turbidites suggesting that they are perhaps not as homogeneous as previously thought. Nonetheless, both the calculated preservation factor (Tables 3 and 4) and the degradation profiles (Figs, 2 and 3) show a strong effect of oxic degradation on GDGTs and C₃₇ alkenones indicating that long-term exposure to oxygen will strongly reduce the concentration of both types of biomarkers.

In general, alkenones, exclusively of marine origin, and total GDGTs, of mixed terrestrial and marine origin, show similar preservation factors. However, calculation of the preservation factor of individual GDGT isomers shows that there is a differential preservation of GDGTs with some isoprenoid GDGT are substantially more degraded, especially when compared to the branched GDGT 5, GDGT 6 and GDGT 7.

For the F-turbidite only 2 % of the original GDGT 0, GDGT 4 and GDGT 4' concentration is left in the upper oxidized part (Table 3). In contrast, ca. 24-29% of the branched GDGT 6 and GDGT 7 is left in the uppermost section of the oxidized part, which represents an even higher preservation than that of TOC (Table 3). For the T2, T6, T10 and T13 turbidites the same trends are observed (Table 4), with GDGT 5, GDGT 6 and GDGT 7 always showing the highest degree of preservation (Table 4). These differential preservations are also reflected in the BIT index which shows a large increase upon oxic degradation (Figs. 2 and 3). Thus, it is clear that the terrestrially derived branched GDGTs are much better preserved than most isoprenoid GDGTs such as crenarchaeol which are predominantly of marine origin.

There may be several reasons for the enhanced preservation of branched GDGTs. Different biomarkers can have different preservation potentials depending on their chemical structure [*de Leeuw and Largeau, 1993; Hoefs et al., 2002; Sinninghe Damsté et al., 2002*], and thus branched GDGTs could be chemically more resistant against degradation than isoprenoid GDGTs. However, some of the isoprenoid GDGTs are better preserved than others in each turbidite (Tables 3 and 4), and this cannot be caused by intrinsic chemical resilience. This suggests that intrinsic chemical resilience may not be the main reason why branched are better preserved than isoprenoid GDGTs. Furthermore, it is difficult to envisage why polar lipids with branched carbon skeletons should be degraded slower than isoprenoid carbon skeletons as degradation is like to start at the functionalized glycerol moiety. Finally, in general it has been observed that branched alkyl chains are more easily degradable than isoprenoid chains [*Peters et al. 2005*]. The results can be better explained by the different origins of the branched GDGTs and isoprenoid GDGTs, i.e. soil derived matter versus marine derived matter. Analysis of a collection of globally distributed soils revealed that, though in low concentration, isoprenoid GDGTs are also present in most soils and this results in terrestrial BIT indices sometimes as low as 0.5 [*Weijers et al., 2006*]. Thus, a better preservation of terrestrial matter would also result in a better preservation of some isoprenoid GDGT isomers that are present in small quantities in the original NW African soils and would influence the TEX₈₆ and BIT values as is observed in our results (Figs. 2 and 3). Depending on the relative distribution of the isoprenoid GDGTs in soils and those in the marine environment the TEX₈₆ may either increase or decrease, explaining the different behaviour of the TEX₈₆ in the different turbidites.

Thus, it seems that GDGTs derived from soil organic matter are much better preserved than isoprenoid GDGTs which are mainly synthesized in the marine environment. The preferential preservation of terrestrial versus marine organic organic compounds, and of OC in general, has been observed before [e.g. *Hoefs et al.*, 1998a; *Sinninghe Damsté et al.*, 2002; *Burdige*, 2005]. However, up to now it was not possible to assess if this preferential preservation was due to the chemical structure of the terrestrial organic matter, or because the mineral matrix protects it from degradation. The enhanced preservation of soil-derived isoprenoid GDGTs which are chemically nearly identical to that of their marine counterpart suggests that the mineral matrix to which soil organic matter is attached enhanced their preservation.

6.4.2 Impact of selective degradation on the TEX_{86} and BIT proxies

Our results indicate large changes in TEX_{86} values upon long term exposure to oxygen showing a different response depending on the turbidite analyzed and can lead to temperature biases of up to 10°C. While in the F-turbidite the TEX_{86} increases after degradation, TEX_{86} values in the T6 and T13 turbidites show a decrease and in the T2 and T10 turbidites no significant changes are observed. In view of the discussion above, these results can be readily explained by an imprint of terrestrial GDGTs on the TEX_{86} values. Depending on the environment TEX_{86} values of isoprenoid GDGTs in soils can be substantially higher or lower than those in marine sediments [*Weijers et al.*, 2006]. In the un-oxidized sediment the contribution of terrestrial GDGTs is relatively minor as evidenced by the low BIT values and the contribution of isoprenoid GDGTs from soils to the total isoprenoids GDGTs will be negligible. Consequently, the TEX_{86} value is based on marine derived GDGTs. In the oxidized part, the TEX_{86} value is also substantially influenced by the isoprenoid GDGTs derived from the continent. Thus, the effect of oxic degradation on the TEX_{86} will depend on the composition of isoprenoidal GDGTs derived from the continent in the original turbidite sediment compared to that in the marine environment and our results suggest that this may vary substantially. If TEX_{86} values on the continent are higher than those in the marine environment then oxic degradation will lead to an increase in TEX_{86} values and *vice versa*. Therefore, the TEX_{86} proxy should be used with care in sediments which have been severely degraded by oxygen exposure.

However, the simultaneous measurement of the BIT index could be a tool in deciphering the impact of oxygen degradation on the TEX₈₆ as large changes in TEX₈₆ due to oxic degradation are always accompanied by concomitant large changes in the BIT index (see Figs. 2 and 3). Thus, in paleoclimatic records where a strong correlation is observed between the TEX₈₆ and BIT index, care should be taken.

6.5. Conclusions

Our study of the Madeira abyssal plain turbidites reveals a sharp decrease in the abundance of both GDGTs and alkenones upon long term oxygen exposure. Branched GDGTs derived from the continent are degraded to a much lesser extent than isoprenoid GDGTs derived from the marine environment. This is likely due to the selective preservation of terrestrial organic matter due to mineral matrix protection. As a consequence of this BIT values increase and TEX₈₆ values either decrease or increase upon long time oxygen exposure up to one order of magnitude and 10°C, respectively. The degree and direction of change in TEX₈₆ will depend on the isoprenoid GDGTs derived from the continent present in the original sediment. This suggests that care has to be taken when analyzing both TEX₈₆ and BIT in cores which have been deposited under prolonged oxic conditions.

Chapter 7

Twentieth century proxy records of temperature and soil organic matter input in the Drammensfjord, southern Norway

Carme Huguet, Rienk H. Smittenberg, Wim Boer, Jaap S. Sinninghe Damsté and Stefan Schouten

Organic Geochemistry in press

Abstract

The Drammensfjord, in Southern Norway, is an enclosed anoxic basin with a laminated sedimentary record. The fjord is a transition area between the marine and terrestrial environments and thus its sedimentary archive contains information on both environments. In order to reconstruct recent environmental changes in Southern Norway, two sediment cores covering the last 90 years, were analyzed. We used the Branched versus Isoprenoid Tetraether (BIT) index as an indicator of terrestrial organic matter input and compared it to the stable carbon isotopic composition of total organic carbon ($\delta^{13}\text{C}_{\text{TOC}}$). The $\delta^{13}\text{C}_{\text{TOC}}$ and BIT index show opposing trends, with $\delta^{13}\text{C}_{\text{TOC}}$ indicating an increase in terrestrial input while the BIT index suggests a decrease towards the present. This contradiction is probably due to the different sources reflected by $\delta^{13}\text{C}_{\text{TOC}}$ (vegetation, soil and anthropogenic input) and the BIT index (only soil organic matter input). In addition, an increase in the recycling of respired CO_2 within the fjord's water column could have depleted the $\delta^{13}\text{C}_{\text{TOC}}$ of the marine component towards more negative values thus seemingly indicating an increase in terrestrial input whilst the BIT index could have been affected by a reduction of riverine input and/or an increase in archaeal biomass production. The TetraEther index of lipids with 86 carbons (TEX_{86}) was determined as a proxy for past water surface temperatures. While some of the signal could be coming from the chemocline our results suggest that TEX_{86} indicates surface (upper 25m) temperatures. Moreover, TEX_{86} temperature patterns seem to follow variations in the historical record of averaged spring to fall Oslo air temperature suggesting the signal is produced during this period. Therefore, TEX_{86} temperature records of fjord sediment cores can potentially be a useful tool in reconstructing past variations of coastal climates.

7.1. Introduction

Fjords are the result of marine inundation of glacially eroded valleys and are diverse and unique coastal ecosystems. Fjords are often stratified, for at least large parts of the year, due to riverine fresh water in the surface layer that floats atop denser marine bottom waters and the presence of a shallow sill between the deeper waters inside and outside the fjord. As fjords are transition areas between rivers and coastal seas the terrestrial input is usually relatively high. This, coupled to the sheltered location, the prevalence of anoxic or sub-oxic conditions and sedimentation rates of more than 0.5 mm per year [Mikalsen *et al.*, 2001], often makes fjords an ideal area to obtain sediment cores for high-resolution studies [cf. Smittenberg *et al.* 2005]. Both large-scale and local climatic variability affect fjords [Mikalsen *et al.*, 2001] and these changes will be registered in the sedimentary record of the fjord, which functions as a high-resolution archive. A variety of parameters such as terrestrial input or temperature can be estimated from fjord records [e.g. Alve, 1991; Mikalsen *et al.*, 2001; Filipsson and Nordberg, 2004; Smittenberg *et al.*, 2005; van Breugel *et al.*, 2005a]. For example, previous studies in western Norwegian fjords have used $\delta^{18}\text{O}$ of foraminifera to study past sea surface temperatures (SSTs) and compared those to the North Atlantic Oscillation index (NAO) and instrumental records [Mikalsen *et al.*, 2001; Kristensen *et al.*, 2004]. In both cases a strong correlation between reconstructed SST, instrumental records and NAO was found.

Determination of marine and terrestrial organic matter input in coastal environments is essential to understand the global carbon budget because a large part of the organic matter is buried there [Wagner and Dupont 1999 and references therein; Hedges and Keil, 1995]. For this reason a variety of proxies such as the CN ratio, the carbon isotopic composition of organic carbon $\delta^{13}\text{C}_{\text{OC}}$ and terrestrial biomarkers such as *n*-alkanes are used [Wagner and Dupont, 1999]. However, the use of these proxies is often complicated because they are typically influenced by more than one parameter [see Wagner and Dupont, 1999 and Pancost and Boot, 2004 for reviews]. Recently a new proxy, the Branched versus Isoprenoid Tetraether (BIT) index [Hopmans *et al.*, 2004] was introduced, which, together with the above methods, can help to trace the origin of organic matter (OM) in marine sediments. This proxy uses the ratio of branched glycerol dialkyl glycerol tetraethers (GDGTs) derived from anaerobic bacteria of terrestrial origin (GDGTs 5, 6, 7; Fig. 1) [Weijers *et al.*, 2006b] and

crenarchaeol (GDGT 4; Fig.1), a GDGT synthesized by group I Crenarchaeota [Sinninghe Damsté *et al.*, 2002]. The anaerobic bacteria which synthesize the branched GDGTs are mainly found in soils and peat bogs [Weijers *et al.*, 2006a] and their lipids are subsequently transported to coastal areas via rivers [Hopmans *et al.*, 2004; Herfort *et al.*, 2006; Kim *et al.*, 2006]. In contrast, marine Group I Crenarchaeota, and thus crenarchaeol, have been found in a wide variety of aquatic environments and are distributed throughout the water column but usually more abundant in the upper hundred meters.

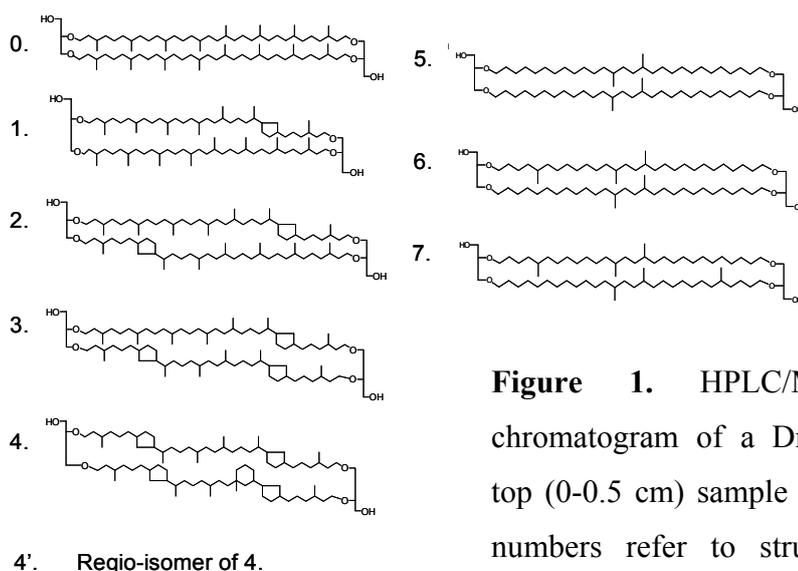

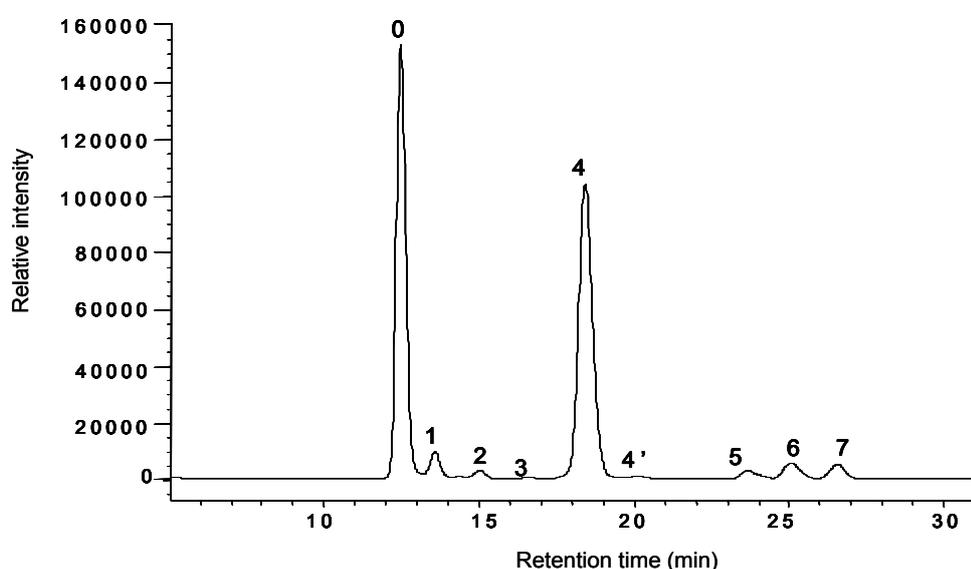

Figure 1. HPLC/MS base peak chromatogram of a Drammensfjord core top (0-0.5 cm) sample of core D2-C. The numbers refer to structures of GDGT shown below.

However, low abundances of crenarchaeol have also been found in soils [Weijers *et al.*, 2006b], lakes [Powers *et al.*, 2004] and rivers [Herfort *et al.*, 2006] although this does not seem to affect the use of the BIT index to a large degree [Kim *et al.*, 2006]. The BIT index can be used to assess the relative fluvial input of terrestrial organic matter in marine environments and ranges from 0-1 with zero referring to pure marine OM and 1 indicating pure terrestrial OM [Hopmans *et al.*, 2004].

Group I non-thermophilic Crenarchaeota biosynthesize isoprenoid GDGTs with a varying number of cyclopentyl moieties (GDGTs 0-4'; Fig.1). The distribution of isoprenoid GDGTs 0-4' of Crenarchaeota has been found to change according to temperature [Schouten *et al.*, 2002; Wuchter *et al.*, 2004]. Thus by determining the distribution of isoprenoid GDGTs, quantified with the TEX₈₆, present in sediments, the temperature at which Crenarchaeota were living can be reconstructed forming the basis of a new SST proxy, [cf. Schouten *et al.*, 2002]. Experiments with Crenarchaeota enrichment cultures and particulate OM studies have shown that this proxy is strongly correlated with temperature and is not dependent on salinity or nutrient concentration [Wuchter *et al.*, 2004; Wuchter *et al.*, 2005].

In this study we analysed the two proxies based on the distribution of GDGTs, BIT and TEX₈₆, to reconstruct both past terrestrial input and water temperatures in the Drammensfjord, Southern Norway (Fig. 2), a silled basin with anoxic bottom waters. The Drammen river feeds the Drammensfjord [Alve, 1990] creating a brackish surface layer and, thereby, a distinct salinity stratification, resulting in euxinic bottom water conditions in the basin. In addition, the Drammen river brings a large volume of particulate matter that is deposited in the fjord. The Drammensfjord has been subject to strong human impact especially during the last century, when domestic and agricultural waste increased drastically [Alve, 1991] (Fig. 3). These environmental changes and anthropogenic impacts have been recorded in the sedimentary record [Alve, 1995; Smittenberg *et al.*, 2005]. While previous work in the Drammensfjord provided information on various biomarkers on a centennial time scale [Smittenberg *et al.*, 2005], in this study we focus on the last century in quasi annual resolution, thereby allowing comparison with instrumental records.

7.2. Material and Methods

7.2.1. Sampling area

The Drammensfjord is a hyposaline (salinity < 32) silled basin with a length of 20 km and a width of 1.6-3 km. (Fig. 2) [Alve, 1991]. The Drammen river that enters at the head of the fjord creates a surface brackish water layer (salinity 1-10) on top of the saline bottom waters (salinity 31) below 40 m water depth [Alve, 1990]. When the cores were taken the chemocline was at 40 m depth (Fig. 2) but this may change both seasonally and annually.

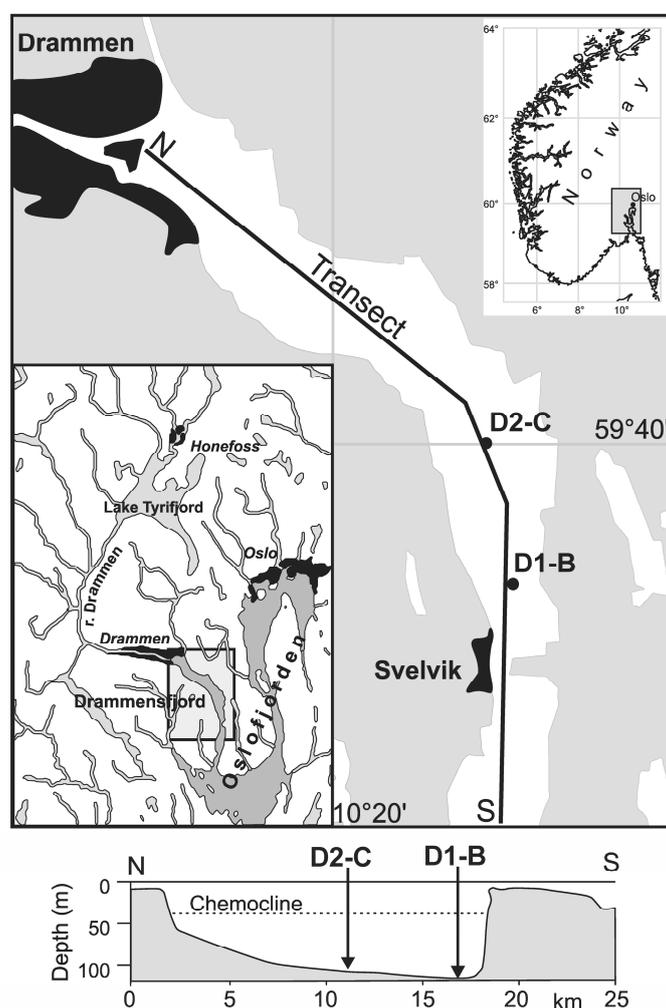

Figure 2. Map and lateral profile of Drammensfjord (modified from Smittenberg et al., 2005). The location of the two sediment cores is indicated.

The annually averaged fresh water supply is $290 \text{ m}^3 \cdot \text{s}^{-1}$. Since 1910 the river water regulations caused a smoothing of the annual fresh water supply and a shift of the main water input from winter to summer [Alve, 1991]. The Drammensfjord is separated from the larger Oslofjord by a sill at Svelvik (Fig. 2), which prevents the exchange of bottom waters with the open ocean. This together with degradation of OM leads to euxinic conditions in the bottom waters [Alve, 1991]. Oxygen depletion was first detected in 1899, and the presence of H_2S was first reported in 1933 [Smittenberg *et al.*, 2005]. Incursions of oceanic waters occur currently once every 3-5 years, mainly between November and May [Alve, 1995]. The sediment is deposited in a laminated structure as the anoxic bottom waters prevent infaunal activity.

7.2.2. Sediment cores

Two standard box cores (300 mm diameter, 550 mm depth) were collected with RV 'Pelagia' on 29 October 1999. Core D2-C was taken in the centre of the Drammensfjord ($59^\circ 40' \text{N}$ $10^\circ 24' \text{E}$) and Core D1-B was taken 3 km south at $59^\circ 38' \text{N}$ $10^\circ 26' \text{E}$ (Fig. 2). In both box cores, sub-cores of 70 mm in diameter were recovered, cut into 0.5 cm slices and subsequently stored frozen at -20°C . Samples were freeze dried prior to geochemical analysis. Core D2-C was analysed for total organic carbon (TOC), $\delta^{13}\text{C}$ of TOC ($\delta^{13}\text{C}_{\text{TOC}}$) and GDGTs whilst core D1-B was analysed for GDGTs only.

7.2.3. Sediment core dating

Core D1-B was analyzed and dated previously using the specific activities of ^{137}Cs and ^{210}Pb [see Zegers *et al.*, 2003 for details]. Core D2-C was analyzed using the same ^{210}Pb method. ^{210}Pb data were decay corrected to the sampling date. Mass AR were derived with the ^{210}Pb CF/CS-model [Appleby and Oldfield, 1992] using a cumulative mass depth to correct for compaction. The model was then used to plot the data.

7.2.4. Bulk parameters

The TOC contents and $\delta^{13}\text{C}_{\text{TOC}}$ of total organic carbon of sediment core D2-C were determined by elemental analysis (EA)/isotope-ratio-monitoring mass spectrometry (EA/irmMS). EA/irmMS analyses were performed on decalcified (by reaction with 1 N HCl for 18 h) sediments using a Carlo Erba Flash elemental analyzer coupled to a Thermofinnigan

Delta^{PLUS} irmMS system. The total organic carbon content was determined using external standards with known carbon content. Stable carbon isotope ratios were determined using lab standards calibrated on NBS-22 oil (IAEA) [Coplen *et al.*, 2006] and reported in Vienna Pee Dee Belemnite (VPDB) notation. On average the samples were measured at least in duplicate and mostly in triplicate and the analytical error was on average 0.3% for the TOC contents and 0.16‰ for the $\delta^{13}\text{C}_{\text{TOC}}$ (Fig. 3).

