Reactions Steps and Related Chlorinated Waste Streams in the Industrial Production of PVC: The Potential of La-based Catalysts for Chlorine Management

Chlorinated C_1 and C_2 hydrocarbons (CHC_{1-2}) are used in many applications. Particularly, the production of polyvinyl chloride (PVC), which accounts for one third of all chlorine consumption, is built up of several reaction steps involving chlorinated hydrocarbons (CHCs). In this introductory chapter, the catalytic conversion of chlorinated waste streams resulting from PVC production using basic oxides is reviewed. First, the use and environmental effects of chlorinated CHC_{1-2} are dealt with. In a second part, the reaction steps and the compounds involved in the production of C_2H_3Cl , which is the monomer for the production of PVC, are discussed. Finally, an overview is provided on the potential of basic oxides for the destruction of CHCs. Special emphasis will be on La_2O_3 -based catalysts. The chapter ends with an outline and motivation of this PhD thesis.

Chapter 1

Introduction

Chlorine is one of the most important chemicals, which is used for the manufacturing of numerous commercial products. In 2004, chlorine production in whole Europe made an all time record of 10.35 million tons.¹ The largest part of the chlorine is used for the production of organic compounds; the production makes up for 85 % of the chlorine applications (Figure 1).¹ In fact, the polyvinyl chloride (PVC) industry is the main consumer of chlorine with more than one third of the chlorine production. Chlorination of organic molecules with chlorine results in activation of the molecules for reactions. This, combined with the fact that the raw material (sodium chloride) for chlorine is available in an almost unlimited amount, makes chlorine chemistry well-suited for large-scale synthesis.

The C-Cl bond in organic chlorinated molecules is covalent in nature. Nevertheless, the strong electronegative chlorine produces a polar component with a shift of the negative charge in the direction of the chlorine: $R_3C^{\delta+}-Cl^{\delta-}$. The energy of the C-Cl bond is relatively low; the manner of dissociation can be heterolytic (ionic) and homolytic (radical), as shown in Reaction Eqs. (1) and (2), respectively.²

This can be used to replace the chlorine in a chlorinated molecule by a different atom or functional group. Thus chlorinated hydrocarbons (CHCs) can be used as components for a whole variety of synthesis reactions and intermediates. Scheme 1 shows the molecular structures of chlorinated methanes, ethanes, ethenes and oxygen-containing organic compounds.

Chapter 1

Chlorinated C₁ and C₂ (CHC₁₋₂) are especially useful for industrial chemical reactions. This is illustrated by the various uses of the CHC₁₋₂, shown in Table 1. Several compounds are used for the production of polymers. C₂H₃Cl and 1,1-C₂H₂Cl₂ are used as monomers for the synthesis of PVC and polyvinylidene chloride (PVDC), respectively. This is illustrated by Reaction Eqs. (3) and (4). In addition, 1,1-C₂H₂Cl₂ is used as a copolymer of C₂H₃Cl, acetonitrile, methacrylonitrile and methacrylate. CH₃Cl is also used as a main reactant to produce silicon polymers via the Rochow synthesis.²

The potential of La-based catalysts for chlorine management

Other CHC_{1-2} are used as a building block in industrial organic reactions. CH_3Cl is used as an intermediate in drug manufacturing. It is also used as a methylating agent, and similarly $\text{C}_2\text{H}_5\text{Cl}$ is used as an ethylating agent. CHCl_3 and $1,1,1\text{-C}_2\text{H}_3\text{Cl}_3$ are used for the production of refrigerants. $1,2\text{-C}_2\text{H}_4\text{Cl}_2$ is converted into vinyl chloride by dehydrochlorination via thermal cracking and is therefore also important for the production of PVC. The CHC_{1-2} are also widely used because of their ability to dissolve organic compounds and their volatility; they are used as degreaser, industrial solvent, blowing agent, propellant, paint stripper, extractant and dry cleaning agent.

Once, CHC_{1-2} were used in many commercial applications, e.g. as refrigerants, spray can propellants, insecticides and pesticides. However, in the last decades their toxic properties and effect on the environment have become better understood. Table 2 shows that, except for $1,1,1\text{-C}_2\text{H}_3\text{Cl}_3$, all compounds listed are either known or at least suspected carcinogens.³ ⁴ The Indiana Relative Chemical Hazard (IRHC) score is used to classify the effect of a compound on human health, ecosystems and environmental health generally.⁵ All CHCs listed in Table 2 have relatively high IRCH scores. Therefore, restrictions on the use and emission of several CHC_{1-2} have been made to reduce the concentrations in water and air worldwide.⁶ ⁷ Particularly, the production and processing of carbon tetrachloride and $1,1,1\text{-C}_2\text{H}_3\text{Cl}_3$ are severely restricted by the Montreal Protocol as well as by the Intergovernmental Panel on Climate Change.^{8, 9} As a result of regulation and introduction of chlorine-free alternatives, the use of CHC_{1-2} in commercial applications has been greatly reduced. Therefore, the use of CHC_{1-2} is almost entirely attributed to industrial applications.

Table 2. Carcinogenicity and IRCH score of common chlorinated CHC_{1-2} . The Indiana Relative Chemical Hazard (IRCH) Score indicates how a chemical compares with others in terms of its capacity to impact human health, ecosystems, or environmental health generally. The IRCH scores of COCl_2 and CO_2 are provided as reference.

Chapter 1

Ironically, the same quality that makes CHCs a favourite for industrial organic chemists, is also the reason for environmental concern and call for a ban on chlorine.¹⁰ The high electron affinity of chlorine makes CHCs effective building blocks for the synthesis of molecular structures. On the other hand, the electron affinity stabilizes some chemical structures, which are not broken down and remain in the atmosphere when emitted. They are then able to reach the stratosphere resulting in ozone depletion. Other compounds, e.g. polychlorinated dioxins and furans (Scheme 1d), combine persistence with accumulation in fat tissue, where they can build up to toxic levels.¹¹ Even CHCs that are not persistent themselves, can decompose into harmful products.

The two-faced character of chlorine is best seen in the production of PVC. The high demand for PVC also results in the formation of large quantities of CHC_{1-2} as by-products. These by-products have to be destroyed to prevent emission and, consequently, the previously mentioned environmental effects. This introductory chapter starts with an overview of the $\text{C}_2\text{H}_3\text{Cl}$ production process, focusing on the chemical reactions, products and process conditions. Next, the catalytic destruction of CHCs over basic oxides is reviewed. The focus will be on La_2O_3 -based materials. The chapter ends with an outline and motivation of the PhD thesis.

Vinyl Chloride Monomer Production: Reactions, Products and Process Conditions

PVC is the second most used plastic in the world after polyethylene (PE). In Europe, more than one third of all chlorine is used to synthesize this product and the annual production of PVC has steadily increased in the last decade.¹ $\text{C}_2\text{H}_3\text{Cl}$ is the main reactant for the industrial synthesis of PVC. The production of $\text{C}_2\text{H}_3\text{Cl}$ is built up out of several steps.² An overview is given in Figure 2.

The first step is the chlorination of ethylene into $1,2\text{-C}_2\text{H}_4\text{Cl}_2$; this is done by either direct chlorination or oxychlorination. Next, the crude $1,2\text{-C}_2\text{H}_4\text{Cl}_2$ is purified and the by-products are separated into fractions. The purified $1,2\text{-C}_2\text{H}_4\text{Cl}_2$ is then thermally cracked to $\text{C}_2\text{H}_3\text{Cl}$. A final purification step yields $\text{C}_2\text{H}_3\text{Cl}$ which is stored and/or used for polymerization into PVC. In this purification step, HCl and $1,2\text{-C}_2\text{H}_4\text{Cl}_2$ are recovered and the remaining by-products are separated. The by-product mixture contains many CHC_{1-2} , which are not commercially attractive for recovery and are processed as waste. In what follows, we will discuss the different reaction steps in more detail.

Chlorination / Oxychlorination of Ethylene into $1,2\text{-C}_2\text{H}_4\text{Cl}_2$

In the direct chlorination reaction, chlorine is used to convert ethylene into $1,2\text{-C}_2\text{H}_4\text{Cl}_2$ (Reaction Eq. (5)). Figure 3 shows the diagram of an industrial reactor used for the direct chlorination of ethylene into $1,2\text{-C}_2\text{H}_4\text{Cl}_2$.¹²⁻¹⁴ This is a bubble-column with external loop used

Chapter 1

for low-temperature chlorination, which is applied in 70 % of the licenses issued for this process. Ethylene and chlorine are both in gaseous state and are fed to the reactor. Here, they dissolve and diffuse in liquid 1,2-C₂H₄Cl₂. In the liquid phase the exothermic reaction of chlorine and ethylene occurs, increasing the temperature. The difference in density between the heterogenic phase and thermal-exchange zones enables the recirculation of the liquid phase. In this way, the reaction temperature (50-70 °C) can be controlled by means of the heat exchanger. The main by-product is 1,1,2-trichloroethane, which is formed according to Reaction Eq. (6). A useful catalyst is FeCl₃, which is soluble in the reaction medium and favours the selectivity towards 1,2-C₂H₄Cl₂ production. High temperature direct chlorination utilizes the reaction heat to distill the 1,2-C₂H₄Cl₂. However, it is less selective than the low temperature process, even though the energy input is lower.

For the synthesis of 1,2-C₂H₄Cl₂, oxychlorination (Reaction Eq. (7)) is often combined with direct chlorination to re-use HCl gas formed in the production of C₂H₃Cl. In this reaction, CuCl₂, supported on γ-alumina, is used as catalyst. The catalytic reaction mechanism follows a three step redox mechanism; 1) chlorination of ethylene by reduction of CuCl₂ (Reaction Eq. (8)), 2) oxidation of CuCl into an oxychloride (Reaction Eq. (9)) and 3) re-chlorination of the oxychloride into CuCl₂ (Reaction Eq. (10)).¹⁵

The reaction is performed at 220-260 °C and 5-6 bar using both air and oxygen in fluid- or fixed-bed reactors.^{16, 17} The main reaction is accompanied by various side reactions. Ethylene undergoes complete and incomplete combustion to give CO and CO₂, as illustrated by Reaction Eqs. (11) and (12).¹⁸ In addition, several CHCs are formed in side-reactions.