7.2.5. GDGT analysis

Freeze-dried sediment samples of ca. 0.1g were extracted using an Accelerated Solvent Extractor (ASE 200, DIONEX) with a mixture of dichloromethane (DCM) and methanol (MeOH) (9:1; vol:vol) at 100°C and $7.6 \cdot 10^6$ Pa. An aliquot of each total extract was divided into an apolar and a polar fraction, using a glass pipette column filled with activated alumina, and sequentially eluting with hexane/DCM (9:1; vol:vol) and DCM/MeOH (1:1; vol:vol), respectively. Polar fractions were analyzed for GDGTs according to the procedure described by Hopmans *et al.* [2000]. Analyses were performed in triplicate with an HP 1100 Series Liquid Chromatography-Mass Spectrometer (LC-MS) equipped with an auto-injector and ChemStation chromatography manager software. Separation was achieved on a Prevail Cyano column (2.1 x 150 mm, 3 μm ; Alltech, Deerfield, Illinois, USA), maintained at 30°C. GDGTs were eluted isocratically first with hexane/isopropanol (99:1; % vol:vol) for 5 min, then using a linear gradient up to 1.8 % vol of isopropanol over 45 min. Flow rate was 0.2 mL min⁻¹. After each analysis the column was cleaned by back flushing hexane/propanol (90:10; vol:vol) at 0.2 mL min⁻¹ for 10 min. Detection was achieved using atmospheric pressure chemical ionization-mass spectrometry (APCI-MS) of the eluent using the following conditions; nebulizer pressure 60 psi, vaporizer temperature 400°C, N₂ drying gas flow 6 L min⁻¹ at 200°C, capillary voltage -3 kV, corona 5 μA (~3.2 kV). Single Ion Monitoring (SIM) was used instead of full mass scanning because SIM increases the signal-to-noise-ratio and thus improves reproducibility [Schouten *et al.* 2007]. SIM was set to scan the five [M+H]⁺ ions of the isoprenoid GDGTs and the three [M+H]⁺ ions of the branched GDGTs with a dwell time of 237 ms for each ion.

The TEX₈₆ ratio was calculated based on the relative abundance of GDGTs as follows [Schouten *et al.*, 2002]:

$$\text{TEX}_{86} = \frac{\text{GDGT 2} + \text{GDGT 3} + \text{GDGT 4}'}{\text{GDGT 1} + \text{GDGT 2} + \text{GDGT 3} + \text{GDGT 4}'} \quad [1]$$

The numbers correspond to structures in Fig. 1. The TEX_{86} values relate to temperature according to the following empirical relationship [Schouten *et al.*, 2002]:

$$\text{TEX}_{86} = 0.015 \cdot T + 0.28 \quad [2]$$

The branched GDGTs (GDGT 5, 6 and 7) and crenarchaeol (GDGT 4; Fig.1) were used to measure the BIT index as follows [Hopmans *et al.*, 2004]:

$$\text{BIT} = \frac{[\text{GDGT 5} + \text{GDGT 6} + \text{GDGT 7}]}{[\text{GDGT 5} + \text{GDGT 6} + \text{GDGT 7} + \text{GDGT 4}]} \quad [3]$$

where the numbers correspond to structures in Fig. 1.

An aliquot of an Arabian Sea sediment extract was measured every 10 samples to assess the analytical reproducibility. The resulting mean TEX_{86} value for 15 repeat analyses was 0.68 with a standard deviation of ± 0.034 , corresponding to $26.6 \pm 0.5^\circ\text{C}$ according to equation [2]. The BIT value of this sample was 0.02 with a standard deviation of ± 0.003 . TEX_{86} were measured at least three times for each sample and the standard deviation of the TEX_{86} was on average ± 0.02 which according to equation [2] correspond to $\pm 0.7^\circ\text{C}$. The BIT samples were measured only once, thus we assume a constant analytical error of ± 0.003 as calculated from the Arabian Sea sample.

7.3. Results

7.3.1. Bulk parameters

The age models of both cores are based on ^{210}Pb measurements and were fitted to a constant accumulation rate model [Appleby and Oldfield, 1992]. The accumulation rates (AR) of sediment of core D1-B is 750 and D2-C is $850 \text{ g}\cdot\text{m}^{-2}\cdot\text{yr}^{-1}$, in agreement with previous studies in the Drammensfjord that reported values of $500\text{-}1000 \text{ g}\cdot\text{m}^{-2}\cdot\text{yr}^{-1}$ between 1000 and 1940 [Smittenberg *et al.*, 2005].

The TOC values of the sediments recovered with core D2-C are usually around 3% with peak values of 5% in sediments deposited from 1945 to 1950 and ca. 6% in those deposited from 1965 to 1970 and in 1989 (Fig. 3a). These TOC values compared well with the 2-4.5 % TOC values reported previously for Drammensfjord sediments [Alve, 1990; Alve, 1991].

The organic carbon AR ranges between 20 and 60 $\text{g}\cdot\text{m}^{-2}\cdot\text{yr}^{-1}$ (Fig. 4a). It is relatively constant from 1923 to 1942 and it shows an increase from ca. 20 to 45 $\text{g}\cdot\text{m}^{-2}\cdot\text{yr}^{-1}$ towards 1945, then it decreases to ca. 25 $\text{g}\cdot\text{m}^{-2}\cdot\text{yr}^{-1}$ until 1951. The main increase in organic carbon AR starts in 1951 and reaches its peak value of 50 $\text{g}\cdot\text{m}^{-2}\cdot\text{yr}^{-1}$ in 1965, then the AR decreases to ca. 25 until 1980 and remains around 20 $\text{g}\cdot\text{m}^{-2}\cdot\text{yr}^{-1}$ until 1989 when there is a peak of 55 $\text{g}\cdot\text{m}^{-2}\cdot\text{yr}^{-1}$ (Fig. 4a). Finally there is a small peak in organic carbon AR between 1993 and 1997 (Fig. 4a).

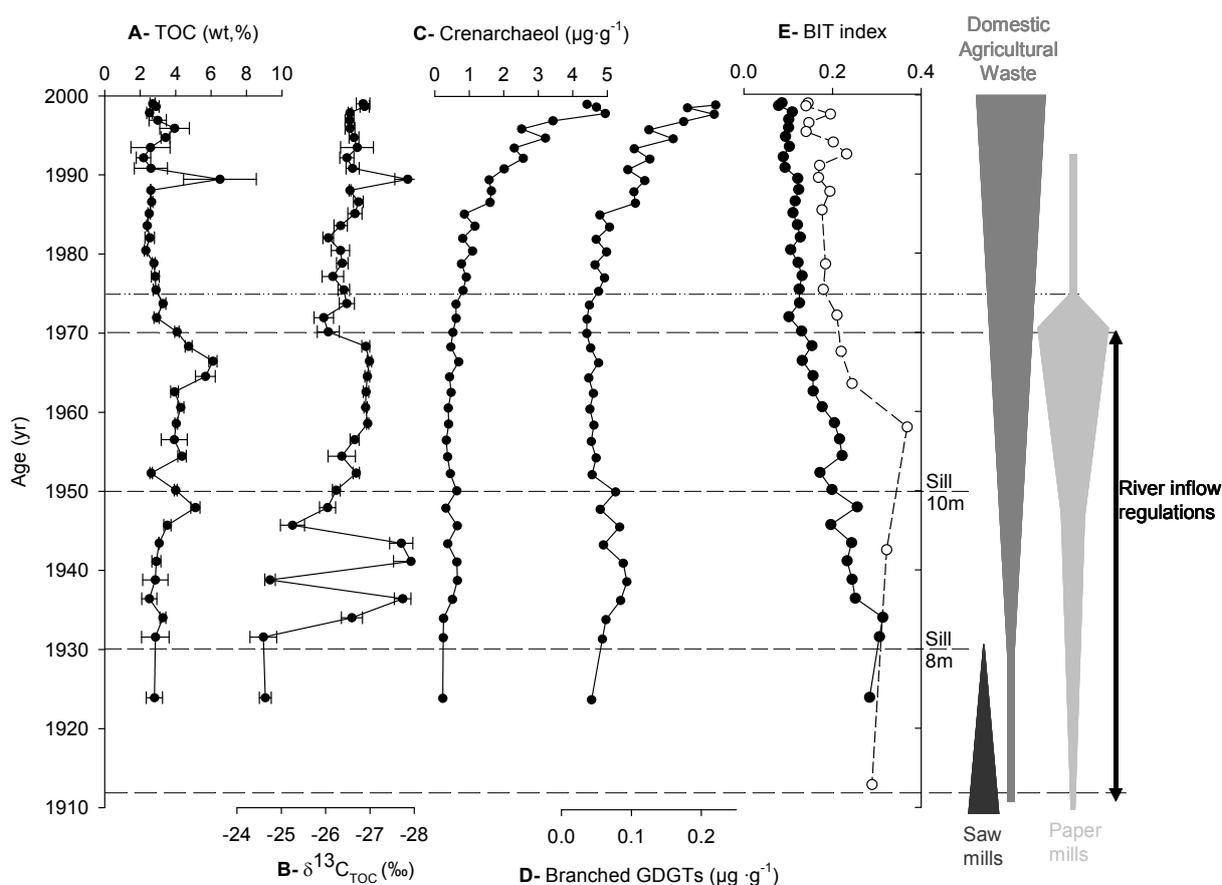

Figure 3. Bulk and GDGT data for core D2-C (filled circles) and D1-B (empty circles), (a) TOC (wt, %), (b) $\delta^{13}\text{C}_{\text{TOC}}$ (‰), (c) crenarchaeol (GDGT-4) concentration ($\mu\text{g}\cdot\text{g}^{-1}$), (d) branched GDGT concentration ($\mu\text{g}\cdot\text{g}^{-1}$) and (e) BIT index. Anthropogenic activities with a potential environmental impact on the fjord are plotted in the right hand side (adapted from *Alve* [1991]).

The $\delta^{13}\text{C}_{\text{TOC}}$ ranges from -24.6 to -27.9‰. The less ^{13}C -depleted values (-24.6‰) are recorded in the oldest sediments deposited between 1923 and 1930 (Fig. 3b). There are subsequently two negative spikes in $\delta^{13}\text{C}_{\text{TOC}}$, one in the late 1930s and another in the late 1940s (Fig. 3b). Then, $\delta^{13}\text{C}_{\text{TOC}}$ values decrease to their more ^{13}C -depleted value of -26.9‰ in 1954 and then remain around this value until 1965 when there is an increase of 1‰. From 1970 to 1999 the $\delta^{13}\text{C}_{\text{TOC}}$ values show a slight depletion in ^{13}C from -26.3‰ to -26.8‰ with the exception of the point at 1989 which shows a value of -27.9‰ (Fig. 3b).

7.3.2. GDGT concentrations and accumulation rates

GDGT analysis of the two cores reveals the presence of GDGTs 0-7 with GDGT-0 and GDGT-4 (crenarchaeol) showing the highest concentrations (Fig.1). Total GDGT concentration in core D2-C ranged from 0.5 to 11 $\mu\text{g}\cdot\text{g}^{-1}$. Concentrations of crenarchaeol in core D2-C ranges from 0.2 to 5 $\mu\text{g}\cdot\text{g}^{-1}$ and show in general an increase towards the surface (Fig. 3c). The branched GDGTs (GDGTs 5, 6 and 7; Fig.1) range in concentration from 0.04 to 0.25 $\mu\text{g}\cdot\text{g}^{-1}$ and their concentration profile strongly resembles that of crenarchaeol (cf. Figs. 3c and 3d). However, the concentration of branched GDGTs shows a larger increase from 1923 up to 1940 before it decreases until 1950 and show quite constant values of 0.05 $\mu\text{g}\cdot\text{g}^{-1}$ between 1950 and 1980 after which it increases to 5 $\mu\text{g}\cdot\text{g}^{-1}$ towards the surface (Fig. 3c and d). The crenarchaeol AR ranges between 0.2 and 4.2 $\text{mg}\cdot\text{m}^{-2}\cdot\text{yr}^{-1}$ showing relatively constant values between 1920 and 1990 and then increase by 2 $\text{mg}\cdot\text{m}^{-2}\cdot\text{yr}^{-1}$ from 1990-2000 (Fig. 4b). The AR of branched GDGTs varies between 0.04 and 0.2 $\text{mg}\cdot\text{m}^{-2}\cdot\text{yr}^{-1}$ and shows a pattern similar to that of crenarchaeol AR. However, the branched GDGTs AR also shows three minor peaks, one between 1930 and 1940, one in 1945 and one around 1950 (Fig. 4c).

7.3.3. BIT index and TEX_{86}

The BIT index ranges from 0.08 to 0.31 in core D2-C and from 0.11 to 0.37 in core D1-B (Fig. 3e) which compares well with BIT indices previously reported for coastal and lacustrine environments [Hopmans *et al.*, 2004]. Both cores show the same trend with decreasing BIT values up core. However, core D2-C shows a decrease of values from 1923 to 1999 while core D1-B indicates an increase from 1912 to 1958 and then a decrease towards 1999 (Fig. 3e).

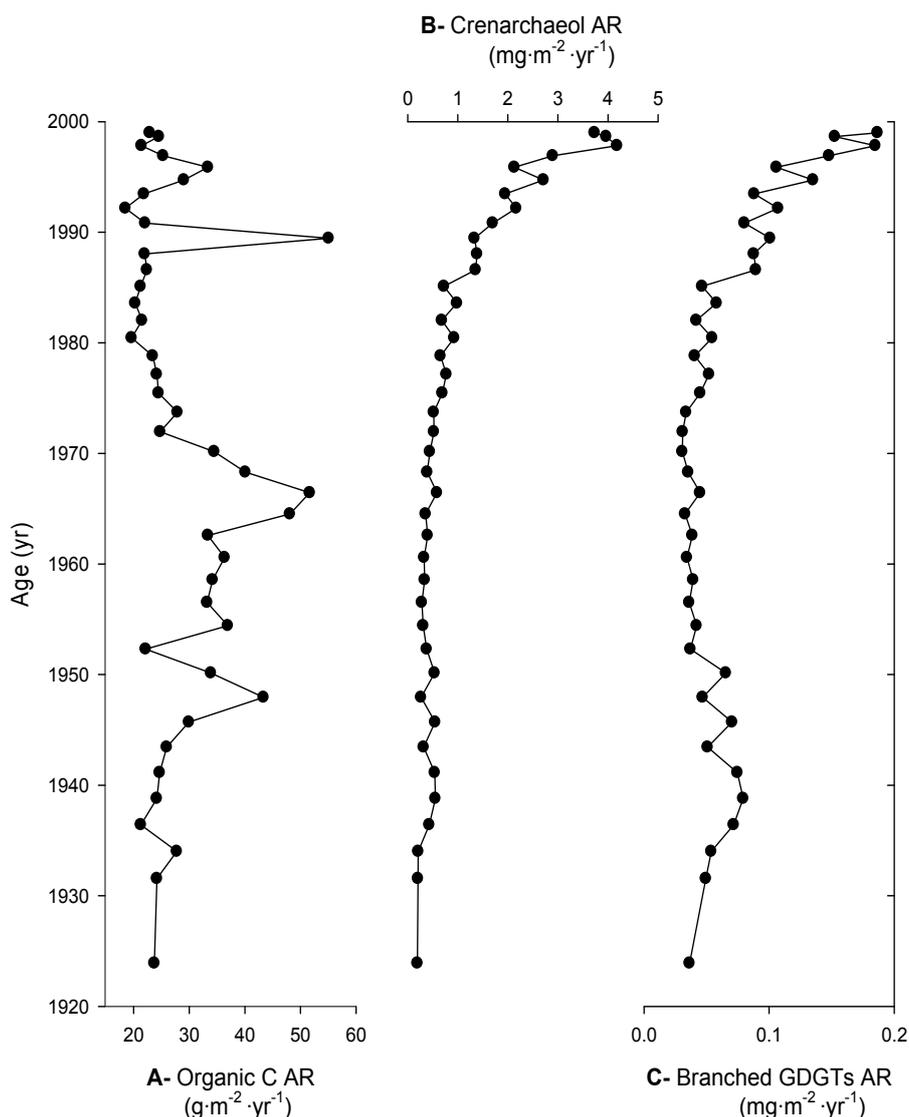

Figure 4. Accumulations rates of (a) organic carbon ($\text{g}\cdot\text{m}^{-2}\cdot\text{yr}^{-1}$), (b) crenarchaeol ($\text{mg}\cdot\text{m}^{-2}\cdot\text{yr}^{-1}$) and (c) branched GDGTs ($\text{mg}\cdot\text{m}^{-2}\cdot\text{yr}^{-1}$) in core D2-C.

TEX₈₆-derived temperatures range between 8.2 and 12.6 C° in core D2-C and between 8.2 and 10.5 C° in core D1-B (Fig. 5). Both TEX₈₆ records show a similar pattern although core D1-B has a lower resolution than D2-C especially between 1910 and 1960. The standard deviation intervals for each point are plotted for both cores (grey filled areas, Fig. 5) and show in general a good overlap between the two cores. TEX₈₆ temperatures show two main peaks one between 1960 and 1972, and the other between 1972 and 1990 with some minor peaks between 1930 and 1940 and in 1952. TEX₈₆ temperatures decrease from 1990 to 1999 (Fig. 5).

7.4. Discussion

7.4.1. Contribution of terrestrial organic matter to the fjord

The $\delta^{13}\text{C}_{\text{TOC}}$ of around -26‰ found in most of the Drammensfjord sediments is close to the average $\delta^{13}\text{C}$ of terrestrial OM (-27‰), [Deines, 1980; Tyson, 1995], suggesting that the sedimentary OM is primarily of terrigenous origin in the Drammensfjord, in agreement with conclusions from *Smittenberg et al.* [2005]. In contrast, the average BIT index of 0.2 suggests a relatively low terrestrial input and shows intermediate values when compared to other coastal environments [Hopmans *et al.*, 2004]. Similar results were observed in the south North Sea with BIT values ranging from 0.02 to 0.26 [Herfort *et al.*, 2006], but BIT values between 0.7 and 0.9 have been reported for particulate OM in rivers in the Mediterranean [Kim *et al.*, 2006] and for sediments from another Norwegian fjord [Hopmans *et al.*, 2004]. Thus, BIT indices between 0.08-0.37 are unexpectedly low as the fjord is directly fed by the river Drammen which has a relatively large catchment area (Fig. 2) and a high river influx [Öztürk, 1995].

Besides seemingly contrasting indications for the relative amount of terrestrial OM in Drammensfjord, the $\delta^{13}\text{C}_{\text{TOC}}$ and BIT index trends are also different (Fig. 3). While the BIT index shows a gradual change towards more marine values in 1999, the $\delta^{13}\text{C}_{\text{TOC}}$ data seems to indicate an increase in ^{13}C -depleted terrestrial versus marine OM up core (Fig. 3). The relatively low BIT values could be explained if the relative amount of terrigenous OM would decrease from the head to the mouth of the fjord. However, the BIT values of core D1-B, in a more southern location than D2-C (Fig. 1) are slightly higher, suggesting that this can not explain the low BIT values. More likely, therefore, is that there is a relatively high input of crenarchaeol, either from production in the fjord by marine Crenarchaeota, or upstream in the extensive lake system (Fig. 2) by fresh water Crenarchaeota [cf. Powers *et al.*, 2004]. In both cases there would be a high crenarchaeol input which would result in a low BIT index. However, the difference in the source between the branched GDGTs and total terrestrial OM has to be taken into consideration as well. Branched GDGTs are only transported by rivers [Hopmans *et al.*, 2004; Herfort *et al.*, 2006; Kim *et al.*, 2006] and are primarily derived from soil OM [Weijers *et al.*, 2006b], while $\delta^{13}\text{C}_{\text{TOC}}$ is affected by the total terrestrial organic carbon input, i.e. including both soil organic matter and terrestrial vegetation.