Apart from water, the contaminants mainly consist of CHCs. Table 3 shows the composition of crude 1,2-C₂H₄Cl₂ composed of both direct chlorination and oxychlorination reactor effluent.¹⁹ Even though the reaction is highly selective towards 1,2-C₂H₄Cl₂ (~98 %), the production scale results in the formation of large quantities of by-products. The crude 1,2-C₂H₄Cl₂ mixture is purified using azeotropic distillation.²⁰ This enables the separation of compounds with small differences in boiling point. Two distillation fractions remain, the so-called light ends and heavy ends.

The potential of La-based catalysts for chlorine management

Thermal Cracking of 1,2-C₂H₄Cl₂ into C₂H₃Cl

The industrial synthesis of C₂H₃Cl is mainly based on the thermal decomposition (cracking) of 1,2-C₂H₄Cl₂ in a non-catalytic gas phase reaction (Reaction Eq. (13)).² The reaction is endothermic and occurs via a first order free radical chain mechanism. The reaction temperature is 500-550 °C and the pressure is kept at 20-30 bar. Figure 4 displays the schematic diagram of an 1,2-C₂H₄Cl₂ cracking furnace. The reactor, equipped with a burner, is designed for plug-flow conditions with tubes placed in the convective zone of the furnace.²

The liquid 1,2-C₂H₄Cl₂ is evaporated in the upper part of the furnace at 200 °C. Cracking takes place in the hotter lower part of the reactor. 1,2-C₂H₄Cl₂ cracking is typically carried out at 50-60% conversion.²¹ Therefore, the main constituents are 1,2-C₂H₄Cl₂, C₂H₃Cl and HCl. In addition, numerous gas phase by-products are formed in small amounts. Apart from the gaseous effluent, tars and coke are formed as by-products.

The crude C₂H₃Cl is cooled and quenched to remove HCl, which can be re-used in the oxychlorination process. In a second distillation column, C₂H₃Cl is drawn off as the main product. From the bottom of the column low-boiling products are removed first by distillation. In the last distillation tower, 1,2-C₂H₄Cl₂ is separated from the other CHCs and is recycled to the cracker via the 1,2-C₂H₄Cl₂ purification step. In Table 4, the reaction mixture composition resulting from the thermal cracking of 1,2-C₂H₄Cl₂ is shown. In this reaction,

Chapter 1

several chlorinated CHC_{1-2} are formed, which are also divided into the light and heavy ends fraction. Moreover, several hydrocarbons are formed as a result of the radical reactions.

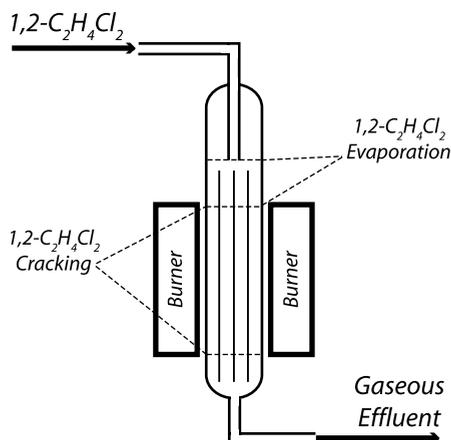

Figure 4. Diagram of an $1,2\text{-C}_2\text{H}_4\text{Cl}_2$ cracking furnace used for the industrial preparation of $\text{C}_2\text{H}_3\text{Cl}$ via thermal dehydrochlorination of $1,2\text{-C}_2\text{H}_4\text{Cl}_2$.

The potential of La-based catalysts for chlorine management

Destruction of Light and Heavy Ends

Because of the previously discussed effects and the restrictions on the emission, the CHC_{1-2} have to be disposed of efficiently. However, CHCs are generally heat-resistant. Moreover, the CHC_{1-2} are able to react into dioxins (Scheme 1d) when heated to a temperature around 400-500 °C. Therefore, the light and heavy ends formed during the production of $\text{C}_2\text{H}_3\text{Cl}$ are incinerated at >1000 °C.²² Although this process is highly efficient (99 %), it is costly as a result of the high temperature. In addition, incineration leads to the loss of feedstock. Currently, incineration is commonly used for the disposal of light and heavy ends. However, to reduce the costs for the conversion of these waste streams and enable recycling of the compounds new techniques are investigated. Catalytic conversion of the CHC_{1-2} using a heterogeneous catalyst possesses great potential due to the practical applicability to industrial waste streams. However, chlorine is a known poison to numerous catalyst materials, which makes catalytic reactions with chlorinated compounds difficult or even cumbersome. In what follows, a state of the art of the catalytic destruction of CHCs over basic oxides is provided, especially focusing on La_2O_3 -based materials.

Catalytic Conversion of CHCs: Catalytic Destruction and Destructive Adsorption over Lanthanide Oxide-Based Materials

Catalytic destruction can be divided in three reaction types: catalytic oxidation, hydrogenolysis and steam reforming. Catalytic oxidation is similar to traditional incineration techniques:²³ the substrate reacts with oxygen, although catalytic oxidation proceeds at lower temperature (300-550 °C). By complete oxidation, CO_2 , H_2O , Cl_2 and HCl are formed exclusively, as shown in Reaction Eq. (14), because HCl and Cl_2 are equilibrated via the Deacon reaction (Reaction Eq. (15)). Catalysts for this reaction are noble metals²⁴⁻³² and transition metal oxides³³⁻⁴⁰, which are supported by various materials, such as SiO_2 , Al_2O_3 , TiO_2 , carbon⁴¹, zeolites⁴²⁻⁴⁶ and cordierites.^{47, 48} Unsupported pillared clays, perovskites and zeolites are also active catalysts for catalytic oxidation.^{49, 50} This reaction is hindered by side-reactions, involving chlorination of the catalyst and formation of CHCs.⁵¹