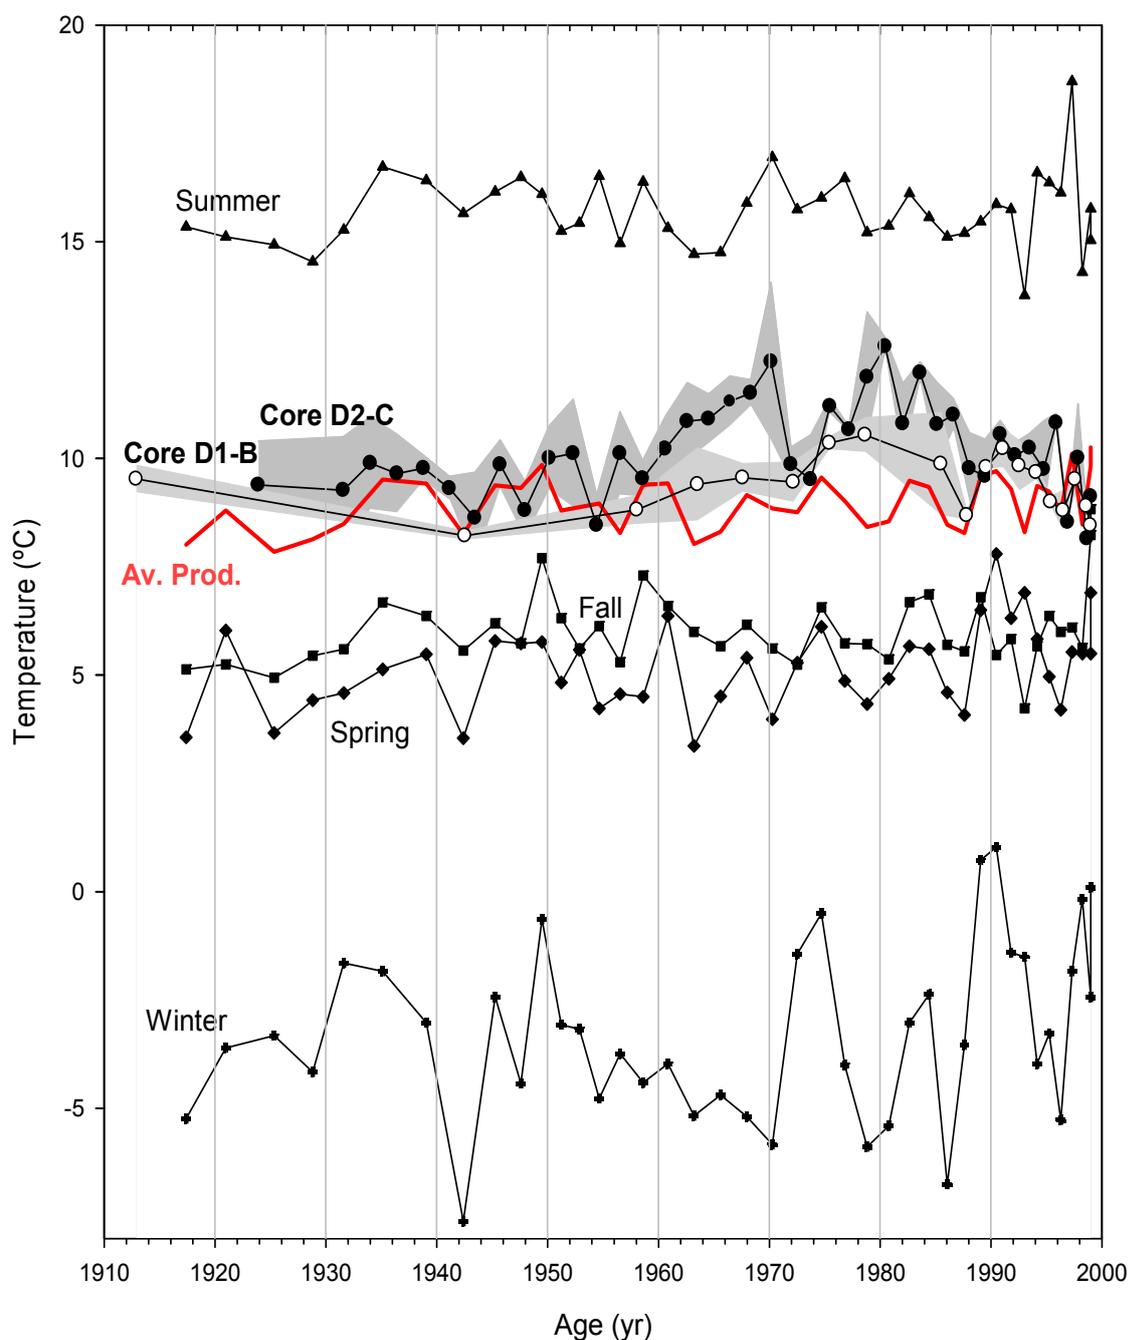

Figure 5. TEX₈₆-calculated temperatures obtained from core D2-C (filled circles) and D1-B (empty circles) compared to averaged seasonal air temperatures in Oslo for Summer (June-August), Fall (October-November), Spring (March-May) and Winter (December-February) (http://met.no/met/vanlig_var/temp.html). Average temperatures of the productive season (Av. Prod; spring, summer and fall) are plotted in red. The grey filled areas indicate the standard deviation for the TEX₈₆ temperatures.

Thus, if there is a large contribution of this latter source and only a minor contribution of soil OM, this could explain the apparent discrepancy between $\delta^{13}\text{C}_{\text{TOC}}$ and the BIT index. Indeed, there has been a large input of wood and paper from industrial sources in Drammensfjord over the last century [Alve, 1991; Fig. 3], which will strongly contribute to the $\delta^{13}\text{C}_{\text{TOC}}$ signal and not to the BIT index. Finally, the $\delta^{13}\text{C}_{\text{TOC}}$ could be affected by a change in the isotopic composition of marine OM through recycling of respired CO_2 . Decaying OM will yield ^{13}C -depleted CO_2 which can be re-used by phytoplankton, thus influencing the isotopic composition of marine OM towards more negative values [e.g. Deevey *et al.*, 1963; Küspert, 1982; Wachniew and Rozanski, 1997]. High amounts of ^{13}C -depleted CO_2 have been observed previously in lakes and fjords where there were anoxic bottom waters and where $\delta^{13}\text{C}_{\text{TOC}}$ was relatively depleted in ^{13}C [van Breugel *et al.*, 2005b]. Indeed, Smittenberg *et al.* [2005] found relatively ^{13}C -depleted crenarchaeol, suggesting that recycling of CO_2 may take place in the Drammensfjord. Thus, the relatively ^{13}C -depleted values of TOC in Drammensfjord may be partly due to relatively ^{13}C -depleted fjord OM rather than high contributions of ^{13}C -depleted terrestrial OM. These factors make it difficult to interpret the $\delta^{13}\text{C}_{\text{TOC}}$ sedimentary record.

The GDGT ARs show relatively constant values between 1923 and 1980, although the branched GDGTs AR show a small increase between 1923 and 1952. The decrease in the BIT index between 1930 and 1970 is thus mainly caused by a decrease in the AR of the branched GDGTs pointing to a relative reduction of the branched GDGTs input (Fig. 4 b and c). The latter would be related to the changes in the riverine input after the strong regulation of the river inflow since 1910 [Bradshaw *et al.*, 1991] with a reduction in floods and hence less wash out of branched GDGTs from soils into the riverine system.

The strongest increase in the ARs of both crenarchaeol and branched GDGTs is between 1980 and 1999. As the Drammensfjord is an anoxic basin and the OC AR does not show the same trend in the upper part of the sediment core (Fig. 4a) this trend seem at first sight unlikely to have been caused by diagenetic processes. However, in general, biomarkers degrade faster than bulk OM [Hoefs *et al.*, 2002]. This may be even more likely in this case since most of the bulk OM seems to be of terrestrial origin (e.g. wood) which is more resilient towards degradation than aquatic OM. Thus, the decreasing ARs of both types of GDGTs (Fig. 4) down to 1923 likely suggest anaerobic mineralization in surface sediments, as has been observed for the many biomarkers in the euxinic Black Sea [Sun and Wakeham, 1994].

Alternatively but less likely, the increased ARs in the top sediment may indicate that there is an increased production of both soil bacteria and crenarchaeota. The former could be related to the changes in the riverine input after the strong regulation of the river inflow since 1910 [Bradshaw *et al.*, 1991]. The latter may have been due to an increase in agricultural and urban waste in the Drammensfjord [Alve, 1991]. This increase in waste would in turn increase the nutrient input such as ammonia into the fjord and result in higher productivity of Crenarchaeota as part of these microbes are using ammonia as an energy source [Könneke *et al.*, 2005; Wuchter *et al.*, 2006a]. This enhanced nutrient input would also stimulate phytoplankton productivity in general and not necessarily be reflected in the TOC deposition as the largest increases in TOC seem to be associated to the period of high paper mill activity (Fig. 3) and is probably a direct reflection of waste dumped in the river by the paper industry.

7.4.2. *TEX*₈₆ temperature record

The *TEX*₈₆ paleothermometer has been applied in marine [Huguet *et al.*, 2006] and lake [Powers *et al.*, 2005] sediment cores but never before in a transition environment like the Drammensfjord and thus our record is unique in this aspect. In principle the *TEX*₈₆ estimates in the Drammensfjord could be compromised by high input of terrestrial GDGTs [Weijers *et al.*, 2006b]. However, BIT values are in general relatively low (<0.3; Fig. 3) and there is no apparent correlation between *TEX*₈₆ and BIT index ($r^2=0.1$). Thus, it seems that the *TEX*₈₆ temperature record is not affected by terrestrial input to a substantial degree.

*TEX*₈₆-derived values (8.2-12.6°C) fall in the middle of the average surface temperature range reported for the Drammensfjord (1-24°C) [Alve, 1995]. As there is, to the best of our knowledge, no long term in-situ water temperatures record available for the Drammensfjord, we compared our *TEX*₈₆ results with a historical monthly air temperature record from a weather station in nearby Oslo as a proxy for the historical changes in surface temperatures of the fjord. Unlike our D1-B core, Oslo air temperature data have an annual resolution and for this reason a variable running average smoothing was applied to the mean annual Oslo air temperature data to match the *TEX*₈₆ temperature temporal resolution in the D1-B core (Fig. 4). The same smoothing was applied to Oslo air monthly temperatures, and the resulting values were then averaged for summer (June-August), fall (October-November), spring (March-May) and winter (December-February) and also for the productive season, i.e. spring,

summer and autumn when predominantly light and, to some degree, temperature are sufficiently high to stimulate phytoplankton growth (Fig. 5). We assume that air temperature changes will be reflected in surface water temperatures and that there is a relatively small offset due to both air water temperature equilibration and age model error. The comparison shows that TEX₈₆-derived temperatures fall between summer and spring/fall air values (Fig. 5) and that they are close to the calculated average air temperature of these three seasons, i.e. the productive season (red line Fig. 5). This suggests that the Crenarchaeota in Drammensfjord are possibly active during the spring/fall period and not during winter. In other areas high Crenarchaeota abundances have actually been noted in winter [Murray *et al.*, 1999; Wuchter *et al.*, 2006b] as then the Crenarchaeota do not need to compete for ammonia with the phytoplankton. The reason why this is different for the Drammensfjord may be the continuous high nutrient supply in the Drammensfjord throughout the year [Alve, 1995]. With a plentiful nutrient supply there is no need to compete with the phytoplankton for nutrients and other factors like the low winter temperatures in the area may become more limiting in archaeal productivity. Alternatively as the food web activity is greatly reduced in the Drammensfjord during the winter months this may lead to a decline in the export of GDGTs from the upper part in the water column to the sediment surface [cf. Wuchter *et al.*, 2005].

We should also consider the possibility that the TEX₈₆ signal is not derived from the surface waters but from deeper in the water column. Crenarchaeota have been shown to be abundant at strong chemoclines such as in the Black Sea [Coolen *et al.* 2007] and this may lead to colder TEX₈₆ temperatures than expected [Menzel *et al.*, 2006]. As the Drammensfjord has a permanent and strong chemocline, it is possible that the Crenarchaeota are living deeper in the water column at the chemocline. The chemocline depth at the time of coring was 40 m (Fig. 1) and according to Alve [1991; 1995] temperatures below 25 m remained around 6°C between 1982 and 1988 in contrast to surface temperatures which ranged from 1 to 24°C. Thus, if Crenarchaeota were only living in the chemocline we would expect no substantial changes in the TEX₈₆ temperatures during this period. This is not the case as temperatures do not only change between 1982 and 1988 but are considerably higher than 6°C (Fig.5). This leads us to conclude that at least part of the TEX₈₆ signal is coming from surface waters (above 25 m). A shift in the position of the chemocline could also have resulted in the observed changes in the TEX₈₆, however, in general TEX₈₆ follows, within the uncertainty of

the age model, Oslo air temperature changes through time making this possibility less likely. This fitting is particularly remarkable when comparing TEX₈₆ values to average air temperature for the productive season (in red, Fig. 5). This suggests a connection between atmospheric temperatures and water temperatures in the fjord. However, the 1970 and 1980 peaks in TEX₈₆ temperatures are not present in the averaged productive season Oslo air temperature record. This might be the result of local factors affecting the water temperature in the fjord. It could also be the result of a shift towards higher summer production by Crenarchaeota, as while the 1970 and 1980 peaks are not present in the averaged productive season Oslo air record they are apparent in the summer Oslo air temperature record (Fig. 5).

7.5. Conclusions

The $\delta^{13}\text{C}_{\text{TOC}}$ and BIT index give contrasting results regarding the relative contribution of terrestrial OM in Drammensfjord. This is likely due to the different types of terrestrial OM recorded by these proxies, i.e. soil OM by the BIT index and vegetation and soil and vegetation OM by $\delta^{13}\text{C}_{\text{TOC}}$. Furthermore, there are uncertainties with the marine end-member value of $\delta^{13}\text{C}_{\text{TOC}}$ which can be affected by recycling of respired CO_2 within the water column of the stratified fjord. This illustrates that proxies to measure the relative contributions of the organic carbon in sediments must be used with great caution and that the use of multiple proxies is essential and complementary. The application of the TEX_{86} in this marine-terrestrial transition area yielded temperatures which are similar to the average of spring to fall (productive season) air temperatures in Oslo. This suggests that Crenarchaeota production mainly takes place during this period. Moreover TEX_{86} temperatures correlate relatively well to annual Oslo air temperature between spring and fall thus indicating a seasonal signal. Therefore, the TEX_{86} may be a suitable temperature proxy to use in transition coastal areas to estimate past temperatures.

Acknowledgements

The authors thank the crew of R/V Pelagia from the Netherlands Institute for Sea Research for their assistance in obtaining the sediment cores. Martin van der Zeijden is thanked for his assistance with TOC and $\delta^{13}\text{C}_{\text{TOC}}$ measurements. This project was supported by grants from NWO-ALW to SS and JSSD (projects. 152911 and 850.20.006, respectively). The two reviewers Dr. Andrew Revill and Dr. Mark Yunker are thanked for their constructive comments.

Abstract

Two sediment cores from the western Arabian Sea, NIOP905 and 74KL were analyzed to determine sea surface temperature (SST) variations over the last 23 kyr. Two organic molecular SST proxies were used, the well established U₃₇^{K'} based on long-chain unsaturated ketones synthesized by haptophyte algae, and the newly proposed TEX₈₆ derived from the membrane lipids of Crenarchaeota. Comparison of NIOP905 and 74KL core top data with present day SST (0-10 m) values, indicate that both proxies yield temperatures similar to local annual mean SSTs. However, TEX₈₆ and U₃₇^{K'} SST downcore records derived from the same cores differ in magnitude and phasing. The alkenone SST record of NIOP905 shows small changes in SST (~0.5°C) over the last 23 kyr while that of core 74KL shows a ~2°C increase from the Last Glacial Maximum (LGM; 23-19 cal kyr BP) through the Holocene (the last 11.5 cal kyr BP) synchronous with changes in the northern hemisphere. In contrast, the TEX₈₆ records of both cores show a large increase in SST from 22-23°C in the LGM to 28-30°C during Termination I (19-11.5 cal kyr BP), decreasing to present day annual means of ~26°C. A cold phase between 14.5 and 12 cal kyr BP that may correspond to the Antarctic Cold Reversal is also observed. This implies a southern hemisphere control on tropical SST reconstructed by the TEX₈₆, possibly related to SW monsoon. Our results suggest that the application of both TEX₈₆ and U₃₇^{K'} give different but complementary information on SST developments in past marine environments.

8.1. Introduction

Evidence of large-magnitude and rapid climate changes on millennial timescales (e.g., Dansgaard-Oeschger events, Heinrich Events) that characterized the last glaciation during the Late Pleistocene have been provided by ice core records [e.g. *Grootes and Stuiver, 1997; Jouzel et al., 2003*] as well as by continental and marine sediment records [e.g., *Schulz et al., 1998; Wang et al., 2001*]. To better understand such abrupt millennial-scale climate changes, their consequences, and their underlying mechanisms, it is essential to construct SST records at a high temporal resolution.

Several geochemical proxies are used for SST reconstruction, the most common being $\delta^{18}\text{O}$ and Mg/Ca ratios of planktic foraminifera [*Chave, 1954; Emiliani, 1955; Nurnberg et al., 1996*] and the $\text{U}_{37}^{\text{K}'}$ index of long-chain unsaturated ketones synthesized by haptophyte algae [*Brassell et al., 1986*]. Reconstruction of SST with these proxies is, however, associated with a number of problems. The use of planktic foraminifera $\delta^{18}\text{O}$ for SST reconstruction is complicated by several uncertainties related to the formation and preservation of shells as well as the carbonate ion concentration, the $\delta^{18}\text{O}$ and the salinity of the original seawater [*Spero et al., 1997; Wefer et al., 1999; Lea, 2003*]. The Mg/Ca ratio [*Elderfield and Ganssen, 2000*] is less affected by these factors, except by species-dependent vital effects and shell dissolution [*Wefer et al., 1999; Lea, 2003*]. The $\text{U}_{37}^{\text{K}'}$ index is often considered more robust, as the values are not directly controlled by sea-water chemistry and, hence, assumptions concerning this are not needed. Furthermore, global surveys of surface sediments and particulate organic matter reveal a strong and identical correlation between the $\text{U}_{37}^{\text{K}'}$ and SST (reviewed by *Herbert [2003]*). However, the biochemical function of alkenones is still unknown and the $\text{U}_{37}^{\text{K}'}$ may be affected by changes in the species composition through time and also by oxic degradation [*Herbert, 2003*].

Recently, *Schouten et al. [2002]* introduced a new SST proxy, the TEX_{86} based on the relative distribution of glycerol dibiphytanyl glycerol tetraethers (GDGTs), which are membrane lipids produced by non-thermophilic Crenarchaeota. These organisms are ubiquitous and abundant in seawater [*Hoefs et al., 1997; Massana et al., 2000; Karner et al., 2001*] and large lakes [*Powers et al., 2005*].

Marine crenarchaeota biosynthesize different GDGTs with a varying number of cyclopentane rings according to temperature [Wuchter *et al.*, 2004]. Therefore, by measuring the relative amounts of GDGTs present in sediments, the temperature at which Crenarchaeota were living can be reconstructed. Experiments with an enrichment culture, containing a single archaeal species falling in the phylogenetic cluster of the marine crenarchaeota, showed that TEX₈₆ is linearly correlated with temperature and that changes in salinity and nutrients do not substantially affect the TEX₈₆ [Wuchter *et al.*, 2004]. Particulate organic matter analysis revealed that the TEX₈₆ correlates well with surface water temperatures (depths <100m) and that the signal in the deeper water layers and surface sediments is primarily derived from these upper 100 meters [Wuchter *et al.*, 2005]. This suggests that the signal from the surface waters is efficiently transported to the sediment probably by grazing [Wakeham *et al.*, 2003]. Indeed, recent studies of sediment trap material showed that the TEX₈₆ signal at different depths in sediment particles is derived from the upper layer of the water column [Wuchter *et al.*, 2006]. This new organic geochemical proxy also seems to be unaffected by water redox conditions [Schouten *et al.*, 2004]. However, a number of factors such as the ecology and physiology of crenarchaeota in different oceanic provinces and its effect on the TEX₈₆, need to be further constrained. But, there are already some developments in those fields, for example, a species of marine Crenarchaeota was recently isolated and shown to be an autotrophic ammonium-oxidizer [Könneke *et al.*, 2005] in agreement with previous observations [Wuchter *et al.*, 2004]. This could explain observed seasonal distributions of marine Crenarchaeota in surface waters, i.e their high abundance during times of low phytoplankton productivity and high nutrients [cf Wuchter *et al.*, 2005 and references therein]. However, to what extent this influences their depth habitat, their seasonality in low and high nutrient environments and how widespread this metabolism is remains unknown. Recently, it has also become clear that GDGTs such as those occurring in marine Crenarchaeota are present in terrestrial organic matter albeit in much lower abundances [Hopmans *et al.*, 2004; Weijers *et al.*, 2004]. Thus, at sites which receive high amounts of terrestrial organic matter, the TEX₈₆ could potentially be biased. Nevertheless, despite these limitations, the TEX₈₆ proxy may be a useful tool to reconstruct SSTs.

Here, for the first time, we applied the TEX₈₆ to Quaternary marine sediment cores and investigated its potential as a tool in multi proxy paleoceanography and paleoclimate studies

in comparison with the $U_{37}^{K'}$. The western Arabian Sea (Fig. 1) was selected for this study as it is an area where organic-rich sediments are deposited with high accumulation rates, allowing the recovery of continuous high-resolution records with sufficient amounts of organic matter. Furthermore, previous low-resolution $U_{37}^{K'}$ records from this area revealed quite contrasting differences between LGM and Holocene SSTs varying between 0.3°C and 3°C [Sonzogni *et al.*, 1998]. Our approach based on two lipid biomarker proxies, $U_{37}^{K'}$ and TEX_{86} , provides detailed information on SST variations in the western Arabian Sea over the last 23 kyr and the impact of the Arabian Sea monsoonal climate system on SST records.

8.2. Material and Methods

8.2.1. Modern atmospheric and oceanographic setting

The western Arabian Sea is predominantly influenced by monsoon climate related annual cycles driven by the pressure gradient that exists between Tibet plateau and the South Indian Ocean [Rixen *et al.*, 2000]. The annual cycle can be divided into four phases; (a) the northeast (NE) monsoon from December to March; (b) the summer intermonsoon from March to June; (c) the southwest (SW) monsoon from June to September; and (d) the fall intermonsoon from September to December [Wakeham *et al.*, 2002] (Table 2). The differential pressure results in southwesterly winds during the SW monsoon and in northeasterly winds during the NE monsoon [Rixen *et al.*, 2000; Andruleit *et al.*, 2000; Bush, 2002]. The SW monsoon induces strong upwelling of nutrient rich, cool waters that leads to lower SST (Fig. 1), higher productivity, an intense oxygen minimum zone and a high particle flux [Wakeham *et al.*, 2002]. The NE monsoon causes a deepening of the mixed layer and no upwelling, resulting in relatively higher SST (Fig. 1) and only a small increase in production and particle flux [Wakeham *et al.*, 2002].

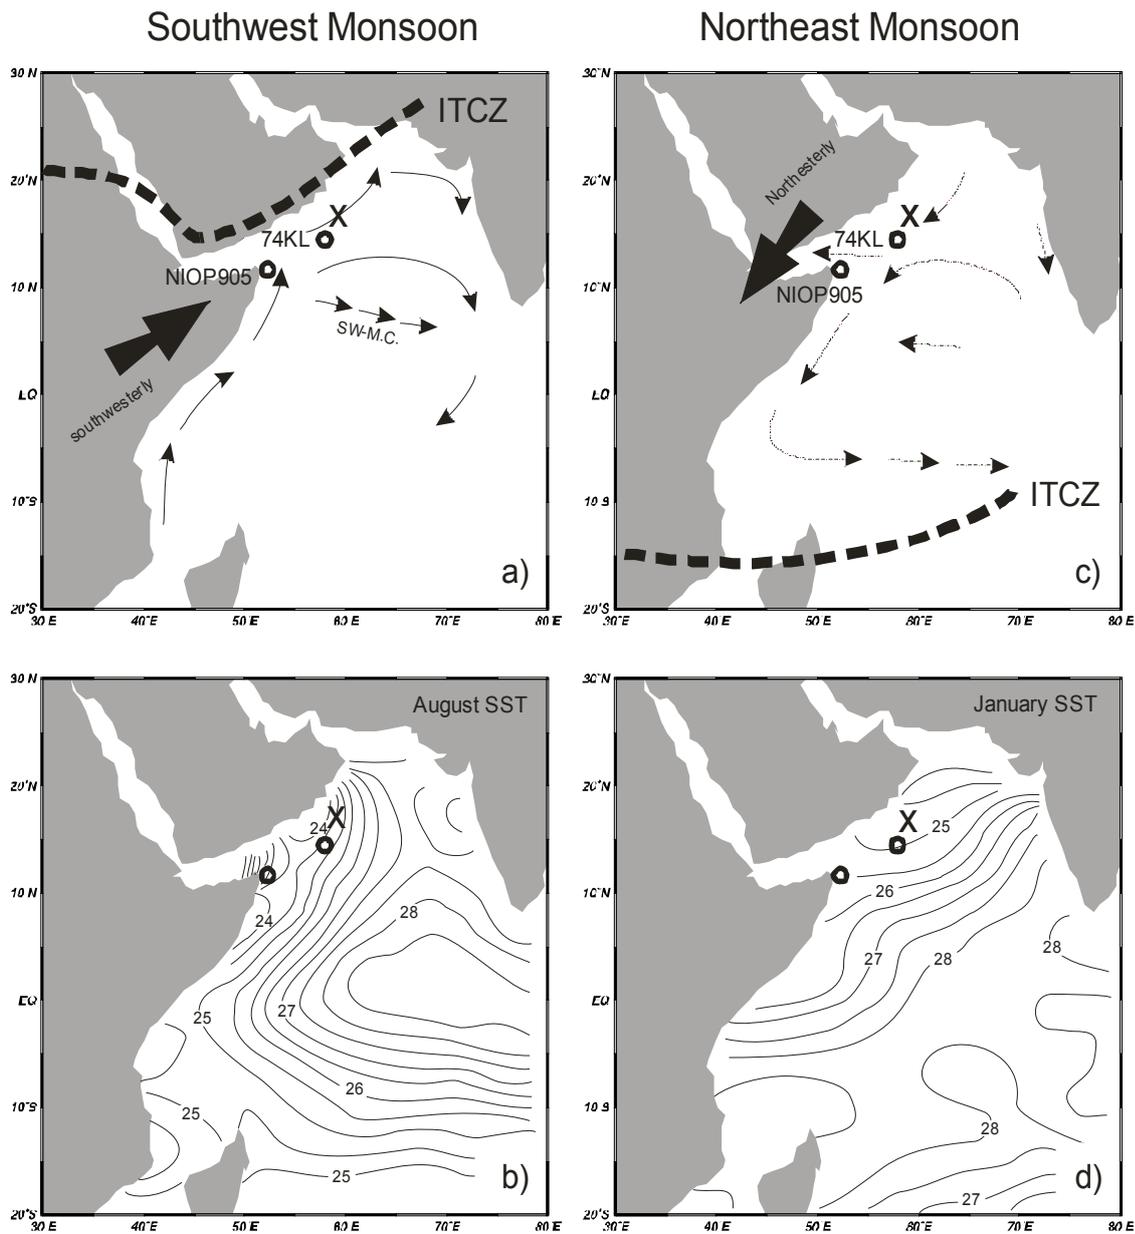

Figure 1. Map of study area showing core locations (open circles), sediment trap location of *Wakeham et al.* [2002] and *Wuchter et al.* [2006] (cross) ITCZ positions, and prevalent wind directions during the SW monsoon and the NE monsoon. (a) Sea surface circulation pattern during the SW monsoon. (b) August SST distribution pattern [Levitus and Boyer, 1994]. (c) Sea surface circulation pattern during the NE monsoon. (d) January SST distribution pattern [Levitus and Boyer, 1994]. Core NIOP905 ($10^{\circ} 47'N$, $51^{\circ} 56'E$) was taken in the Somalia Basin, under the Socotra upwelling. Core 74 KL ($14^{\circ} 19.26'N$, $57^{\circ}20.82'E$) taken off the Oman coast.

8.2.2. Sample collection and stratigraphy

Two sediment cores (NIOP905 and 74KL) from the western Arabian Sea were investigated in this study. Core NIOP905 (10°47'N, 51°56'E) was taken in the Socotra upwelling cell of the Somalia Basin (Fig. 1), ca. 80 km off the coast of Somalia and at 1567 m water depth. Core 74KL (14°19'N, 57°20'E) was obtained from the East Sheba Ridge, 1000 m above the turbidity plain of the Indus fan, 300 km south of the Arabian continental margin (Fig. 1). Core NIOP905 was sampled at 2 to 5 cm intervals and core 74KL at 2.5 cm intervals. Both cores have been studied previously in detail for the $\delta^{18}\text{O}$ of foraminifera [Sirocko *et al.*, 1993; Ivanova, 2000; Jung *et al.*, 2002; Ivanochko, 2005a] and, in case of NIOP905, trace elements [Ivanochko, 2005a].

The age models of cores NIOP905 and 74KL were established by nineteen accelerator mass spectrometry (AMS) ^{14}C dates from mixed planktic foraminifera and thirteen AMS ^{14}C determinations on *Globigerinoides ruber*, respectively (Table 1) which were published previously [Sirocko *et al.*, 1993; Ivanova, 2000; Jung *et al.*, 2002; Ivanochko, 2005a]. We employed a correction for the regional ^{14}C reservoir age (ΔR = the deviation from the surface ocean average of 400 years) of 190 ± 25 years for the western Arabian Sea [Southon *et al.*, 2002], although the ΔR in the Arabian Sea can vary substantially through time as demonstrated by Staubwasser *et al.* [2002]. However, the age model based on the varying ΔR of Staubwasser *et al.* [2002] from the eastern Arabian Sea (not shown) does not affect the conclusions made in this study. Continuous time scales for both cores were obtained by linear interpolations between the age control points after converting the ^{14}C ages into calendar years (years before 1950) using the latest version of the radiocarbon-calendar year calibration software CALIB 5.0.1 [Stuiver *et al.*, 2005]. The average temporal resolution is ~200 years for NIOP905 and ~300 years for core 74KL.

8.2.3. Lipid extraction

For core NIOP905, freeze-dried and homogenized sediment samples were ultrasonically extracted with MeOH, MeOH/DCM (1:1;v/v) and finally with DCM. The supernatants were collected and after evaporating the solvents, the extracts were dried over a sodium sulfate column.

^aMean values were used for the age model.

^bThe regional reservoir age (AR) for the western Arabian Sea was used according to Southon *et al.* [2002]. n.a. Analytical errors are not available for these data. Therefore, we assumed ± 50 years for the analytical determination.

Table 1. Age control points for sediment cores NIOP905 and 74KL

An aliquot of the total lipid extract was used to analyze the alkenones for determination of the $U_{37}^{K'}$ ratio. The total extract was derivatized with diazomethane and BSTFA/pyridine. The derivatized total extract was analyzed by gas chromatography (GC) and gas chromatography/mass spectrometry to quantify alkenones. For GDGT analysis an aliquot of the total lipid extract was fractionated into apolar and polar fractions using a small column with activated alumina and using hexane/DCM (9:1;v/v) and DCM/MeOH (1:1;v/v) as eluents, respectively. The polar fractions were analyzed for GDGTs.

For core 74KL, the samples were extracted in a similar way than NIOP905. Subsequently, the total extracts were separated into DCM and MeOH/DCM (1:1;v/v) fractions, using a silica gel cartridge (Varian Bond Elute; 1 cc per 100 mg). The DCM fraction was saponified at 80°C for 2 h with 300 μ l of 0.1 M KOH in 90:10 MeOH/H₂O. The neutral fraction containing the alkenones was obtained by partitioning into hexane. The MeOH/DCM (1:1;v/v) fraction was used for GDGT analysis.

8.2.4. Alkenone analysis and $U_{37}^{K'}$ SST

Peak areas of $C_{37:2}$ and $C_{37:3}$ alkenones were determined by GC analysis [cf Kim et al., 2004]. The alkenone unsaturation index $U_{37}^{K'}$ was calculated from $U_{37}^{K'} = (C_{37:2}) / (C_{37:2} + C_{37:3})$, where $C_{37:2}$ and $C_{37:3}$ are the di- and tri-unsaturated C_{37} methyl alkenones [Prahl and Wakeham, 1987]. The $U_{37}^{K'}$ values were converted into temperature values applying the global core-top calibration ($U_{37}^{K'} = 0.033 \times T + 0.044$) of Müller et al. [1998].

8.2.5. GDGT analysis and TEX_{86} SST

For cores NIOP905 and 74KL, the polar fractions (DCM/MeOH, 1:1; v/v) were analyzed for GDGTs according to the procedure described by *Hopmans et al.*, [2000]. Aliquots of polar fractions blown down under a stream of nitrogen, re-dissolved in hexane/propanol (99:1;v/v), and filtered through 0.45 μ m PTFE filters. The samples were analyzed with an HP (Palo Alto, CA, USA) 1100 series LC-MS equipped with an auto-injector and Chemstation chromatography manager software. Separation was achieved on a Prevail Cyano column (2.1 x 150mm, 3 μ m; Alltech, Deerfield, Illinois, USA), maintained at 30°C. The GDGTs were eluted using a changing mixture of (A) hexane and (B) propanol as

follows, 99 A:1 B for 5 min, then a linear gradient to 1.8 B in 45 min. Detection was achieved using atmospheric pressure chemical ionization-mass spectrometry of the eluent. Single Ion Monitoring (SIM) was used as it gives better reproducibility than full mass scanning by reducing the signal to noise ratio. The SIM method was set to scan the 5 $[M^+]+H$ ions of the GDGTs with a dwell time of 237 ms for each ion. All TEX₈₆ analyses were performed at least in duplicate.

The TEX₈₆ ratio ($TEX_{86} = (GDGT_2 + GDGT_3 + \text{Crenarchaeol-isomer}) / (GDGT_1 + GDGT_2 + GDGT_3 + \text{Crenarchaeol-isomer})$) was calculated based on the relative abundance of GDGTs and converted into temperature values applying the calibration ($TEX_{86} = 0.015 \times T + 0.028$) of Schouten *et al.* [2002].

8.2.6. Analytical reproducibility

To determine the analytical reproducibility of the $U_{37}^{K'}$ and TEX₈₆ SST values, a set of 12 sub-samples from a large homogenized batch of sediment from GeoB 1707-1 (recovered during METEOR cruise M20/2 at 1232 m near the Angola coast in the Atlantic Ocean; 19°41'S, 10°39'E) were extracted independently and measured at regular intervals during the analysis of the 74KL sample series. The standard deviation of the $U_{37}^{K'}$ and TEX₈₆ SST analysis of these sub-samples was 0.2°C ($\pm 1\sigma$) and 0.4°C ($\pm 1\sigma$), respectively.

8.3. Results

8.3.1 Core NIOP905

The $U_{37}^{K'}$ SST range for NIOP905 is fairly narrow and varies between 25.0 and 26.5°C for the time interval between 23 and 0 cal kyr BP. This is in contrast to the $\delta^{18}O$ record of *G. ruber* [Jung *et al.*, 2001] which shows a gradual decrease during Termination I (Fig. 2a). $U_{37}^{K'}$ SST during the LGM (23-19 cal kyr BP) was 25.5°C with only a small, relatively abrupt increase in SST during the glacial-interglacial transition between 18 to 16 cal kyr BP of ~0.5°C (Fig. 2b). After this rise, the NIOP905 record shows a small drop in $U_{37}^{K'}$ SST of ~0.5°C between 16 and 14 cal kyr BP and a rise of ~0.5°C between 14 and 12.5 cal kyr BP.

This is followed by a decrease of $\sim 0.7^{\circ}\text{C}$ between 12 and 10.5 cal kyr BP. Then SST stabilized around 25.7°C until 5 cal kyr BP and then rose to the core top value of 26.3°C .

The TEX_{86} record for NIOP905 is quite different from the U_{37}^K SST record and the $\delta^{18}\text{O}$ record. TEX_{86} SST values for the studied interval of 23-0 cal kyr BP range from 22 to ca. 30°C with a few data points above 30°C (Fig. 2c). TEX_{86} SST is $\sim 22.5^{\circ}\text{C}$ during the LGM (23-19 cal kyr BP) and increased to 29°C between 18 and 16 cal kyr BP. This $\sim 6^{\circ}\text{C}$ increase is significant compared to the analytical error of 0.4°C . After the rapid warming of SST between 18 and 16 cal kyr BP there was a substantial lowering of SST from $\sim 26^{\circ}\text{C}$ between 16 and 14 cal kyr BP (Fig. 2c). After this cooling, the TEX_{86} SST increased again by up to 5°C to a maximum of 31°C at 12 cal kyr BP before rapid cooling of $\sim 3^{\circ}\text{C}$ until 11 cal kyr BP. An additional SST spike of $\sim 3^{\circ}\text{C}$ is noticeable at around 10.5 cal kyr BP and SST then slowly decreased from 27°C at 10 cal kyr BP to the present day core top value of 25.7°C .

8.3.2. Core 74KL

The U_{37}^K SST range for 74KL is larger than for NIOP905 and varies from 24.8 to 27.3°C between 23 and 0 cal kyr BP (Fig. 3b). SST during the LGM (23-19 cal kyr BP) was again 25°C as with NIOP905 but the increase in SST during Termination I was larger ($\sim 1.5^{\circ}\text{C}$) and more gradual in 74KL and was synchronous with the decrease in $\delta^{18}\text{O}$ values of *G. ruber* (Fig. 3a and 3b). After Termination I U_{37}^K SST increased slightly up to the core top value of 27.3°C .

The TEX_{86} record at 74KL is again quite different from U_{37}^K SST record, but closely resembles the pattern evident in the TEX_{86} record from core NIOP905. TEX_{86} SST values for 74KL have a somewhat smaller range than in NIOP905 and vary between 24 and 30°C (Fig. 3c). LGM SSTs for 74KL ($\sim 24^{\circ}\text{C}$) were slightly higher than at NIOP905 ($\sim 22.5^{\circ}\text{C}$). TEX_{86} SST values then rapidly increased to $\sim 30^{\circ}\text{C}$ between 18 and 16 cal kyr BP followed by a drop in SST down to 26°C between 16 and 14 cal kyr BP. SST then rapidly increased again to 29°C at 12.5 cal kyr BP followed by a rapid drop to 27.5°C . SST then slowly decreased to the core top value of 26.4°C .

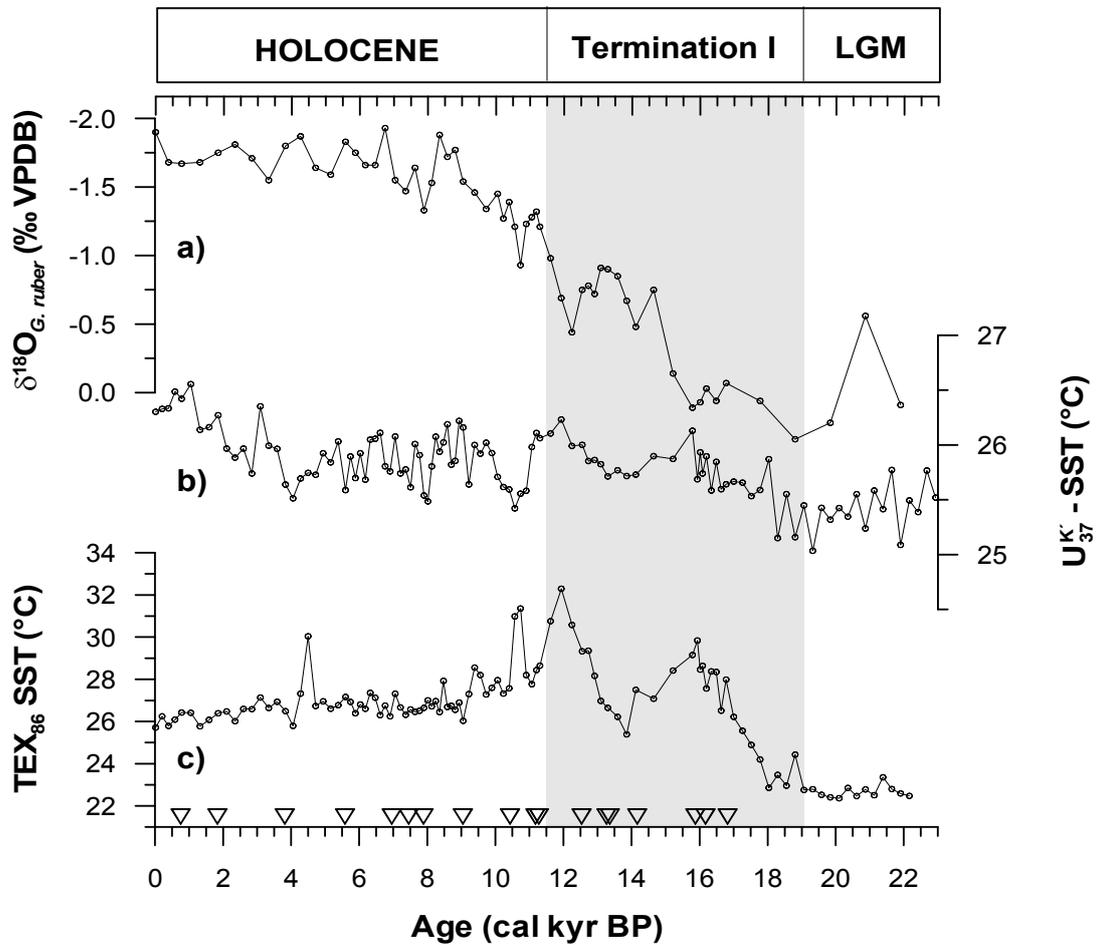

Figure 2. Time series of (a) stable $\delta^{18}\text{O}$ record of the planktic foraminifera *G. ruber* [from Jung *et al.*, 2001] and (b) U_{37}^{K} and (c) TEX_{86} SST records for core NIOP905, plotted against calendar ages. Open triangles on lower axis show age control points. Broad grey bar indicates the time interval for Termination I.

8.4. Discussion

8.4.1 Comparison of core tops and present day SSTs

One way of establishing the origin of the reconstructed SST of proxies is to compare core top reconstructed SSTs (0-2.5 cm depth representing the last ~300 years) with those of annual mean and seasonal mean SST (0-10 m depth). For NIOP905 the TEX_{86} and the U_{37}^{K} give a core top SSTs of 25.7 and 26.3°C, respectively.

Considering the analytical error of 0.4°C and 0.2°C , respectively, these results correspond well with present day annual mean SST of 26.0°C (Table 2). Similarly, at site 74KL both TEX_{86} and U_{37}^{K} SST, with core top values of 26.4°C and 27.3°C , respectively, correspond well with present day annual mean SST of 26.8°C .

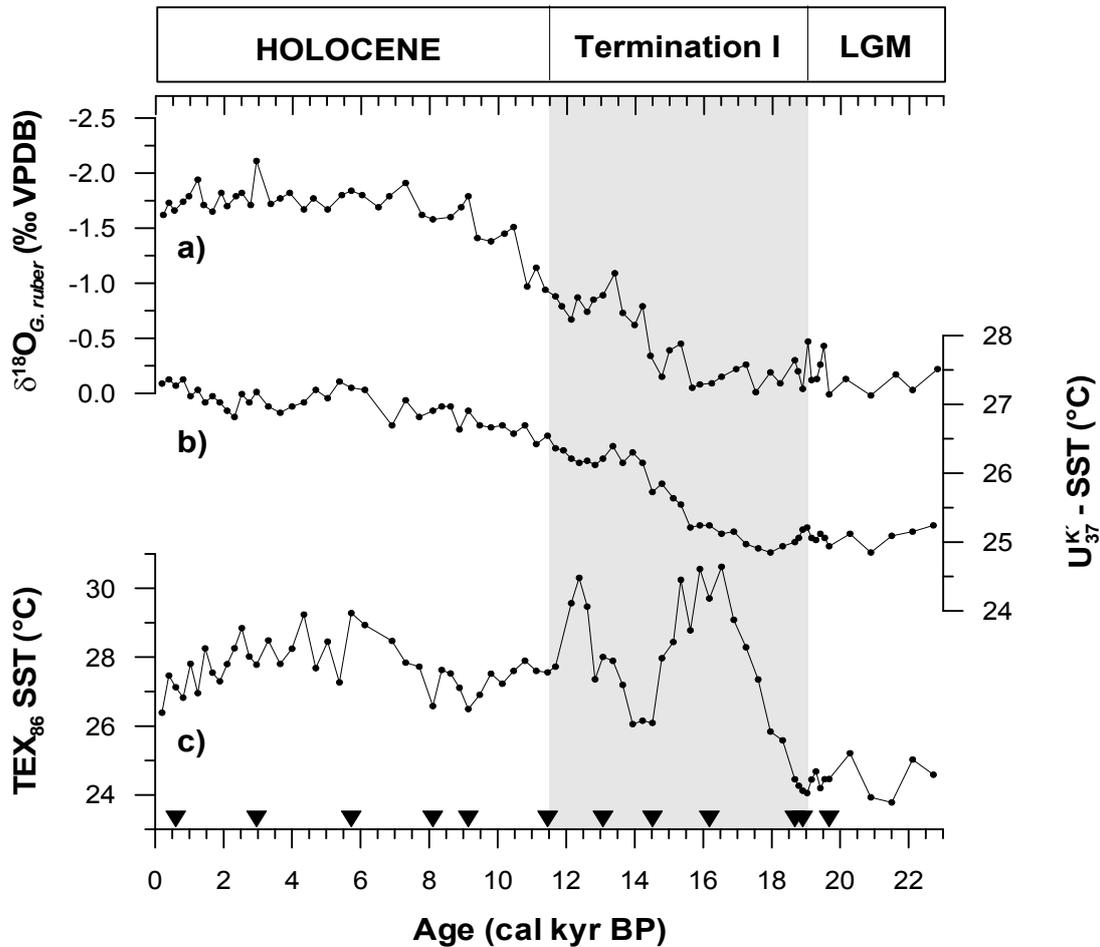

Figure 3. Time series of (a) stable $\delta^{18}\text{O}$ record of the planktic foraminifera *G. ruber* [Sirocko *et al.*, 1993] and (b) U_{37}^{K} and (c) TEX_{86} SST records for core 74KL, plotted against calendar ages. Solid black triangles on lower axis show age control points. Broad grey bar indicates the time interval for Termination I.