Hydrogenolysis is the reaction in which C-Cl bonds are broken under formation of HCl in the presence of hydrogen at temperatures mostly below 200 °C (Reaction Eq. (16)). Pd and Pt catalysts, supported on SiO_2 , Al_2O_3 , TiO_2 , ZrO_2 and carbon, are the most active for this reaction.⁵²⁻⁵⁶ This technique offers several advantages, including the recycling of the reaction products. However, it is not used often, because of the fast deactivation of the catalyst by chlorine poisoning and coke formation.

Chapter 1

Catalytic steam reforming of CHCs is a process which uses steam to remove chlorine from CHCs. This reaction yields HCl and oxygenated products, such as CO and CO₂. Two groups of catalyst materials can be distinguished: supported noble metals and supported metal oxides.⁵⁷⁻⁶² Support materials are SiO₂, Al₂O₃ and TiO₂. The temperature range is between 400 and 750 °C. Similar to the other catalytic systems, the catalyst is progressively poisoned by the CHCs and can slowly be regenerated by treatment with steam. It was found, however, that basic oxides are active and stable materials for the catalytic reforming of CHCs. The next section will deal with the catalytic destruction of chlorinated methanes over basic oxides, focusing on lanthanide oxides.

Destructive Adsorption and Catalytic Destruction of CCl₄ over Basic Oxides

Basic metal oxides, such as alkaline earth metal oxides and lanthanide oxides, can convert CHCs into oxygenated products, while they undergo transformation into the corresponding metal chlorides. This reaction is known as destructive adsorption and was pioneered by Klabunde and co-workers.⁶³⁻⁶⁸ The reaction proceeds by adsorption of the gas phase CHC at the catalytic surface of the metal oxide. The chlorine atoms of the CHC are transferred to the solid and, in exchange, lattice oxygen is donated to the gas phase molecule. Most studies have been done on the destructive adsorption of CCl₄ over metal oxides, because it only possesses C-Cl bonds (Reaction Eq. (17)) and is therefore a model reactant. It was found that increased basicity of the metal oxide results in higher efficiency of destructive adsorption of CCl₄. Moreover, the chlorination of the metal oxides is accompanied by the formation of intermediate oxychloride phases.⁶⁹

The destructive adsorption behaviour for CCl₄ of several alkaline earth oxides and lanthanide oxides at 300 °C is shown in Figure 5.^{69, 70} The following trend in activity is observed: BaO > SrO > La₂O₃ > Pr₂O₃ > Nd₂O₃ >> CaO ≈ MgO. The hypothesis that this process could be made catalytic by regeneration of lattice oxygen was investigated by the regeneration of the materials with steam according to Reaction Eq. (18). This equation is illustrated for different materials by Figure 6.⁷¹⁻⁷³ The regeneration of the alkaline earth metal oxides, especially for BaO and SrO, is difficult. The ability to regenerate lattice oxygen appears to increase with decreasing basicity for the alkaline earth metal oxides. The rare earth metal oxides show a higher regeneration capacity, with Pr₂O₃ and Nd₂O₃ nearly fully regenerated after 4 h of steam treatment. The dechlorination of La₂O₃ is slightly slower than for the other rare earth metal oxides.

The potential of La-based catalysts for chlorine management

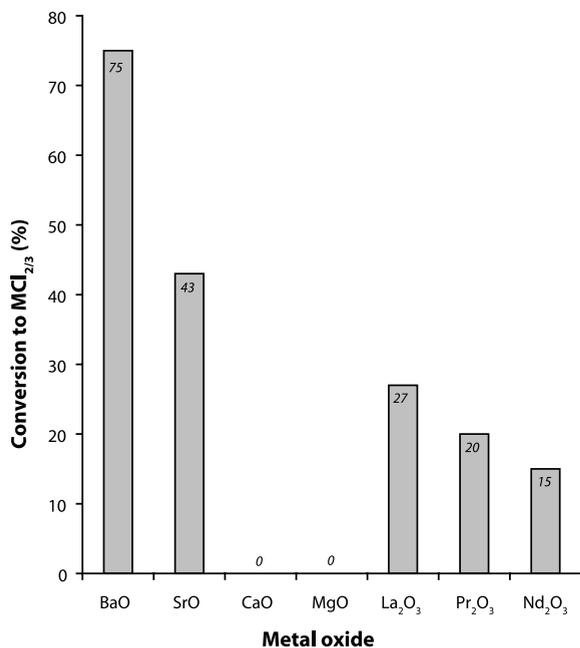

Figure 5. Destructive adsorption of CCl_4 on earth alkaline and lanthanide oxides at 300 °C. The efficiency of the process (%) is expressed as the percentage of the metal oxide transformed into the metal chloride after injecting 250 μ l CCl_4 in a He stream for a molar ratio of 20 (CCl_4 : metal oxide).^{69, 70}