Although both proxies seem to record annual mean SSTs, it has been reported that both Crenarchaeota [Massana *et al.*, 1998; Murray *et al.*, 1999; Wuchter *et al.*, 2005a] and haptophyte algae [e.g. Bac *et al.*, 2003] vary considerably in abundance during the annual cycle. In the Arabian Sea primary production is strongly associated with upwelling dynamics and monsoonal cycles (Fig. 1). This most likely determines the annual cycle of the abundance of organisms that produce the biomarkers on which the SST proxies are based. Trap studies in the coastal and central Arabian Sea show that more than 50% of the particle flux to the sediments occurs during the SW monsoon and to a lesser extent (~25%) during the NE monsoon [Prahl *et al.*, 2000; Wakeham *et al.*, 2002]. Wakeham *et al.* [2002] described a distinct succession in phytoplankton biomarker fluxes. During the early SW monsoon the biomarker flux is dominated by C₃₀-diol and C₃₀-ketols from *Proboscia* diatoms [Sinninghe Damsté *et al.*, 2003]. This is followed by maximum fluxes of alkenones, and diatom and dinoflagellate sterols. At the end of the upwelling season the flux of 25:3 highly branched isoprenoid produced by *Rhizosolenoid* diatoms increase substantially. These findings are in good agreement with results from other sediment trap studies in central Arabian Sea area, where a sharp peak in the flux of alkenones was measured in the middle of the SW monsoon as well as a minor peak during the NE monsoon [Prahl *et al.*, 2000]. Taken together these studies indicate that sedimentary alkenones are mainly derived from alkenones produced during the SW monsoon and, to a lesser extent, during the NE monsoon. A recent study on the same sediment trap material from the Wakeham *et al.* [2002] in the Arabian Sea, showed that fluxes of GDGT material in a location near 74KL (Fig. 1) were also highest during the SW monsoon and to a lesser degree in the NE monsoon [Wuchter *et al.*, 2006]. However, GDGT fluxes only moderately increased during both monsoon periods compared to the intermonsoon periods (ca. 3 times). In contrast, the fluxes of alkenones were substantially higher (ca. 9 times) during monsoon periods than in intermonsoon periods. Wuchter *et al.*, [2006] suggested that this is because the relative abundance of Crenarchaeota during upwelling is lower than outside the upwelling period, while the opposite is observed for phytoplankton abundance. This is in agreement with previous studies which showed a negative correlation between Crenarchaeota and phytoplankton abundance [Massana *et al.*, 1998; Murray *et al.*, 1999; Wuchter *et al.*, 2005]. Based on the above considerations, U₃₇^K SST values in the

present-day Arabian Sea should correspond to the SST prevalent during the SW monsoon, while the crenarchaeotal TEX₈₆ is also influenced by SST from periods outside the SW monsoon and, thus, perhaps reflects a more annual mean signal.

| Phase | Month | Site NIOP905 | | Site 74KL | |

^aCalculated using flux data of Prahl et al. [2000] and mean monthly SST

^bCalculated using flux data of Wuchter et al. [2005b] and mean monthly SST

^cAccording to the calibration of Prahl *et al.* [1988]: $T [^{\circ}\text{C}] = (U_{37}^{K'} - 0.039)/0.034$

^dAccording to the calibration of Sonzogni *et al.* [1997]: $T [^{\circ}\text{C}] = (U_{37}^{K'} - 0.317)/0.023$

^eAccording to the calibration of Müller *et al.* [1998]: $T [^{\circ}\text{C}] = (U_{37}^{K'} - 0.033)/0.04$

Table 2. Mean monthly sea surface temperature (0-10 m) data corresponding to core sites [World Ocean Atlas 1998, On-line version at www.nodc.noaa.gov/OC5/WOA98F], calculated flux weighted TEX₈₆ and U₃₇^{K'} SST and core top TEX₈₆ and U₃₇^{K'} SST values for NIOP905 and 74KL.

Based on the sediment trap studies reported we can estimate the flux weighted annual SST for alkenones and GDGTs, i.e. the annual mean SST corrected for the times of the largest fluxes of these components, by combining alkenone and GDGT flux data from the central Arabian Sea [Prahl *et al.*, 2000; Wakeham *et al.*, 2002; Wuchter *et al.*, 2006] and monthly average SST (Table 2). The flux weighted annual SST for alkenones is 1.4°C lower than $U_{37}^{K'}$ SST core top value for NIOP905 but only 0.8°C lower than core top $U_{37}^{K'}$ SST at 74KL (Table 2). The comparison of core top values to monthly mean SSTs (Table 2) suggests that the $U_{37}^{K'}$ is not recording the upwelling of cold water between June and September. During the SW monsoon, the Arabian Sea shows substantially lower SSTs, especially at NIOP905 where SSTs are up to 3°C lower than annual mean SST (Table 2). Hence, it seems that the pulses in alkenone production during upwelling seasons do not have a substantial effect on the temperature signal recorded by $U_{37}^{K'}$ in the sediment. It should be noted, however, that most sediment trap studies cover just one cycle at one specific location and that interannual variability in production could be of importance [Herbert, 2003]. Furthermore, it is important to take into account that the core top (0-2.5 cm) represents an integrated SST signal of up to 300 years. Finally, the SST estimate from $U_{37}^{K'}$ analysis will also depend on the calibration used and can vary by up to 0.7°C (Table 2). However, other studies in the Arabian Sea show similar results, in that the flux of alkenones to the sediment is seasonal, yet an annual mean SST is recorded in the sediment core tops [Doose-Rolinski *et al.*, 2001; Rosell-Melé *et al.*, 2004]. A similar calculation for GDGT flux-weighted TEX_{86} SST yields 26.0°C and 26.8°C for NIOP905 and 74KL, respectively (Table 2). These values are identical to the actual annual mean SST and are within analytical error of the core top TEX_{86} value. The flux weighted TEX_{86} SST is higher than the flux-weighted $U_{37}^{K'}$ SST in agreement with the relatively higher fluxes of alkenones compared to GDGT during the SW monsoon. This suggests that the TEX_{86} is recording annual mean SST although, based on the above considerations for the $U_{37}^{K'}$, we can not exclude that certain seasonal periods may have a substantial influence on the TEX_{86} .

We can thus not rule out that there is a seasonal component in our SST proxies, even though this is not apparent from our core top results. It is also possible that the seasonal signal

was stronger during certain periods of time, e.g. during the LGM, which may explain why the proxies show different behavior in our sedimentary record (see below).

8.4.2 Comparison of SST proxy records

The $U_{37}^{K'}$ records of the two cores differ in both timing and magnitude of SST variations during deglaciation but both record relatively small variations in SST of $<3^{\circ}\text{C}$. Remarkably, $U_{37}^{K'}$ SSTs reconstructed for the LGM for both sites are very similar at 25°C but the rise in SST during Termination I was much larger at 74 KL (2°C) than at NIOP905 (0.5°C). This is in agreement with previous results of *Sonzogni et al.* [1998] who showed that the $U_{37}^{K'}$ SST rising during Termination I is only 0.3°C for NIOP 905 but $1\text{-}3^{\circ}\text{C}$ at other sites in the Indian Ocean. The reasons for the different $U_{37}^{K'}$ records of the two sites are unclear but based on the study of *Sozogni et al.* [1998] the unusual $U_{37}^{K'}$ record at NIOP905 seems to be a local feature. After Termination I, $U_{37}^{K'}$ SST in both records vary by $<1^{\circ}\text{C}$ suggesting relatively stable conditions. Remarkably, the $U_{37}^{K'}$ record at 74KL is roughly similar in phase to changes in $\delta^{18}\text{O}$ record, which contains a substantial SST component, in contrast to the $U_{37}^{K'}$ record at NIOP905 which is dissimilar to the $\delta^{18}\text{O}$ record. However, it should be noted that comparison of $U_{37}^{K'}$ record and $\delta^{18}\text{O}$ record should be done with caution as SST is not the only factor determining $\delta^{18}\text{O}$ (e.g. $\delta^{18}\text{O}$ of sea water, salinity) and, despite being analysed in the same sediment layer, could represent SST of different ages [cf. *Ohkouchi et al.*, 2002]

Both 74KL and NIOP905 cores gave similar TEX_{86} SST records, taking into account the errors in TEX_{86} analysis and the age models. However, they are quite different from the $U_{37}^{K'}$ records at both sites show substantially larger variability in SST. For example, SSTs rose by $4\text{-}6^{\circ}\text{C}$ during Termination I with a pronounced cooling between 15.5 and 12 cal kyr BP whilst $U_{37}^{K'}$ SST rose fairly smoothly by only $0.5\text{-}1.5^{\circ}\text{C}$. The trends in the TEX_{86} SST records are also different from those in $\delta^{18}\text{O}$ records, e.g. they show a more gradual trend from LGM to Holocene and no pronounced cooling between 15.5-12 cal kyr BP. However, comparison between the TEX_{86} record and $\delta^{18}\text{O}$ record are hampered by the same problems as discussed for the $U_{37}^{K'}$ record and $\delta^{18}\text{O}$ record. In contrast, the differences between the two organic SST

proxy records, TEX₈₆ and U₃₇^{K'}, are unlikely to be caused by sea water composition changes and are more likely to be caused by the different response of the proxy-producing organisms to changes in climatic conditions such as monsoon and upwelling intensity, as has been documented for this area [e.g. *Ivanochko et al.*, 2005b]. Thus, both proxies probably do not record annual mean SST but are strongly influenced by seasonal SSTs. Below we attempt to explain the impact of this component on LGM SST reconstruction, and the phasing of SST changes.

8.4.3 LGM SST reconstructions

Large discrepancies exist in estimates of tropical LGM temperatures [*Mix et al.*, 2001]. These discrepancies are dependent on the method used to estimate LGM temperatures. Transfer function values of distributions of planktic foraminifera show small SST changes for the glacial-interglacial transition, e.g. the CLIMAP project reconstruction suggests SSTs of 2°C lower for the LGM in the Arabian Sea [*CLIMAP*, 1981]. *Mix et al.*[2001] suggested that CLIMAP might have underestimated ice-age cooling in the tropics, and that SST could have cooled almost 3°C. U₃₇^{K'} studies in the Arabian Sea and Indian Ocean show differences between the LGM and present day SST of 1.5 to 2.5°C [*Bard et al.*, 1997; *Sonzogni et al.*, 1998; *Schulte and Müller*, 2001; *Rosell-Melé et al.*, 2004]. Analyses of Mg/Ca ratios of planktic foraminifera at tropical areas in the equatorial Atlantic and Pacific show a 2.5-3°C cooler SST during the LGM [*Hastings et al.*, 1998; *Lea et al.*, 2000] while a recent summary suggested 2-3.5°C lower SSTs in tropical areas during the LGM [*Barker et al.*, 2005, and references cited therein]. Sr/Ca ratios in corals indicate up to 5°C difference in SST between the LGM and the present [*Guilderson et al.*, 1994]. Reconstructions of SST in the western Arabian Sea using artificial neural networks based on quantitative analysis of planktonic foraminifera suggests LGM SST 2°C below Holocene values [*Naidu and Malmgren*, 2005], in agreement with predictions based on atmosphere-ocean models [*Mix et al.* 2001, and references therein]. Some modeling results also suggest relatively cool temperatures in the tropics with LGM SST values ca. 4°C lower than Holocene SST values for the Arabian Sea [*Toracinta et al.*, 2004]. In general, proxy data suggest LGM SSTs between 1.5-5°C lower than present-day values, suggesting that Arabian Sea LGM temperatures were between 21.5 and 24.5°C.

The proxy records in this study also reveal a difference, i.e. SSTs estimated for the LGM are $\sim 23^{\circ}\text{C}$ with TEX_{86} and $\sim 25^{\circ}\text{C}$ with the $U_{37}^{\text{K}'}$. Thus, the temperature increase from the LGM to present day is $0.5\text{-}1.5^{\circ}\text{C}$ when measured with $U_{37}^{\text{K}'}$, and $3\text{-}4^{\circ}\text{C}$ when we use the TEX_{86} . The LGM SST values reconstructed with TEX_{86} are slightly lower than other LGM estimates (see above). However, LGM SST TEX_{86} estimates are still well within the range measured by other proxies in the tropical area. Furthermore, preliminary measurements of Mg/Ca ratio of planktic foraminifera in the NIOP905 core suggest that calcification temperatures were up to 3°C lower during the LGM compared to the late Holocene (*Anand et al., personal communication*). This is in good agreement with the TEX_{86} proxy estimates of glacial-interglacial SST changes in the Arabian Sea.

On the other hand, $U_{37}^{\text{K}'}$ SSTs in both cores indicate that the LGM was only $0.5\text{-}1.5^{\circ}\text{C}$ cooler than present day and suggest LGM SSTs of 25°C . These temperatures are somewhat higher than SST estimates based on inorganic proxies and the TEX_{86} . Several studies show that in general alkenone-based SSTs give smaller changes from the LGM to the Holocene in tropical and subtropical areas compared to other proxies such as Sr/Ca or $\delta^{18}\text{O}$ [*Rosell-Melé et al., 2004; Toracinta et al., 2004*] for reasons which are presently unclear. Thus, it seems that the LGM TEX_{86} SST estimates are somewhat lower than estimates using other proxies and modeling results while our $U_{37}^{\text{K}'}$ LGM SST estimates are somewhat higher.

The strong control of primary production in the area by upwelling may explain why alkenone-based glacial SSTs are substantially higher than those based on the TEX_{86} . A decrease in the upwelling intensity has been documented for the Arabian Sea during the LGM [*e.g. Naidu and Malmgren, 2005*] and the Ba/Al record from NIOP905, a measure for marine productivity, shows lower ratios during the LGM and at the beginning of Termination I [*Ivanochko et al., 2005a*] suggesting lower productivity. It is reasonable to assume that these large changes could affect the seasonal abundance of the organisms living in the upwelling region. A decrease in the intensity of the SW monsoon during the LGM would indeed affect the depth of alkenone production, increase the stratification of surface waters and reduce production. All those changes would affect the alkenone temperature signal [*Mix et al., 2000, Prahl et al., 2003*] and could, likewise, affect the production and flux of crenarchaeotal GDGTs during the annual cycle. It has been suggested that the monsoon dynamics might have

been different during the LGM with a very weak SW monsoon and relatively strong NE monsoon resulting in a shift in alkenone production to the winter months in the Arabian Sea [Higginson *et al.*, 2004]. This would result in relatively higher SSTs during the LGM as temperatures during the SW monsoon are lower than during the NE monsoon (Table 2). The idea of a seasonal shift in alkenone production has indeed been used to explain the relatively warm glacial SST measured by U_{37}^K in the subtropical North Atlantic [Chapman *et al.*, 1996]. If this also occurred at our study sites then the U_{37}^K glacial SSTs values may be reflecting preferentially NE monsoon SST during the LGM. This is in contrast to the present day situation in which the alkenones seem to record annual mean temperature. Possibly, such changes in monsoon strength were of lesser importance for the TEX₈₆ SST record as the seasonal abundance of Crenarchaeota is probably not so tied to upwelling dynamics and the relative GDGT flux increase during monsoon periods is lower than for the alkenones [Wuchter *et al.*, 2006]. Alternatively, the location of strong upwelling sites, such as those at NIOP905 and 74KL, may have shifted through changes in ocean circulation during the last 23 kyr and in this way have affected the dynamics of the organic proxies.

8.4.4 Phasing of SST records during Termination I

Comparison of the TEX₈₆ SST records with ice core records reflecting temperature from Antarctica (δD EPICA Dome C; Fig 4f) [Jouzel *et al.*, 2003] and Greenland ($\delta^{18}O$ GISP2; Fig 4a) [Dansgaard *et al.*, 1993] shows that the increase in TEX₈₆ SST from the LGM to the Early Holocene is in phase with the southern hemisphere warming, suggesting that this proxy is primarily forced by southern hemisphere climate (Fig. 4). The TEX₈₆ SST records also show a cooling during Termination I in phase with the Antarctic Cold Reversal, which has been noted exclusively in the southern hemisphere [Stenni *et al.*, 2001] (Fig. 4). The U_{37}^K SSTs at 74KL lag Antarctic records and resemble more the Arctic ice record (Fig. 4) while U_{37}^K SST record at NIOP905 does not show much variation at all and perhaps only slightly resembles the Antarctica record (Fig. 4).

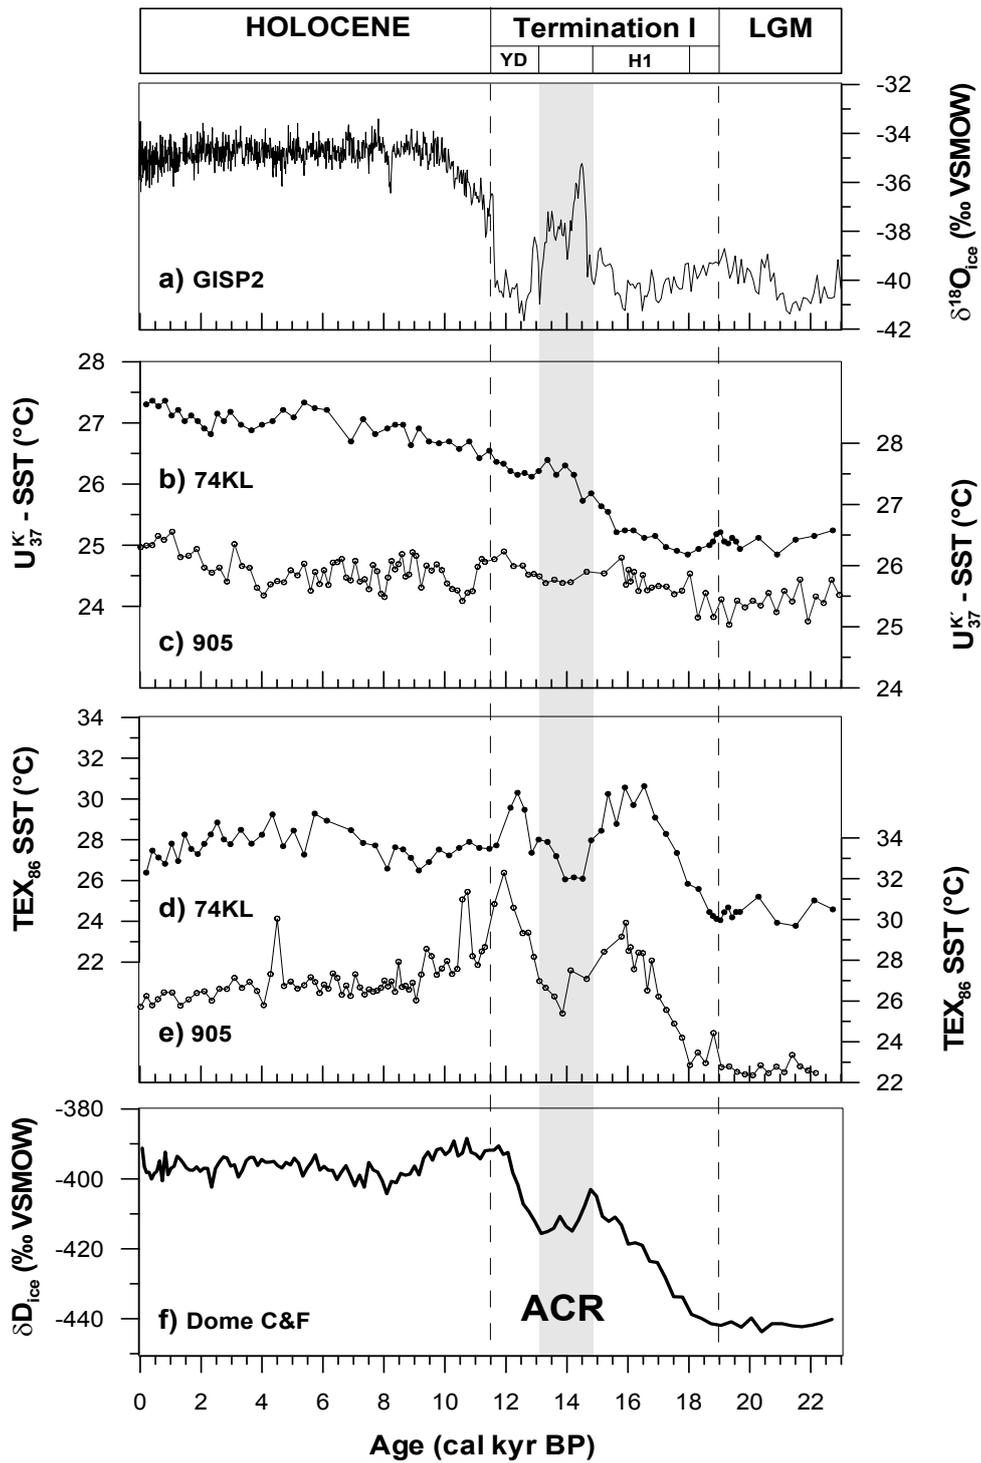

Figure 4. Comparison of SST records from the western Arabian Sea with ice core isotope records from Greenland and Antarctica. (a) GISP2 $\delta^{18}\text{O}$ record from Greenland [Dansgaard *et al.*, 1993], (b) U_{37}^K SST for 74KL, (c) U_{37}^K SST for NIOP 905, (d) TEX_{86} SST from 74KL, (e) TEX_{86} SST from NIOP 905, and (f) δD from Dome C in Antarctica [Jouzel *et al.* 2003].

In addition, the $U_{37}^{K'}$ SST record at 74KL shows a small drop in SST in phase with the Younger Dryas in the northern hemisphere. Previous studies in the Arabian Sea area show that the $U_{37}^{K'}$ records from the Oman and Pakistan Margins are also predominantly affected by northern hemisphere climate dynamics [Schulte and Müller, 2001; Dooze-Rolinski et al., 2001; Higginson et al., 2004]. The reason why the $U_{37}^{K'}$ SST record at NIOP905 is not reflecting northern hemisphere dynamics is unclear. It should be noted that the NIOP 905 $U_{37}^{K'}$ record is very different from other $U_{37}^{K'}$ records in the area [Sonzogni et al., 1998], suggesting that local features may have overwritten the global change in SST.

The question thus remains why we detect southern hemisphere dynamics with the TEX_{86} proxy, even at 74KL, and not with the $U_{37}^{K'}$ proxy. This may only be explained if the TEX_{86} proxy is more influenced by the SW monsoon, when the southern hemisphere dynamics dominate the area, even when this was substantially reduced during the LGM and Termination I. In contrast, the $U_{37}^{K'}$ may be more influenced by the NE monsoon during this time, as suggested previously [Higginson et al., 2004] and therefore records northern hemisphere climate. To the best of our knowledge SST records of tropical oceans have not revealed, until now, a dominant southern hemisphere component making it difficult to speculate what the mechanism behind the control on the TEX_{86} SST is.

8.4.5 Holocene SST reconstructions

Similar to the ice core records no large short-term changes in SST are observed during the Late Holocene in either the TEX_{86} and $U_{37}^{K'}$ SST records. However, both TEX_{86} and $U_{37}^{K'}$ values for NIOP905 and 74KL show relatively consistent opposing SST trends during the Holocene. While the TEX_{86} values show a slight decrease in SST from Termination I to present day values, the $U_{37}^{K'}$ record indicates a small increase in SST in this time period. Using artificial neural networks analysis of the distributions of planktic foraminifera, Naidu and Malmgren [2005] show a cooling trend in the Arabian Sea in the Holocene, which is more pronounced in boreal winter than in boreal summer. This cooling trend is also observed in the western Pacific, eastern Atlantic and western Mediterranean as well as in the Arabian Sea [Naidu and Malmgren, 2005, and references cited therein]. In contrast, $U_{37}^{K'}$ SST records

over the last 7 kyr have shown a general warming in the tropics [Kim *et al.*, 2004]. A data-model comparison study based on globally distributed U_{37}^K SST records and transient ensemble climate simulations suggests that the Holocene warming in the tropics is due to an orbitally-driven insolation increase during the boreal winter (December-January-February) in the low-latitudes [Lorenz *et al.*, 2006]. The apparent discrepancy between TEX_{86} SST records and U_{37}^K SST records is most likely caused by the fact that SST proxies are not consistently recording annual mean SST but seasonal SST.

8.5. Conclusions

U_{37}^K and TEX_{86} SST records from two sites in the Arabian Sea revealed different temperature variations over the last 23 kyr for each proxy. TEX_{86} SST records were similar at two sampling sites in the Arabian Sea over the last glacial-interglacial cycle and they are in phase with temperature changes recorded in Antarctica ice core records. This suggests that the TEX_{86} records of SST in the area are mainly controlled by the southern hemisphere climate dynamics during the SW monsoon. U_{37}^K SST records from the same cores are different in magnitude of change and differ also in phase, and are partly in phase with northern hemisphere climate dynamics during the NE monsoon. This is likely due to different growing seasons of the biomarker source organisms, and to a change in the upwelling dynamics and monsoon strengths between the LGM and the Holocene. Our results suggest that if the impact of seasonality on the different organic proxies can be better constrained, then complementary information on SST can be obtained by this multiproxy approach.

Acknowledgements

We would like to thank Martijn Woltering and Annemiek Vos van Avezaathe for analytical support, Lydie Herfort and Gert Jan Reichart for useful comments and Ellen Hopmans for assistance with the HPLC/MS, Tjeerd van Weering, Erica Koning and Geert Jan Brummer for providing access to the NIOP905 core and Frank Sirocko for the 74KL sediment samples. Andreas Lückge, Joe Werne and two anonymous reviewers are thanked for constructive comments on earlier drafts of this paper. This project was supported by NWO-ALW (Project nr. 152911) and by the EU project 6C (Contract no. EVK2-2001-00179-6C).

Abstract

In the Northern hemisphere, large-magnitude and rapid climate changes on millennial timescales (e.g., Dansgaard/Oeschger events and Heinrich events) characterized the last climate cycle, i.e. the past 130 ky. A recent study in the Alboran Sea (western Mediterranean, core ODP-977A) revealed that the sea surface temperature (SST) derived from the alkenone index ($U^{k'}_{37}$) also displays stadial-interstadial changes over the penultimate climate cycle, i.e. from 244 to 130 ky BP. To independently confirm these observations we applied the TEX_{86} proxy in the same core. The TEX_{86} temperature record shows similar stadial-interstadial patterns as those observed with the $U^{k'}_{37}$. However, the amplitude of the variations estimated by the two proxies are different during the penultimate glacial or marine isotope stage (MIS) 6 (190-130 cal. ky BP) compared to the preceding interglacial or MIS 7 (244-190 cal. ky BP). During MIS 7 there is a good correspondence in absolute temperature estimates between the two proxies. However during MIS 6 the TEX_{86} shows much larger temperature changes compared to the $U^{k'}_{37}$. We hypothesize that this may be caused by changes in the season in which the haptophytes and Crenarchaeota are blooming and/or variations in the depth habitat of Crenarchaeota. As the climate forcing differs between glacials and interglacials, a change in seasonal patterns and/or depth habitat can be expected when changing from the inter-glacial MIS 7 to glacial MIS 6, which would have a strong and differential effect on the TEX_{86} and $U^{k'}_{37}$ proxies. To fully understand the factor(s) causing the difference between the two proxies during MIS 6, further work is needed to establish the effects of seasonality and depth habitat on both proxies in the Alboran Sea.

9.1. Introduction

Northern hemisphere climate variations include some large and rapid climate changes on millennial timescales [i.e. Dansgaard/Oeschger (D/O) oscillations and the Heinrich events (HEs)] and longer term variations such as the glacial-interglacial changes described by the marine isotope stages (MISs). The MISs are alternating cold and warm periods in Earth's climate deduced from oxygen isotope data of benthic foraminifera and have time scales on the order of 100 ky [Martinson *et al.*, 1987]. The D/O events are rapid temperature changes (<1 ky) inferred from ice cores [Dansgaard *et al.*, 1993; Grootes and Stuiver, 1997] and the HEs are associated with catastrophic iceberg discharges and southern migrations of the Arctic front and their effects in marine sediment records [Heinrich, 1988]. These events took place during the last climate cycle, but similar rapid changes have also been found in older periods [McManus *et al.*, 1999; Martrat *et al.*, 2004].

The impact of the millennial scale northern hemisphere climate variability in the Alboran Sea, western Mediterranean has been extensively documented [e.g. Cacho *et al.*, 1999; Cacho *et al.*, 2000; Cacho *et al.*, 2001; Moreno *et al.*, 2004; Martrat *et al.*, 2004] (Fig. 1). This latitudinal teleconnection is thought to be controlled by both cold Atlantic waters and wind patterns inducing rapid changes in the Mediterranean thermohaline circulation, and seem to be independent from direct iceberg discharges [Cacho *et al.*, 1999; Moreno *et al.*, 2004] (Fig. 1b). Past changes in the thermohaline circulation could be caused by the extension of polar waters reaching a more southern position than previously thought leading to an influx of polar water through the Gibraltar Strait [Cacho *et al.*, 1999]. High frequency changes in the westerly wind patterns could account for the variability in deep-water ventilation in the western Mediterranean [Moreno *et al.*, 2004].

Previous studies in the Alboran sea showed a good correspondence between sea surface temperature (SST) proxy data and northern hemisphere climatic changes reconstructed from the GISP 2 ice-core, revealing that SST changes are related to both glacial-interglacial transitions and D/O or HE events [Cacho *et al.*, 2000; Cacho *et al.*, 2002]. However, little is known from the penultimate glacial as the deepest sections of the Greenland ice cores that cover the penultimate glacial are distorted by basal deformation [Grootes and Stuiver, 1997]. To provide a better understanding of the millennial scale variation over the penultimate glacial, Martrat *et al.* [2004] constructed a high-resolution alkenone SST record from a core

in the Alboran Sea spanning the past 250 ky. This record indicated that during MIS 6 there were SST changes reflecting stadial-interstadial patterns but of lower magnitude than those of MIS 3 and that the most prominent events occurred during MIS 7. They also reported abrupt SST changes which were referred to warming or cooling episodes that happened at a rate equal to or faster than the SST variation over the last deglaciation (i.e., an average warming of 2.6°C/ky in core ODP-977A) [Martrat *et al.*, 2004]. However, confirmation of these trends using other temperature proxies was lacking.

We applied another molecular SST proxy to provide an independent record to the previously reported SST U_{37}^k one. We used the TEX₈₆ proxy, which is based on the relative distribution of glycerol dibiphytanyl glycerol tetraethers (GDGTs; Schouten *et al.* [2002]) as it has provided complementary information to the U_{37}^k in previous studies [e.g. Huguet *et al.* 2006]. The TEX₈₆ record in this study was obtained from the same sediment samples as those used to construct the U_{37}^k record [Martrat *et al.*, 2004].

9.2. Material and Methods

9.2.1. Study area

The Alboran Sea (western Mediterranean) is a transition area between the Atlantic and the Mediterranean and, therefore, any changes in either the Atlantic or Mediterranean will be reflected in the water column structure, temperature gradient and nutrient distribution. The Alboran Sea is also influenced by the surrounding land masses through fluvial and aeolian inputs coming from North Africa and the southern Iberian peninsula, although the riverine input is low and irregular [Fabres *et al.*, 2002]. Strong winds result in wind-driven upwelling resulting in high surface production [Garcia-Gorriz and Carr, 1999]. There is a stable gyre structure composed of a western Alboran gyre (WAG) and the eastern Alboran gyre (EAG) (Fig. 1a). The area presents a complex water column structure with deep Mediterranean and surface Atlantic water masses (Fig. 1b). The water column in the Alboran sea has a surface layer of inflowing Atlantic sea water (0-300m), an intermediate layer formed by out-flowing Levantine intermediate water (LAW) (300-600m) which is formed in eastern Mediterranean and a deep water mass (>600m) consisting of western Mediterranean deep water (WMDW) [Fabres *et al.*, 2002].

The area is also characterised by local turbulence caused by the water exchange and coastal upwelling caused by the gyres which result in very high primary productivity of up to $200 \text{ g C}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$ [Fabres *et al.*, 2002]. The highest primary productivity takes place in coastal areas and at the periphery of the WAG [Garcia-Gorriz and Carr, 1999]. At present, SST in the area ranges between 14°C in February and 25°C in August with a phytoplankton bloom period from November to March and lowest primary production from May to September [Garcia-Gorriz and Carr, 1999].

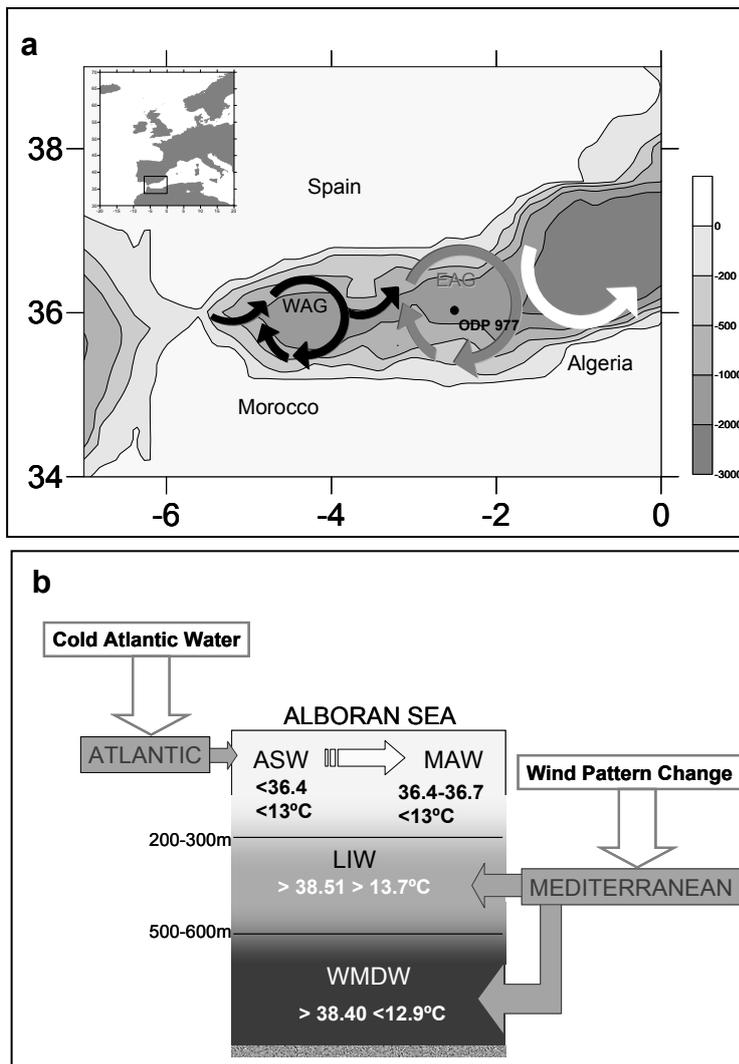

Figure 1. a) Map of the study area showing the core location and the two stable gyres in the area, the Western Alboran gyre (WAG) and the Eastern Alboran gyre (EAG); **b)** Water column structure with the different water masses, Atlantic surface water (ASW), Modified Atlantic water (MAW), Levantine intermediate water (LIW) and western Mediterranean deep water (WMDW), average temperatures and salinities are indicated (adapted from [Fabres *et al.*, 2002]).

9.2.2. Sampling strategy

Core ODP-977A (36°1.907'N, 1°57.3198W') was retrieved from the eastern sub-basin of the Alboran sea during leg 161 of the Ocean Drilling Program in 1996 [Comas *et al.*, 1996] (Fig. 1a). In the previous study by Martrat *et al.* [2004], the analysis of the 40m spanning ODP-977A core permitted the high-resolution reconstruction of the climatic history along the past 250 ky, using stable isotopes (n=794 samples) and sea surface temperature derived from the alkenone index (n=655 samples) with an average time resolution of 386±131 years. In this study, covering MISs 6 and 7, the average temporal resolution remains comparable at centennial scale throughout the whole period studied (244-145 cal. ky BP; n=199 samples). The age model of the investigated interval of the core was constructed by comparing the $\delta^{18}\text{O}$ profile of *G. bulloides* with thirteen defined orbital tuned isotopic events assuming constant sedimentation rates between control points (see Martrat *et al.*, [2004] for details).

9.2.3. GDGT analysis

Freeze-dried sediment samples were extracted using an Accelerated Solvent Extractor 200 (ASE 200, DIONEX) with a mixture of dichloromethane (DCM) and methanol (MeOH) (9:1; vol:vol) at 100°C and $7.6 \cdot 10^6$ Pa. An aliquot of each total extract was divided into a ketone and a polar fraction, using a glass pipette column filled with activated alumina, and sequentially eluting with hexane/DCM (1:1; vol:vol) and DCM/MeOH (1:1; vol:vol), respectively.

The polar fraction was analyzed for GDGTs according to the procedure described by [Hopmans *et al.*, 2000] and [Schouten *et al.* 2007]. Analyses were performed in triplicate with an HP 1100 Series Liquid Chromatography-Mass Spectrometer (LC-MS) equipped with an auto-injector and ChemStation chromatography manager software. Separation was achieved on a Prevail Cyano column (2.1 x 150mm, 3 μm ; Alltech, Deerfield, Illinois, USA), maintained at 30°C. GDGTs were eluted isocratically first with hexane/isopropanol (99:1 % ;vol:vol) for 5 min, then using a linear gradient up to 1.8 % vol of isopropanol over 45 min. Flow rate was 0.2 mL/min. After each analysis the column was cleaned by back flushing hexane/isopropanol (90:10; vol:vol) at 0.2 mL/min for 10 min. Detection was achieved using atmospheric pressure chemical ionization-mass spectrometry (APCI-MS) of the eluent with the following conditions; nebulizer pressure 60 psi, vaporizer temperature 400°C, N₂ drying gas flow 6 L/min at 200°C, capillary voltage -3kV, corona 5 μA (~3.2kV). Single Ion

Monitoring (SIM) was used instead of full mass scanning because SIM increases the signal-to-noise-ratio and thus improves reproducibility [Schouten *et al.* 2007]. SIM was set to scan the five $[M+H]^+$ ions of the GDGTs and the three $[M+H]^+$ ions of the branched tetraethers with a dwell time of 237 ms for each ion. The TEX₈₆ ratio was calculated according to Schouten *et al.* [2002]. The TEX₈₆ values relate to temperature according to the following empirical relationship [Schouten *et al.*, 2002]:

$$\text{TEX}_{86} = 0.015 \cdot T + 0.28 \quad [1]$$

The BIT index was calculated according to Hopmans *et al.* [2004]. Samples were run in triplicate and the average standard deviation for TEX₈₆ was 0.004 or 0.3 °C, whilst the average standard deviation for BIT index was 0.01.

9.3. Results

The TEX₈₆ ranged between 0.36 and 0.65 or 5.5 and 24.8°C when translated to temperature using the temperature calibration of Schouten *et al.* [2002] (Fig. 2a). The average TEX₈₆ value was lower in the glacial MIS 6 (14.4°C) than during the interglacial MIS 7 (18.2°C). TEX₈₆-derived temperatures in MIS 6 show great variability and corresponded well with known cold events (stadials, vertical numbers in Fig. 2c) and warm events (interstadials; horizontal number in Fig. 2c) previously reported for this core by Martrat *et al.* [2004]. During MIS 7 temperatures were more stable with only six stadials and interstadials. Most of the changes in TEX₈₆ temperatures were synchronous with the ones previously reported using the U^k₃₇ palaeothermometer [Martrat *et al.*, 2004] (Figs. 2a and c).

We also measured the BIT index which is a relative ratio of marine-derived crenarchaeol versus terrestrially-derived branched tetraether lipids [Hopmans *et al.*, 2004] and it is used to estimate riverine input of terrestrial organic matter. The BIT values ranged between 0.01 and 0.17 indicating only a small input of riverine terrestrial organic matter [cf. [Hopmans *et al.*, 2004; Weijers *et al.*, 2006]], consistent with the absence of a large river system in the area. The average BIT values were nearly identical for MIS 6 (0.05) and MIS 7 (0.06). There were six peaks in BIT record of up to 0.15 during MIS 6 (149.9, 153.6, 166.7, 176.6, 181.4 and 184.5 cal. ky BP) (Fig. 2b).

During MIS 7 a small increase of this index is observed between 191 and 194 cal. ky BP and 223 and 230 cal. ky BP with a smaller peak at 238 cal. ky BP.

9.4. Discussion

The Alboran Sea area is strongly influenced by the surrounding land masses [Fabres *et al.*, 2002] and, thus, large amounts of terrestrial organic matter may be present in the sediment which can compromise the TEX₈₆ temperature estimates [Weijers *et al.*, 2006]. However, BIT values are always low (<0.2) and there is no correlation between TEX₈₆ and BIT index (Fig. 3a). This is in agreement with the idea that BIT is reflecting fluvial input which is known to be relatively small in the Alboran Sea [Fabres *et al.*, 2002]. Therefore, the TEX₈₆ record can be interpreted with confidence as reflecting a marine temperature signal.

The trends in TEX₈₆ temperatures are consistent with both the $\delta^{18}\text{O}$ record of planktonic foraminifera *G. bulloides* and $\text{U}^{\text{k}'}_{37}$ temperatures (Figs. 2c-e), suggesting that the TEX₈₆ proxy reflects temperature changes in the Alboran Sea. The changes in temperatures are nearly always synchronous between TEX₈₆, $\text{U}^{\text{k}'}_{37}$ and $\delta^{18}\text{O}$ suggesting no temporal offset due to dissimilar sedimentation processes between archaea, coccolithophores and foraminifera in agreement with previous observations in the Alboran Sea [Martrat *et al.*, 2004] but in contrast to results from radiocarbon studies in other areas [e.g. Ohkouchi *et al.*, 2002; Mollenhauer *et al.*, 2005]. But most importantly, the TEX₈₆ record confirms the presence of stadial-interstadial episodes during MIS 6 and MIS 7 and also corroborates that these periods were less stable than previously thought.

However, while the patterns in temperature change are the same, the absolute temperature ranges are different for the two molecular proxies. The TEX₈₆ varies over a 15°C range, which is considerably larger than the 11.5°C range of the $\text{U}^{\text{k}'}_{37}$. While TEX₈₆-derived temperatures are similar to those derived with the $\text{U}^{\text{k}'}_{37}$ during MIS 7 they show a much wider range during MIS 6, i.e. during MIS 6 TEX₈₆ temperatures are higher than $\text{U}^{\text{k}'}_{37}$ temperatures during interstadials and lower during stadials (Figs. 2 and 3).

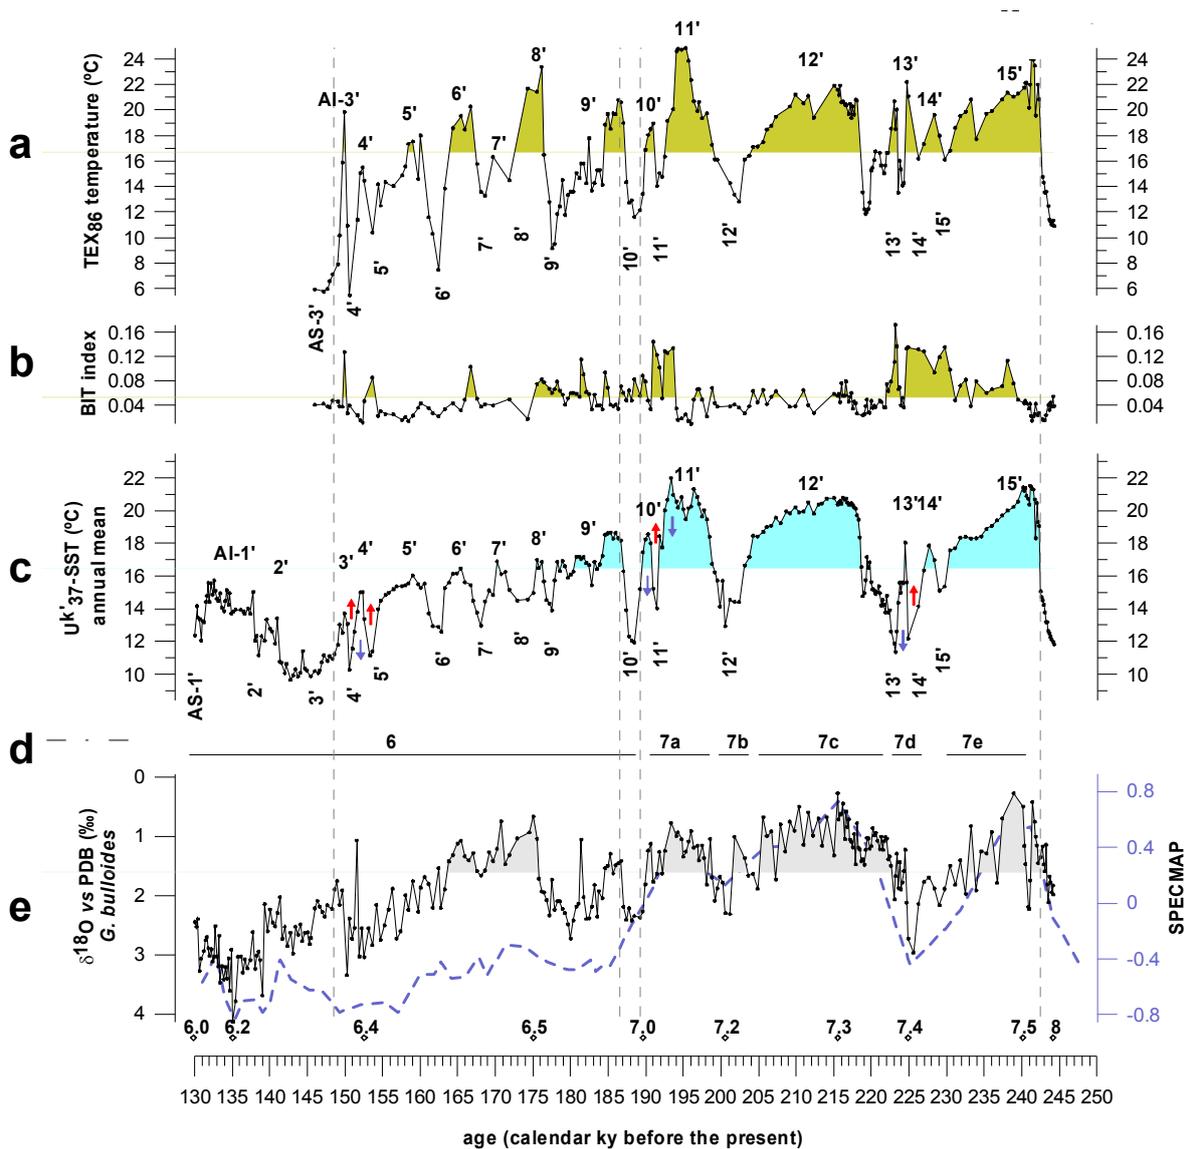

Figure. 2. Palaeoenvironmental records over MIS 6 and MIS 7 in ODP-977A: **a)** TEX₈₆ temperature record **b)** BIT index record, **c)** U^k₃₇-SST record. This record show fifteen warm (AI-1' to 15') and fifteen cold (AS-1' to 15') spells and abrupt changes were defined as warming (red arrows) or cooling (blue arrows) episodes that happened at rate equal to or faster than the SST variation over the last deglaciation [(2.6°C/ky) [Martrat et al., 2004].; **d)** Glacial (6) and interglacial (7) marine isotope stages (MISs); **e)** δ¹⁸O of *Globigerina bulloides* [Martrat et al., 2004] compared with the SPECMAP standard isotope curve, which is shown by the dotted line [Martinson et al., 1987]. Diamonds show some of the control points used for the age model. Values above average are indicated by the filled areas.