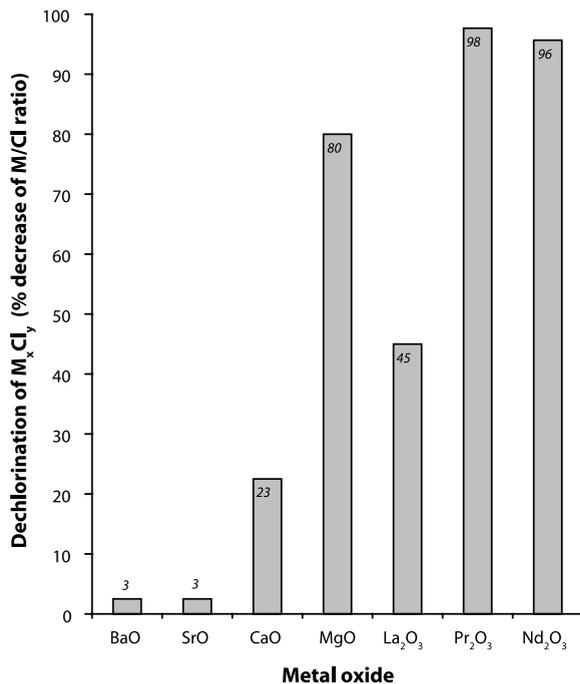

Figure 6. Dechlorination of earth alkaline and lanthanide oxides at 300 °C in the presence of steam for 4 h. The efficiency of the process is expressed as the Cl/M ratio before (grey) and after (black) dechlorination.⁷¹

Chapter 1

Thus, different behaviour is observed for the separate destructive adsorption and dechlorination reaction over basic metal oxides. An over amount of steam was added to the CCl_4 feed to verify whether a net catalytic reaction is possible (Reaction Eq. (19)) and to determine the relative activities of the materials. The conversion for the catalytic destruction of CCl_4 after 7 h time on stream over the metal oxide series is shown in Figure 7.⁷¹⁻⁷³ La_2O_3 and Pr_2O_3 were found to have the best combination of activity for destructive adsorption and in situ regeneration of the catalyst.

The metal oxides were supported on $\gamma-Al_2O_3$ to increase the destruction capacity of the catalyst by increasing the catalytic surface area. The conversion after 7 h on stream over the supported metal oxide catalysts is shown in Figure 8.⁷¹⁻⁷³ The supported La_2O_3 catalyst possesses a high destruction capacity compared to other catalytic systems.⁷¹⁻⁷⁴ The catalyst was also tested for a substantial time on stream and was found to be highly stable for the catalytic conversion of CCl_4 (Figure 9).⁷¹⁻⁷³ Because of the promising results, La_2O_3 was chosen as a catalyst material for further study of the conversion of CHCs.

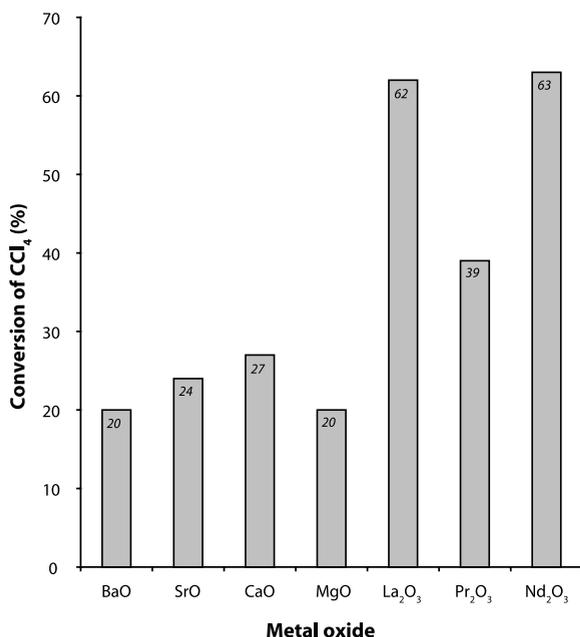

Figure 7. Conversion of CCl_4 and H_2O to CO_2 and HCl after 7 h on stream at 350 °C over alkaline oxides and lanthanide oxides ($H_2O/CCl_4 = 61$).⁷¹

The potential of La-based catalysts for chlorine management

Chapter 1

Behaviour of La₂O₃-based Catalysts during Conversion of CCl₄

The pure La₂O₃ catalyst was characterized with Raman spectroscopy during the steam reforming of CCl₄.^{71, 72} The Raman spectra of the catalyst reveal the bulk phase composition of the catalyst as a function of time and position in the reactor (Figure 10).^{71, 72} Initially, only bands assigned to La₂O₃ are observed at 106, 190 and 408 cm⁻¹. After 8 h, other bands appear in the spectrum at 438, 334, 210, 186 and 122 cm⁻¹, indicating partial conversion of the bulk phase into LaOCl according to Reaction Eq. (20). Even though the bulk phase composition changed, full conversion was still maintained. When only LaOCl was observed in the Raman spectra after 24 h of reaction, full conversion was still obtained. This means that, in addition to La₂O₃, LaOCl is also a highly active phase. Typical bands of LaCl₃ at 208 and 183 cm⁻¹ arise after 36 h, indicating a second conversion of the bulk phase of LaOCl into LaCl₃ (Reaction Eq. (21)). The bands due to LaOCl, however, remain present in the spectra even after 48 h time-on-stream. In summary, the chlorination of the catalyst first proceeds via a fast reaction, converting La₂O₃ into LaOCl. This is followed by a more gradual transformation of LaOCl into LaCl₃. This process resembles destructive adsorption, but in this case the added steam delays the chlorination of the catalyst. A higher H₂O/CCl₄ ratio can further delay the chlorination of the catalyst material, as illustrated in Table 5.⁷¹