This phenomenon can be best illustrated by cross correlating the TEX_{86} record with the $U^{k'}_{37}$ record for MIS 6 and MIS 7 separately (Figs. 3b-d). The degree of correlation between $U^{k'}_{37}$ and TEX_{86} is similar during the interglacial ($r^2=0.56$) and the glacial period ($r^2=0.52$) but the slope of the correlation differs substantially, 0.89 for MIS 7 and 1.35 during MIS 6 (Fig. 3). Thus, a change of 1°C in the $U^{k'}_{37}$ record is reflected as a $\sim 1.4^\circ\text{C}$ change in the TEX_{86} temperature record in MIS 6 and a $\sim 0.9^\circ\text{C}$ change during MIS 7.

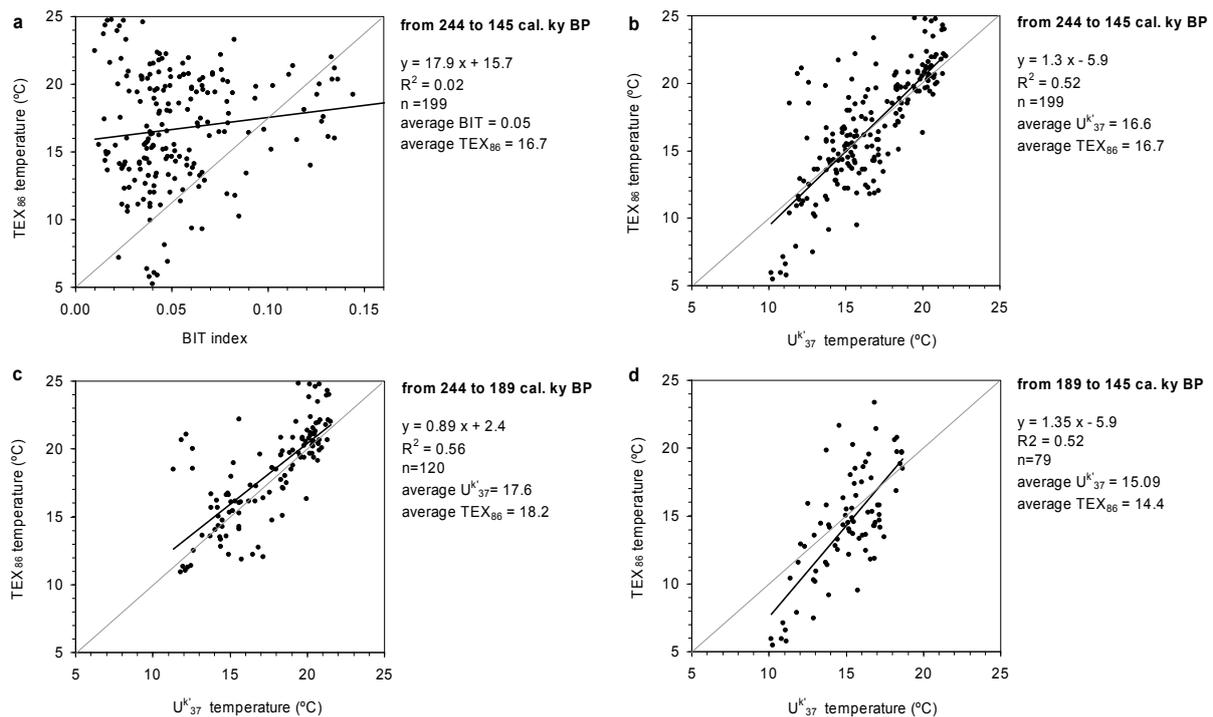

Figure 3. **a)** Correlation between TEX_{86} temperatures and the BIT index for the whole period studied (244-145 cal. ky BP) and correlations between $U^{k'}_{37}$ and TEX_{86} temperatures for different time spans: **b)** from 244 to 145 cal. ky BP; **c)** from 244 to 189 cal. ky BP (MIS 7); **d)** from 189 to 145 cal. ky BP (most of MIS 6). Fitted linear equations, the R^2 values, number of data points used (n) and average values are indicated. The 1:1 correlation is indicated by the grey line.

The remarkable agreement between TEX_{86} and $U^{k'}_{37}$ temperatures during MIS 7 suggests that the organisms producing the lipids on which these proxies are based are reflecting temperatures of the same season and similar depth (<100m). In the Alboran Sea two main regimes occur; the fall to winter bloom (November-March) and the non-bloom period (May to September) [Garcia-Gorriz and Carr, 1999]. Thus, it seems likely that haptophytes would be growing mainly in fall-winter in the study area and thus, presently, $U^{k'}_{37}$ may preferentially record winter temperatures in the area. Present temperatures in the bloom period (November-March) are on average 16-17°C [Garcia-Gorriz and Carr, 1999] which is similar to the average $U^{k'}_{37}$ values for the interglacial MIS 7 of 17.6°C. The similar average TEX_{86} temperature for MIS 7 (18.2°C) suggests that Crenarchaeota also may have thrived in fall-winter. Unfortunately, it is not known what the seasonal abundance of Crenarchaeota is in the Alboran Sea and this hypothesis cannot be tested at present.

During MIS 6, TEX_{86} and $U^{k'}_{37}$ behave differently with TEX_{86} temperatures being higher than $U^{k'}_{37}$ temperatures during interstadials and lower during stadials. There may be two reasons for this differential response of the TEX_{86} and $U^{k'}_{37}$: seasonality and/or depths habitats. Possibly, the Crenarchaeota shifted to a different season, i.e. from fall-winter during MIS 7 to spring-summer during MIS 6. However, this difference in seasonality can only explain why TEX_{86} during interstadials shows higher SSTs than $U^{k'}_{37}$ (Fig. 3b). It does not explain why in stadials TEX_{86} -reconstructed SSTs are substantially lower than those based on the $U^{k'}_{37}$ unless during stadials Crenarchaeota and haptophytes are blooming in opposite seasons, i.e. fall-winter for Crenarchaeota and spring-summer for haptophyte algae.

Alternatively, the TEX_{86} proxy signal could be derived from a different depth than the $U^{k'}_{37}$ during MIS 6 in contrast to what seems to be the case for MIS 7. As haptophytes are light dependent they are constrained to surface waters (<100 m). Indeed, the maximum abundances of alkenones range from 30-100m in the western Mediterranean [Terrois *et al.*, 1997; Sicre *et al.*, 1999; Bentaleb *et al.*, 1999]. However, as Crenarchaeota are chemoautotrophs, they are not light dependent and can thrive deeper in the water column as has been shown in numerous studies [e.g. Massana *et al.*, 1998; Murray *et al.*, 1999; Karner *et al.*, 2001; Herndl. *et al.*, 2005]. However, previous studies have shown that the TEX_{86} correlates well with surface water temperatures (depths <100m) and that the signal in the deeper water layers and sediments is primarily derived from these surface waters [Wuchter *et*

al., 2005; *Huguet et al.* 2006], which also seems to be the case for the interglacial MIS 7. However, recent evidence suggests that sometimes TEX_{86} reflects subsurface temperatures rather than SST [*Huguet et al.* 2007, in press]. Currently, there is not a strong temperature gradient in the water column (Fig. 1b) [*Fabres et al.*, 2002] and thus the difference in depth habitat between haptophytes and Crenarchaeota would have a fairly small effect ($<1^{\circ}\text{C}$), which could also explain the good correspondence between TEX_{86} and $U^{k'}_{37}$ during MIS 7. However, during glacial MIS 6 there could have been a much larger temperature gradient with depth. Indeed, a multiproxy study in the Alboran Sea revealed that the Atlantic-Mediterranean temperature gradient was larger during glacial periods ($\sim 4^{\circ}\text{C}$) than during the Holocene ($1-2^{\circ}\text{C}$) [*Cacho et al.*, 2001], suggesting a steeper temperature gradient between Atlantic and Mediterranean water masses during cold periods. This is supported by other studies in the area that indicated a change in the ventilation of the Alboran sea during glacial stages which will have resulted in change of the water column structure and temperature gradient and the occurrence of colder, more oxygenated deep water masses during stadials [*Cacho et al.*, 2002; *Moreno et al.*, 2004]. Therefore, at times of abrupt climate change and likely nutrient reorganisation and stratification [*Moreno et al.*, 2004], Crenarchaeota could be moving to deeper, colder waters such as the LIW or WMDW (Fig. 1b) and thus reflect colder water temperatures than the $U^{k'}_{37}$, especially during the glacial MIS 6. However, while this may explain the colder TEX_{86} values during stadials it does not explain the warmer values during interstadials. Thus, at present, no single hypothesis can fully explain the difference observed between $U^{k'}_{37}$ and TEX_{86} during MIS 6 but a combination of both seasonality and depth changes could explain both the higher and lower TEX_{86} values during stadial and interstadial episodes, respectively. To fully understand our results further work in the Alboran Sea is necessary to establish both the seasonality and depth distribution of Crenarchaeota and haptophyte algae, especially during glacial periods.

9.5. Conclusions

The TEX₈₆ record of the Alboran Sea shows very similar trends to the U^k₃₇ and confirms the previously inferred stadial and interstadial episodes detected with the U^k₃₇. The absolute temperature estimates of TEX₈₆ and U^k₃₇ agree well during MIS 7 but there is substantial difference between the two proxies in temperature range during MIS 6 with TEX₈₆ showing more extreme temperature variations compared to the U^k₃₇. We propose two hypotheses to explain the differences between the two proxies during MIS 6 i.e. a change in the growth season or depth distribution of the Crenarchaeota. A shift of Crenarchaeota seasonality towards summer could explain the warmer TEX₈₆ interstadial temperatures. During stadials Crenarchaeota could be moving deeper in the water column while haptophytes would remain in the surface water. A combination of these two processes could potentially explain both the higher and lower TEX₈₆ values during stadial and interstadials during MIS 6. However a better constrain of the seasonality and depth distribution of Crenarchaeota and haptophyte algae is needed to resolve that issue.

Summary

Determination of past sea surface temperature (SST) is of primary importance for the reconstruction of natural climatic changes, modelling of climate and reconstruction of ocean circulation. A number of geochemical proxies for SST reconstruction are currently used but their application are associated with several uncertainties and thus there is a need for new SST proxies to complement presently used proxies. Recently, a new SST proxy was introduced, the TetraEther index of lipids with 86 carbons (TEX₈₆), which is based on temperature-related changes that occur in the composition of creanarchaeotal membrane lipids. The membranes of Crenarchaeota are composed of glycerol dibiphytanyl glycerol tetraethers (GDGTs) and changes in the relative abundance of these lipids allow them to adjust their membrane fluidity as a response to fluctuations in water temperature. An empirical correlation between TEX₈₆ values of sediment core tops from a wide variety of geographical locations and annual mean SST has been used to calibrate the TEX₈₆ proxy. The main objective of the work described in this thesis was to improve, validate and apply the TEX₈₆ proxy. To do this we focused on a) the analytical aspects of the TEX₈₆, b) the transport of GDGTs to the sediment and the influence of diagenesis and c) the application of the proxy in various settings.

Regarding the analytical aspects, a comparison of different extraction techniques revealed no significant differences in TEX₈₆ values. Comparison of TEX₈₆ analysis using different mass spectrometry techniques, i.e. Single Ion Mode (SIM) and mass scanning detection, showed that SIM is up to two orders of magnitude more sensitive. The detection limit of the GDGTs was also established and shown to be 0.05 ng GDGTs injected on-column. Application of SIM improved the analytical reproducibility to 0.3°C. Thus, the TEX₈₆ can now be measured with a much better accuracy than was previously possible. A new synthetic internal GDGT standard was used which greatly improved the accuracy of GDGT abundance measurements. With this method the standard deviation in the determination of the abundance was only 5% compared to 43% when using an external standard. This increases the potential of GDGTs in (paleo)ecological studies substantially.

The transport and diagenesis of GDGTs were also subject of study as they are essential in understanding and applying the TEX₈₆ as palaeothermometer.

Summary

Although several studies have established that Crenarchaeota are distributed throughout the water column, previous studies have shown that TEX₈₆ values of particulate organic matter, sediment traps and sediment core tops are better correlated with SST (depth <100 m) than with deeper water temperatures. However, Crenarchaeotal cells do not have sufficient density to sink to the sediment after cell death and this would prevent the TEX₈₆ signal from reaching the sediment surface. To investigate this, GDGTs were analysed in stomachs and intestines of crustacean decapods, which are key element of most pelagic food webs. This study revealed the presence of GDGTs in both stomachs and, in lower amounts, in the intestines showing uptake of GDGTs by decapods. This, together with pigment analysis, suggests that both passive (by sinking particles) and active (by organism migration) transport mechanism can explain, at least in part, the transport of GDGTs from surface waters to the sediment. GDGT abundances are significantly lower in intestines, but TEX₈₆-derived temperatures are not significantly different between stomachs and intestines (<1°C), suggesting that TEX₈₆ values are not altered during gut transit. In contrast to these results, a study using sediment traps and a sediment core covering the last 150 years in the Santa Barbara Basin revealed that TEX₈₆ values were always substantially lower than sea surface temperatures (SST), indicating a sub-surface origin, likely between 100-150 m. This could be related to the depth origin of the TEX₈₆ signal and be ultimately controlled by the phytoplankton surface community and water column dynamics. This result highlights the importance of performing calibration studies using sediment traps and core tops before applying the TEX₈₆ temperature proxy in a given study area.

To investigate the effect of degradation by long term exposure to oxygen we analyzed GDGTs abundance, TEX₈₆ and Branched versus Isoprenoid Tetraether index (BIT) in several Madeira Abyssal Plain turbidites across an oxidation front. A decrease by several orders of magnitude in the concentrations of GDGTs was found and also substantial shifts in the BIT and TEX₈₆. The shifts are interpreted to be caused by a strong relative increase in soil-derived GDGTs relative to the marine-derived GDGTs. This selective preservation of soil-derived lipids which are chemically nearly identical to that of their marine counterpart strongly suggests that the mineral matrix to which soil organic matter is attached enhanced its preservation. This indicates that care has to be taken when analyzing TEX₈₆ in sediments which have been exposed to oxygen for a long time.

Finally the application of the TEX₈₆ to a range of environments and time resolutions in combination with other SST proxies allowed the validation of the TEX₈₆ proxy as a paleothermometer. Analysis of two cores in the Drammensfjord, Norway, with a centennial time scale at an almost annual resolution, suggested that TEX₈₆ recorded surface (upper 25m) temperatures. Moreover, TEX₈₆ temperature patterns followed variations in the historical record of averaged spring to fall Oslo air temperature relatively closely, suggesting the signal is produced during this period. Therefore, TEX₈₆ temperature records of fjord sediment cores can potentially be a useful tool in reconstructing past variations of coastal climates. We also compared the TEX₈₆ and U₃₇^{K'} index derived from long-chain alkenones from haptophyte algae during the last glacial-interglacial transition in two cores in the Arabian Sea. TEX₈₆ SST records were similar at the two sites over the last glacial-interglacial cycle and were in phase with temperature changes recorded in Antarctica ice core records. This suggests that the TEX₈₆ records of SST in the area are mainly controlled by the southern hemisphere climate dynamics during the SW monsoon. U₃₇^{K'} SST records from the same cores are different in magnitude of change and differ also in phase, and are partly in phase with northern hemisphere climate dynamics during the NE monsoon. This is likely due to different growing seasons of the biomarker source organisms, and to a change in the upwelling dynamics and monsoon strengths between the LGM and the Holocene.

In the oldest sediments analysed, TEX₈₆ was applied to a sediment core spanning the Marine Isotope Stadials (MIS) 6 and 7 in the Western Mediterranean. A recent study in the Alboran Sea (Western Mediterranean, core ODP-977A) revealed that alkenone records not only show temperature trends similar to $\delta^{18}\text{O}$ records of *G. bulloides*, but also stadial-interstadial temperature changes during the penultimate climate cycle (from 244 to 130 cal. ky BP). To independently confirm these abrupt changes, we applied the TEX₈₆ proxy to reconstruct SST using the same sediment core. The TEX₈₆ indicated similar stadial-interstadial temperature changes as detected with the U₃₇^{K'}, thus providing independent evidence for rapid temperature changes. However, the two proxies behaved differently during glacial marine isotopic stage (MIS-6) and interglacial MIS-7. During MIS-7 there is good correspondence in absolute SST estimates between the two proxies, but in MIS-6 the TEX₈₆ showed much larger temperature changes compared to the U₃₇^{K'}. We hypothesize that this may

Summary

be caused by changes in the season in which the haptophytes and Crenarchaeota are blooming and/or variations in the depth habitat of Crenarchaeota. As the climate forcing differs between glacials and interglacials, a change in seasonal patterns and/or depth habitat can be expected which could have a strong and differential effect on the TEX₈₆ and U^k₃₇ proxies.

In summary, the results described in this thesis resulted in a substantial improvement of the analytical aspects of TEX₈₆, resulting in a better reproducibility in measuring this proxy. The origin and transport of the GDGT signal was also studied and shown to be mediated by both passive and active transport mechanisms. This work also provided essential information about constraints and pitfalls of the proxy such as its varying depth origin and the effects of long-term oxic degradation. Finally, the proxy was validated through core measurements and comparison with other proxies. This thesis shows that TEX₈₆ is a useful SST proxy which can provide complementary information to other SST proxies.

Samenvatting

Het bepalen van vroegere oppervlakte zeewatertemperaturen (OZT) is van groot belang voor de reconstructie van natuurlijke klimaatveranderingen en de oceaancirculatie in het verleden. Deze informatie is op haar beurt weer van belang om klimaatmodellen, die onder andere gebruikt worden om het toekomstige klimaat te voorspellen, te testen. Een aantal geochemische proxies voor de reconstructie van OZT zijn op dit moment beschikbaar maar aan hun toepassing kleeft een aantal onzekerheden. Nieuwe proxies voor OZT zijn dus noodzakelijk om de momenteel beschikbare proxies te complementeren. Recentelijk is een nieuwe OZT proxy geïntroduceerd; de TetraEther indeX van lipiden met 86 koolstofatomen (TEX₈₆), gebaseerd op temperatuurgerelateerde veranderingen in de samenstelling van membraanlipiden van pelagische Crenarchaeota, een groep micro-organismen die binnen het domein van de archaea vallen. De membranen van Crenarchaeota zijn samengesteld uit glycerol dibiphytanyl glycerol tetraethers (GDGTs) en veranderingen in de relatieve hoeveelheden van deze lipiden maken het mogelijk de membraanfluiditeit aan te passen aan veranderingen in watertemperatuur. Een empirische correlatie tussen TEX₈₆ in oppervlakesedimenten van geografisch verschillende herkomst en OZT is gebruikt voor de calibratie van deze proxy. Het belangrijkste doel van het werk beschreven in dit proefschrift was het verbeteren, valideren en toepassen van de TEX₈₆ proxy. Daartoe werden 1) analytische aspecten van de TEX₈₆, 2) het transport van GDGTs naar het sediment en de invloed van diagenese en 3) de toepassing van de proxy in verschillende milieus bestudeerd.

Betreffende de analytische aspecten liet een vergelijking tussen verschillende extractietechnieken zien dat er geen significante verschillen in TEX₈₆ zijn. Vergelijking van verschillende massaspectrometrische detectietechnieken [Single Ion Monitoring (SIM) en detectie door middel van massa scanning], liet zien dat de SIM methode tot twee ordes van grootte gevoeliger is. De detectielimiet van de GDGT analyse werd bepaald op 5 pg GDGTs on-column geïnjecteerd. Toepassing van de SIM methode verbeterde ook de analytische reproduceerbaarheid van de TEX₈₆ tot 0.3°C, een aanzienlijke verbetering ten opzichte van de eerder toegepaste methode. Het gebruik van een nieuwe synthetische GDGT interne standaard verbeterde de kwantificering van GDGTs aanzienlijk:

met deze methode was de standaarddeviatie slechts 5% terwijl bij gebruik van een bepaling met een externe standaard een standaarddeviatie van 43% werd behaald. Deze verbetering maakt het potentiële gebruik van GDGTs in (paleo)ecologische studies veel groter.