Raman spectroscopy provides insight into the changes in the bulk phase composition of the catalyst. Therefore, the catalyst was also analyzed before and after reaction with X-ray photoelectron spectroscopy (XPS) to determine the extent of chlorination of the catalytic surface.^{71, 72} The O/La and Cl/La ratios that were found from the XPS spectra are shown in Table 6. There is a significant difference between the Raman and XPS results; more chlorine is present in the bulk phase than on the catalytic surface. This is explained by the fact there is bulk diffusion of chlorine atoms from the surface to the centre of the catalyst particle. This results in more chlorinated bulk phase and more oxygenated catalytic surface. The

Chapter 1

Mechanism of Catalytic Destruction over La_2O_3 -based Materials

Two reaction mechanisms were investigated for the catalytic destruction of CCl_4 : 1) destructive adsorption of CCl_4 and 2) the dechlorination reaction with steam. The results of Density Functional Theory (DFT) calculations indicate that destructive adsorption proceeds via step-wise donation of chlorine to the catalytic surface.^{71, 72} The reaction is built up from several elementary steps:

As CCl_4 approaches the surface, the carbon atom becomes activated by a basic lattice oxygen site. Simultaneously, a chlorine atom is drawn towards two La^{3+} Lewis acid sites. The C-Cl bond is elongated and eventually the chlorine atom is transferred to the lattice, bridged between the two La atoms. The remaining fragment is present on the surface as an $\text{O}-\text{CCl}_3$ species (Reaction Eq. (22)). This reaction step is predicted to be exothermic as shown in the energy diagram in Figure 12. Next, the $\text{O}-\text{CCl}_3$ species donates a chlorine atom to the lattice and removes an oxygen atom from the solid (Reaction Eq. (23)). This reaction step is similar to the first removal of a chlorine atom and results in the formation of phosgene. Phosgene is re-adsorbed and can again donate two chlorine atoms to the surface in exchange for an

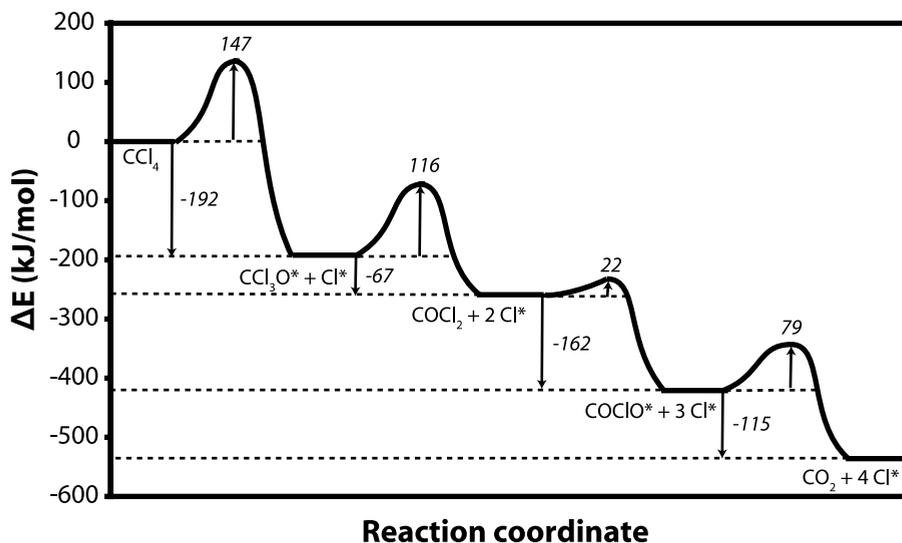

Figure 12. Energy diagram for CCl_4 decomposition on La_2O_3 (001). Reference energy is defined as $\text{CCl}_4 + 2 \text{H}_2\text{O} + \text{La}_2\text{O}_3$.⁷¹

The potential of La-based catalysts for chlorine management

oxygen atom (Reaction Eq. (24) and (25)). All reaction steps are exothermic and the first step (Reaction Eq. (22)) is predicted to be the rate-determining step in the destructive adsorption of CCl_4 .

The calculations were repeated for the destructive adsorption of CCl_4 over LaOCl (001).⁷¹ The reaction occurs via the same mechanism of step-wise donation of chlorine to the surface. The reaction energetics, on the other hand, are significantly different. Both the barrier for the formation of O-CCl_3 (Reaction Eq. (22)) and COCl_2 (Reaction Eq. (23)) are lower than for La_2O_3 at 73 and 24 kJ/mol, respectively. The barrier for steam dechlorination increases from around 180 to 506 kJ/mol compared to the reaction over La_2O_3 . These calculations suggest the catalytic destruction of CCl_4 consists of two self-accelerating reactions; the dechlorination reaction rate is expected to accelerate with decreasing catalyst chlorine content, whereas the destructive adsorption reaction rate is expected to accelerate with increasing chlorine content. Therefore, an optimal catalyst composition may exist, which balances both reactions.

Because the chlorination of the bulk phase during reaction was observed with Raman spectroscopy, calculations were performed on the diffusion of chlorine atoms on the surface and into the bulk.⁷¹ The chlorine atom is not limited to the position of the original oxygen atom. It was found that the barrier for surface diffusion is estimated at approximately 80 kJ/mol. The diffusion of chlorine atoms into the bulk is an endothermic process by 68 kJ/mol and results in migration of subsurface oxygen to the catalytic surface. The estimated activation energy is 208 kJ/mol, which is larger than for any of the destructive adsorption reaction steps. This means that the diffusion of chlorine into the bulk becomes the rate-determining step when no steam is added to the feed.

DFT calculations were also performed on the dechlorination of LaCl_3 .^{71, 72} The reactions are all predicted to be endothermic (Figure 13). Two reaction pathways are predicted, namely a step-wise hydroxyl formation and a subsequent dehydroxylation (Reaction Eqs. (26)-(28)), or by the reaction of surface chlorine and a hydroxyl group (Reaction Eqs. (26) and (29)). The latter reaction occurs at increased surface chlorine coverage. However, no significant differences in energetics were found with varying amounts of surface chlorine for the dechlorination steps of LaCl_3 .

The catalytic destruction of CCl_4 was performed on La_2O_3 and LaOCl samples and the gas phase composition was monitored with in situ infrared spectroscopy (IR).⁷⁵ It was found that the initial temperature of reaction is lower for LaOCl than for La_2O_3 (Figure 14). The initial temperature of reaction is not influenced by the amount of sample used. This means that the LaOCl phase is more active than La_2O_3 rather than possessing more active sites.

Chapter 1

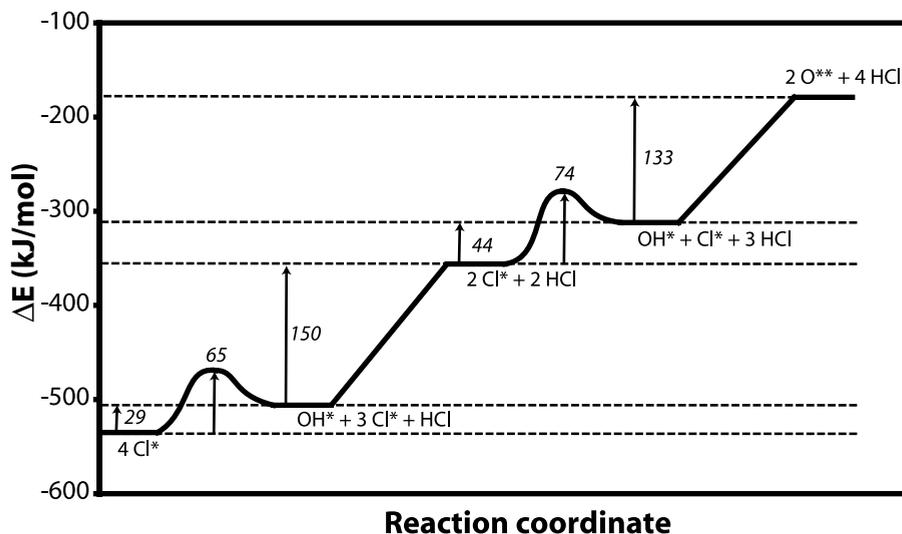

Figure 13. Energy diagram for removal of surface chlorine with steam on La₂O₃ (001). The reference energy is defined as CCl₄ + H₂O + La₂O₃.⁷¹

The calculations indicate that the rate-determining step is the dissociation of CCl₄ over an acid-base pair, resulting in the donation of a chlorine atom to the surface and the formation of O-CCl₃. The La³⁺ Lewis acid site initializes the split and the basic oxygen site stabilizes the remaining CCl₃ fragment. Therefore, the acid-base properties of the catalyst are expected to be of major influence on its activity for the destructive adsorption and catalytic destruction of CCl₄.

Acid-Base Properties of La₂O₃-based Catalysts

The acid-base properties of La₂O₃, LaOCl and LaCl₃ have been investigated using DFT calculations and IR probing with CO, pyridine, dimethylpyridine (DMP) and CO₂.⁷⁶ The adsorption of CO on the catalyst materials occurs at low temperature (77 K), and results in a shift of the CO vibrational frequencies for the adsorbed CO compared to the gas phase. The shift is a measure for Lewis acidity of the La³⁺ sites (Figure 15). The following trend in Lewis acidity was observed: La₂O₃ < LaOCl < LaCl₃. This Lewis acidity trend is confirmed by DFT estimates on CO adsorption and Lowest Unoccupied Molecular Orbital (LUMO) energies. The stronger basic molecules pyridine and DMP adsorb primarily on Brønsted acidic sites. In the case of LaOCl and LaCl₃ the probe molecules become protonated. By combining the probing experiment with pyridine and DMP with temperature programmed desorption, the same trend in acid strength was found as for the Lewis acid strength (Figure 16). The results for the Lewis and Brønsted acidity of the La-based materials are summarized in Table 7.