Ook het transport van GDGTs van de waterkolom naar het sediment en mogelijke effecten van diagenese in het sediment werden onderzocht, omdat een goed begrip van deze processen essentieel is voor een correcte toepassing van de TEX₈₆ palaeothermometer. Hoewel verschillende studies hebben laten zien dat Crenarchaeota voorkomen in de gehele waterkolom, heeft ander onderzoek aangetoond dat de TEX₈₆ van gesuspendeerd organisch materiaal, sedimentvallen en oppervlaktesedimenten beter correleren met OZT (diepte <100m) dan met de temperatuur van het diepere water. De kleine cellen van Crenarchaeota hebben echter niet een voldoende hoge dichtheid om na de celdood te bezinken naar het sediment waardoor het TEX₈₆ signaal de zeebodem niet zou kunnen bereiken. Om dit nader te bestuderen werden GDGTs geanalyseerd in de maag en darmen van decapoda (tienpotigen), die een sleutelrol vervullen in de pelagische voedselketen. Deze studie liet zien dat GDGTs aanwezig zijn in zowel de maag als in de darmen, zij het in lagere hoeveelheden. Dit toonde aan dat GDGTs opgenomen worden door kreeftachtigen. Samen met pigmentanalyse suggereerde dit dat zowel passief (via zinkende deeltjes) als actief (via migratie van organismen) transport kan verklaren waarom GDGTs uit oppervlaktewater preferent getransporteerd worden naar het sediment. Hoewel de GDGT concentraties significant lager zijn in de darmen, waren de TEX₈₆-waarden niet significant verschillend tussen de maag en darmen. Dit suggereerde dat de TEX₈₆ niet veranderde tijdens degradatie in de maag.

Een studie van sedimentvallen en een sedimentkern afgezet in de laatste 150 jaar in het Santa Barbara Basin liet zien dat de berekende TEX₈₆ temperaturen altijd substantieel lager waren dan de gemeten OZT, en meer overeenkwamen met de temperatuur van diepere wateren, rond de 100-150 m. Dit komt waarschijnlijk door een diepere oorsprong van het TEX₈₆ signaal die ook nog eens variabel is door de dynamiek van de waterkolom. Dit resultaat onderstreept het belang van het verrichten van calibratiestudies door middel van sedimentvallen en oppervlaktesedimenten voordat de TEX₈₆ proxy toegepast kan worden in palaeoklimaatreconstructies.

Om het effect van degradatie door lange-termijn blootstelling aan zuurstof vast te stellen werden GDGT concentraties, de TEX₈₆ en de Branched versus Isoprenoid Tetraether

index (BIT) geanalyseerd in een aantal Madeira Abyssal Plain turbidieten over een oxidatiefront. GDGT concentraties waren ordes van grootte lager in de geoxideerde turbidietlagen. Er werden ook substantiële veranderingen gevonden in de BIT and TEX₈₆. Deze veranderingen worden veroorzaakt door een relatieve toename van GDGTs afkomstig uit bodems ten opzichte van GDGTs afkomstig uit het mariene milieu. Deze selectieve preservatie van lipiden afkomstig van bodems en die chemisch gezien vrijwel identiek zijn aan die afkomstig uit het mariene milieu suggereerde dat de minerale matrix waarmee het organische bodemmateriaal geassocieerd is de conserveringskansen sterk doet toenemen. Dit geeft ook aan dat men voorzichtig moet zijn met de analyses van TEX₈₆ in sedimenten die langdurig zijn blootgesteld aan zuurstof.

Tenslotte werd de TEX₈₆ toegepast in verschillende milieus en met verschillende tijdsresolutie in combinatie met andere OZT proxies om de TEX₈₆ proxy verder te valideren als paleothermometer. De analyse van twee kernen uit Drammensfjord, Noorwegen, afgezet in de laatste eeuw en bemonsterd met een jaarlijkse tijdsresolutie suggereerde dat de TEX₈₆ de OZT (< 25 m) weergaf. Bovendien co-varieerden de TEX₈₆ temperatuurvariaties met de historische variaties in de gemiddelde lente-herfst luchttemperatuur in Oslo. Dit suggereerde dat het TEX₈₆ signaal in deze tijdsperiode werd geproduceerd. TEX₈₆ temperatuur profielen van fjordsedimenten kunnen dus potentieel nuttig zijn voor de reconstructie van vroegere variaties in kustklimaten. Door middel van analyse van twee boorkernen uit de Arabische Zee werden temperatuurschattingen van de laatste glaciaal-interglaciaal overgang verkregen en met behulp van de TEX₈₆ vergeleken met die verkregen met behulp van de U₃₇^{K'} index. De U₃₇^{K'} index is gebaseerd op de samenstelling van alkenonen afkomstig van haptofyte algen. De met de TEX₈₆ verkregen OZT profielen waren zeer goed vergelijkbaar in de twee kernen over de laatste glaciaal-interglaciaal cyclus en in fase met temperatuurveranderingen geregistreerd in Antarctische ijskernen. Dit suggereerde dat de met de TEX₈₆ gereconstrueerde OZT in dit gebied voornamelijk bepaald werden door klimaatveranderingen op het zuidelijk halfrond gedurende de zuidwest passaat. OZT profielen op basis van de U₃₇^{K'} van dezelfde boorkernen verschilden in de mate van temperatuurveranderingen en ook in fase, en zijn gedeeltelijk in fase met klimaatveranderingen op het noordelijk halfrond. De verschillen in temperatuursignalen geregistreerd met de TEX₈₆ en de U₃₇^{K'} index worden waarschijnlijk veroorzaakt door verschillen in het groeiseizoen van de organismen die de biomarkers

produceerden en door veranderingen in de opwellingdynamiek en sterkte van de passaatwinden tussen het laatste glaciaal en het Holoceen.

De TEX₈₆ methode werd ook toegepast op een boorkern uit de Westelijke Middellandse Zee die sedimenten afgezet tijdens de Mariene Isotoop Stadia (MIS) 6 en 7 bevatte. Een recente studie aan deze kern liet zien dat OZT profielen die gebaseerd zijn op distributies van alkenonen niet alleen temperatuurveranderingen lieten zien die vergelijkbaar zijn met die gebaseerd op $\delta^{18}\text{O}$ waarden van de foraminifeer *G. bulloides*, maar ook stadiaal-interstadaal temperatuurveranderingen gedurende de op één na laatste klimaatcyclus (van 244 tot 130 cal. ky BP). Ter vergelijking werd de TEX₈₆ proxy toegepast op dezelfde sedimentkern om OZT te reconstrueren. Het TEX₈₆ profiel liet stadiaal-interstadaal temperatuurveranderingen zoals eerder gedetecteerd met behulp van de U_{37}^{K} zien en leverde dus onafhankelijk bewijs voor snelle temperatuurveranderingen. De twee proxies gedroegen zich echter verschillend tijdens het glaciële MIS-6 en het interglaciële MIS-7. Gedurende MIS-7 was er een goede overeenkomst tussen de absolute OZT-schattingen van de twee proxies maar gedurende MIS-6 waren temperatuurvariëaties gereconstrueerd met de TEX₈₆ veel groter dan die gereconstrueerd met de U_{37}^{K} index. Dit wordt mogelijk veroorzaakt door de verandering in het seizoen waarin de haptofyten en de Crenarchaeota groeiden of door variaties in de diepte van het water waarin de Crenarchaeota leefden. Omdat het regionale klimaat en milieu verschillend waren tussen glacialen en interglacialen kunnen er verschillen worden verwacht in seizoenspatronen en leefdiepte wat een sterk effect kan hebben op de temperaturen gereconstrueerd met de TEX₈₆ en U_{37}^{K} proxies.

Samenvattend kan gesteld worden dat de resultaten beschreven in dit proefschrift geleid hebben tot een substantiële verbetering in de analyse van de TEX₈₆. Dit heeft geresulteerd in een verbeterde reproduceerbaarheid in de bepaling van deze proxy. De oorsprong en het transport van het GDGT signaal werd ook bestudeerd waaruit bleek dat zowel actieve als passieve transportmechanismen een rol spelen. Deze studie gaf ook essentiële informatie over de beperkingen van de proxy zoals de variërende diepteoorsprong en de effecten van langdurige blootstelling aan zuurstof. Tenslotte werd de proxy gevalideerd door metingen aan sedimentkernen en vergelijking met andere proxies. Dit proefschrift laat zien dat de TEX₈₆ een nuttige OZT proxy is die additionele informatie kan geven ten opzichte van andere OZT proxies.

Resum

Determinar la temperatura superficial del mar (SST) és essencial per a reconstruir el canvi climàtic natural versus l'antropogènic, modelar el clima i reconstruir la circulació oceànica. Tot i que existeixen diverses SST proxies, totes presenten incerteses, per aquesta raó són necessàries noves proxies per a complementar els resultats existents. Una nova SST proxy basada en els canvis en la composició lipídica de les membranes dels Crenarchaeota, la TetraEther index of lipids with 86 carbons (TEX₈₆) ha sigut introduïda recentment. Les membranes dels Crenarchaeota estan formades per glicerol dibiphytanyl glicerol tetraethers (GDGTs), i els canvis en l'abundància relativa d'aquests lipids permet a aquests organismes adaptar la fluïdesa de la membrana a fluctuacions en la temperatura de l'aigua on viuen. La TEX₈₆ ha sigut calibrada amb una correlació empírica entre els valors de TEX₈₆ d'una gran varietat d'àrees geogràfiques amb la SST mitja anual. L'objectiu principal d'aquesta tesi era millorar, validar i aplicar la TEX₈₆. Per aquesta raó la tesi es centra en a) aspectes analítics de la TEX₈₆, b) el transport de GDGTs als sediments i la influència de la diagènesi i c) l'aplicació de la proxy a diverses àrees d'estudi.

En relació als aspectes analítics no s'observen diferències significatives a l'usar tècniques d'extracció diferents. Però quan s'analitza la TEX₈₆ utilitzant diferents tècniques d'espectrometria de masses com: Single Ion Mode (SIM) i Mass Scanning Detection (MSD), els resultats indiquen que la tècnica SIM és dos ordres de magnitud més sensible. Els experiments també han permès establir el límit de detecció a 0.05 ng de GDGTs injectats en columna. L'aplicació de la tècnica SIM ha millorat la reproducibilitat de les mesures de TEX₈₆ amb un error de només 0.3°C. Gràcies a aquestes millores la TEX₈₆ pot ser mesurada molt més acuradament que abans. La precisió de la mesura de les abundàncies absolutes de GDGTs també ha sigut millorada degut a la introducció d'un standard sintètic a la mostra. Amb aquest nou mètode, la desviació estàndar en la determinació d'abundàncies de GDGTs ha millorat fins al 5% respecte al 43% amb l'estàndar extern. Incrementant així el potencial d'ús de GDGTs en estudis (paleo)ecològics.

El transpor i la diagènesi de GDGTs també és essencial per a entendre i aplicar la TEX₈₆. Tot i que hi ha evidència de que les Crenacheotes poden viure a tota la columna d'aigua, estudis previs indiquen que els valors de TEX₈₆ de partícules orgàniques i sediments de superfície estan més ben correlacionades amb SST (profunditats <100m) que amb temperatures a més gran profunditat. Però les cel·lules de Crenachota son massa petites (< 1 µm) per a sedimentar després de morir i això evitaria que el senyal de la TEX₈₆ arribés al sediment. Per tal d'investigar això, estomacs i intestins de decapodes (elements clau en moltes xarxes tròfiques pelàgiques) foren analitzats per establir la presència de GDGTs. El nostre estudi revela la presència de GDGTs a estomacs i en menor quantitat a intestines, indicant que els decapods ingereixen GDGTs. Aquests resultants en combinació amb anàlisis de pigments sugereixen que el transport de GDGTs de la superfície als sediments pot ocórrer tant per mecanismes passius (sedimentació de partícules) com actius (migració). El més rellevant és que tot i que l'abundància de GDGTs està significativament reduïda als intestins, no hi ha una diferència significativa (<1°C) entre TEX₈₆ a estomacs i intestins, sugerint que el transit a través del sistema digestiu no altera els valors de TEX₈₆. Contrastant aquests resultats, un estudi usant trampes de sediment i sediment cores cobrint els últims 150 anys a la Santa Barbara Basin ha revelat que els valors de TEX₈₆ es trobaven sempre per sota de les SST, indicant per tant un origen sub-superficial, segurament entre 100 i 150m. Això podria estar relacionat amb la profunditat d'origen de la senyal de TEX₈₆ i podria estar controlat per la communitat planctònica superficial i per la dinàmica de la columna d'aigua. Aquests resultats posen de manifest la importància de realitzar estudis de calibració usant trampes de sediment i sediments superficials abans d'aplicar la TEX₈₆ a qualsevol area d' estudi.

Per tal d'investigar els efectes de la degradació deguda a una exposició a llarg termini a l'oxigen, vem analitzar l'abundància de GDGTs així com, TEX₈₆ i Branched versus Isoprenoid Tetraether index (BIT) a diverses turbites de la Madeira Abyssal Plain al llarg d'un front d'oxidació. Els resultats indiquen una reducció en l'abundància de GDGTs que resulta en canvis substancials en TEX₈₆ i BIT. Nosaltres postulem que els canvis son deguts a un increment realtiu dels GDGTs d'origen terrestre versus els d'origen marí. Aquesta conservació selectiva de GDGTs terrestres amb una estructura química quasi idèntica als d'origen marí sugereix que és la matriu mineral la que protegeix els GDGTs terrestres. Això

indica que cal tenir cura quan s'aplica la TEX_{86} a sediments que hagin estat exposats a oxygen durant llargs períodes de temps.

Gràcies a l'aplicació de la TEX_{86} a diferents arees amb diferents resolucions temporals i en combinació amb altres proxies, aquesta tesi valida la TEX_{86} com a paleotermometre. Dos cores del Drammensfjord, Noruega, analitzats amb una resolució quasi-anual cobrint els últims 100 anys suggereix que la TEX_{86} reflexa temperatures superficials (0-25 m). Ademés les temperatures calculades amb la TEX_{86} segueixen bastant accuradament canvis en el record històric de temperatures mitjanes de l'aire a Oslo, concretament entre primavera i tardó indicant que el senyal es produeix en aquest període. En conclusió sembla que mesurar la temperatura amb la TEX_{86} a sediments de fjords pot ser una eina important per a reconstruir variacions climàtiques a zones costaneres. També hem comparat la TEX_{86} and l'índex $U_{37}^{K'}$ (que es deriva de les alkenones de cadena llarga de les algues haptophytes) durant l'última transició glacial-interglacial en dos cores al mar d'Arabia. Les temperatures calculades amb la TEX_{86} eren iguals als dos cores. A més a més els canvis observats durant l'últim cicle glacial-interglacial estaven en fase amb els canvis trobats a cores de gel de l'Antartida. Aquests resultats indiquen que els canvis de la TEX_{86} en aquesta àrea estan principalment controlats pel clima de l'hemisferi sud durant el SW monzón. En canvi temperatures mesurades amb la $U_{37}^{K'}$ indiquen no només diferents magnituds a les mesurades amb TEX_{86} , sinó que semblen estar en fase amb l'hemisferi nord durant el NE monzón. Segurament aquestes diferències son degudes a que els organismes que sintetizen els compostos utilitzats en les dues proxies creixen en diferents estacions de l'any, combinat amb un canvi en la dinàmica del monzón i l'upwelling local entre el LGM i l'Holocè.

El sediment més antic analitzat en aquesta tesi es d'un core que cobreix els Marine Isotope Stadials (MIS) 6 and 7 al mar d'Alboran, Mediterrani oest. Un estudi recent en aquesta zona (core ODP-977A) revela que les alkenones no només presenten tendències de temperatura similars a la $\delta^{18}O$ de *G. bulloides*, sinó també canvis de temperatura entre stadials interstadials durant el penúltim cicle climàtic (from 244 to 130 cal. ky BP). Per tal de confirmar aquests canvis de forma independent, la TEX_{86} es va aplicar al mateix sediment core i els resultants indicaren canvis similars durant stadials interstadials. De tota manera les dues proxies presenten una millor correlació durant MIS-7 que durant MIS-6. Durant MIS-6

la TEX_{86} indica uns canvis de temperatura molt més accentuats que els de la $U_{37}^{K'}$, per aquesta raó presentem la hipotesi que aquestes diferències es poden explicar per un canvi en la estació de creixement de les haptophytes i Crenarchaeotes i/o variacions en la profunditat de l'habitat de les Crenarchaeotes. Com que el clima és diferent durant glacials i interglacials, un canvi en la dinàmica estacional i/o la profunditat es bastant probable i en qualsevol dels casos això tindria un efecte diferent en les dues proxies.

En resum, els resultats d'aquesta tesi esdevenen una millora substancial dels aspectes analítics de la TEX_{86} , millorant en torn la precisió de la determinació de la proxi. L'origen i transport de GDGTs també s'ha estudiat i sembla que pot ser mediat tant per mecanismes passius com actius. El treball d'aquesta tesi també ha sigut essencial per a determinar els límits d'aplicació i problemes associats a l'ús de la TEX_{86} , com els canvis de profunditat o la degradació òxica a llarg termini. Finalment l'ús de la proxi en diferents àrees, i en conjunt amb altres proxies ha permès de validar la TEX_{86} . Aquesta tesi il·lustra que la TEX_{86} pot ésser una bona mesura de SST i que pot aportar informació complementària a les altres proxies.

Acknowledgements

I want to thank Dr. Micheo, Dr. Cabezos, R. Gomez, N. Grifoll, M. Reina, J. Garcia, B. Madden, P. Shnabel and many more that helped me in many ways, because the boat can not float without water.

My four years of doctorate have been made lighter, shorter and so much more enjoyable by many people at the NIOZ which usually go unnoticed, that is why I would like to thank all the people in the cleaning, reception, administration and personnel departments. Especially I want to acknowledge Joke Mulder who made my dealing with Netherlands bureaucracy that much smoother. Also I would like to thank the IT department for rescues during the journey, and all the others that were there to lend a hand at crucial moments.

I would like to thank all the MBTers for so many things, from lunch discussions to seminars, to much needed help in and out of work. Not to forget many kilos of cream delivered by countless birthday cakes and other celebrations, dank u wel!

Special thanks go to, Lydie Herfort mercy, thank you Jung-Hyun Kim, danke Cornelia Wuchter, Astrid Forster and Andrea Jaeschke for graphs, fruitful discussion, corrections and generally bearing with me. Not to forget taking care of me, and of course for all the delicious dinners and bottles of wine we shared. I could not have made it without you and I can not thank you enough, I know it was not always easy.

I would like to thank Michiel Kienhuis for useful comments and computer rescue, but also Dutch translations, administrative dealings recipe swapping and for general mood improvement (Gracias).

To Marianne Baas for teaching me how to work in a chemical lab and turning me into a budding geochemist which is not without merit with my biological background and genetic clumsiness. Also to Jort Ossebaar, Sebastian Rampen (keep smiling) and Martijn Woltering for assistance in the lab and out of it too.

Acknowledgements

Thank you also Ellen Hopmans for teaching me how to use an HPLC/MS, and helping me in so many other occasions (I still remember those 100 samples that you helped me pick up from the floor on my first HPLC-MS measuring day). Thanks are also given to Wim Boer for lead 210 analysis and Eilke Berghuis for pigment analysis.

I would also like to thank all the people that gave me samples and made this thesis not only possible but so much better, thus, thank you very much Frank Sirocko, Jung-Hyun Kim, Gert J. de Lange, Rienk H. Smittenberg, Joan Cartes, Belen Martrat, Joan Grimalt, Arndt Schimmelmann and Karin Zonneveld.

Thanks are also due to Lluís Camarero for making me realize how much was still to be learnt in science and how enjoyable the journey could be. Also to Pere Abelló who opened a door back to biology for me and has had tons of patience holding it open for me since. Joan Cartes is also thanked for helping me keep in touch with Spanish science and for taking such a gamble with me. Special thanks go to Joan Grimalt who gave me a very good advice about my career which I intend to follow.

And of course I would like to thank Stefan Schouten specially as after my confession in the interview that I did not know any analytical chemistry, paleocenaography or statistics he still gave me the job and then went on to put up with me for four years. Thank you for the many answer to my many questions for the speed of light corrections and for never loosing faith in the data even when I had given up. Thanks are also due to Jaap Sinninghe Damsté for project supervision and article corrections as well as data discussion. I would also like to thank both of them for letting me do things my own way and only interfering when strictly necessary and teaching me a lot of things on the way.

And last but not least, one must not forget the hand that feeds one, thus thanks go to the NWO-ALW (Project nr. 152911) as it allowed me, for the first time, to make money out of my passion for science.

Curriculum Vitae

Carme Huguet Micheo was born the 11th of October 1976 in Barcelona, Spain. After finishing 4 years of pure science high school she went on to pursue a Bachelors degree in Biology at the Universitat Autònoma de Barcelona, Spain. She specialised in systems ecology and after obtaining an Erasmus grant, she spent the last year of her degree in St. Andrews University, Scotland where she specialised in marine ecology and biology. In St. Andrews she did a project on “Diatom distribution along the shore in the Eden Estuary” under the supervision of Dr. Patterson. After finishing her Bachelors degree in 1999 she went on to study a master in Oceanography at the University of Southampton, UK. During her masters she specialized in deep-sea marine ecology and did a project on “Distribution of Decapod crustaceans in the Continental Slope and Abyssal Plain” under the supervision of Dr. Billett. In 2000 she returned to Spain where she taught English and worked voluntarily first at the Universitat de Barcelona (EMERGE European program) and then in the CMIMA oceanographic institute in Barcelona. The Study of high mountain lake basin soils in the Pyrenees within the EMERGE European program, supervised by Dr. Camarero was finished in 2001 and an article was published in *Biogeochemistry* in 2007. From 2001 to the present she has been collaborating with Dr. Abelló and Dr. Cartes at the CMIMA in Barcelona and so far two articles were published, one at the *Journal of sea research* in 2003, and one at *Deep-Sea Research I* in 2007. From April 2003 to April 2007 she completed her PhD studies at the Royal NIOZ under the supervision of Dr. Schouten and Dr. Sinninghe-Damsté. Currently she is a postdoctoral research associate at the University of Washington in Seattle.

Scientific Assessment committee

Prof. Dr. J.W. de Leeuw

Royal Netherlands Institute for Sea Research, Marine Biogeochemistry and Toxicology, P.O. Box 59,1790 AB Den Burg (Texel), The Netherlands

And

Faculty of Geosciences, Utrecht University, P.O. Box 80.021, 3508 TA Utrecht, The Netherlands

Prof. Dr. G. J. de Lange

Faculty of Geosciences, Utrecht University, P.O. Box 80.021, 3508 TA Utrecht, The Netherlands

Prof. Dr. J. O. Grimalt

Department of Environmental Chemistry, Institut d' Investigacions Químiques i Ambientals de Barcelona, Consell Superior d'Investigacions Científiques (CSIC) 08034 Barcelona, Spain.

Prof. Dr. J. Volkman

CSIRO Marine Research, Castray Esplanade, Hobart, Tasmania, Australia.