CO_2 was used as a probe molecule in combination with IR to evaluate the strength of the basic oxygen sites, because it readily reacts to form carbonates when adsorbed on a basic oxygen site.⁷⁶ Carbonates were indeed formed upon adsorption of CO_2 on La_2O_3 and LaOCl . On LaCl_3 no significant carbonate formation was observed, indicating an absence of oxygen adsorption sites on LaCl_3 . The carbonates on La_2O_3 were assigned as polydentate and bulk species, whereas bridged carbonates dominated the spectrum of CO_2 adsorbed on LaOCl . The experiments show that carbonates are formed more readily on La_2O_3 than on

Chapter 1

Arrows indicate chlorine atoms that can be substituted for an oxygen atom to obtain an additional equivalent surface oxygen site on LaOCl and LaCl_3 .⁷⁶

LaOCl , which suggests the oxygen adsorption sites are more basic on the former. However, the accurate determination of basicity of the La-based materials is hindered by the formation of different types of carbonates on each material.

The unit cells of the surface models that were used in the DFT calculations are shown in Figure 17. The energetics of the initial reaction step over La_2O_3 , LaOCl and LaCl_3 (partially dechlorinated surface) were calculated, as shown in Figure 18. The activation energy for the initial breaking of a C-Cl bond, which is considered the rate-determining step, follows the trend: $\text{La}_2\text{O}_3 > \text{LaCl}_3$ (partially dechlorinated surface) $> \text{LaOCl}$. The calculations suggest that the La^{3+} Lewis acid site initializes the reaction by elongating the C-Cl bond until chlorine is donated to the surface. The fact that LaOCl is a more active phase than La_2O_3 indicates that a different surface composition directly influences the activity. These two deductions are in agreement with the trend in Lewis acidity that was found from the IR probing results. However, a real connection between CHC destruction activity and the acid-base properties of the La-based catalysts is still missing.

Catalytic Destruction of CHCl_3 and CH_2Cl_2 in the Presence of Steam

CCl_4 is a model compound that only possesses C-Cl bonds, so the behaviour of C-H bond containing chlorinated C_1 (CHC_1) may differ from the reaction with CCl_4 . Moreover, the chlorinated waste mixtures (light ends) also contain other chlorinated methanes, such as CHCl_3 and CH_2Cl_2 . Therefore, $\gamma\text{-Al}_2\text{O}_3$ -supported and unsupported La_2O_3 catalyst were tested for the catalytic destruction of CHCl_3 and CH_2Cl_2 .^{71, 73}

The potential of La-based catalysts for chlorine management

Chapter 1

The activity results on the bulk catalyst show that the main difference with the catalytic destruction of CCl_4 was the formation of CO as the main product for both CHCl_3 and CH_2Cl_2 .^{71, 73} Trace amounts of CO_2 were also observed. The conversion after 7 h time-on-stream at 350 °C for all reactants over La-based catalysts is shown in Table 8. The conversion decreases with an increasing chlorine content of the reactant. This difference was attributed to the increasing number of C-H bonds ($E_b = 411$ kJ/mol) in the reactant, which is more difficult to break than the C-Cl bond ($E_b = 327$ kJ/mol). The fact that CO is formed and not CO_2 , is thought to be a result of the direct composition of the reaction intermediate according to Reaction Eqs. (30)-(33). This is, however, a hypothesis and should be considered with care, because no CH_2O , CHClO and H_2 were detected at any time. Minor coke formation was also observed in the reactions with CHCl_3 and CH_2Cl_2 in contrast to the reaction with CCl_4 .

When $\gamma\text{-Al}_2\text{O}_3$ -supported catalysts were used, the conversion was higher than for the bulk catalysts because of the increased surface area.^{71, 73} Moreover, in the case of CH_2Cl_2 the product distribution is completely different from that of the unsupported catalyst. CH_3Cl was also formed as a major product, which indicates that there must be two reaction mechanisms: one over La_2O_3 and one over the support. The nature of these reaction mechanisms was not investigated further, however. In summary, La-based catalysts are also active for the catalytic destruction of H-containing CHCl_1 . The reactions of CHCl_3 and CH_2Cl_2 over La_2O_3 resemble the catalytic destruction of CCl_4 (Reaction Eqs. (34) and (35)), but different products and activities were found.

Table 8. Catalytic activity (conversion in %) of bulk La_2O_3 , LaOCl and LaCl_3 for CCl_4 , CHCl_3 and CH_2Cl_2 destruction after 7 h on stream in the presence of steam at 350 °C. The reported activity of LaCl_3 materials should be considered with care since hydrated LaCl_3 easily transforms during heating in the reactor into LaOCl , so the activity of LaCl_3 could be partially due to the presence of LaOCl instead of LaCl_3 .⁷³

Compound	CCl_4	CHCl_3	CH_2Cl_2
La_2O_3	62	34	15
LaOCl	60	26	14
LaCl_3	5	24	11

Motivation and Outline of the PhD thesis

Catalytic conversion is a suitable method to lower the energy consumption of the destruction of the light and heavy ends during C_2H_3Cl production. In addition, the CHC_{1-2} could potentially be recycled into feedstock or fuel. Chlorine and chlorine-containing compounds are, however, known to be poisonous to many catalyst materials. Therefore, the challenge lies more in finding a suitable stable catalyst rather than a more active or selective catalyst. La_2O_3 -based catalysts are not only resistant to chlorine poisoning, but incorporation of chlorine ions into the lattice of the catalyst is in fact a way to tune activity and selectivity. This PhD thesis illustrates the versatility of La_2O_3 -based compounds as potential catalysts in chlorine-mediated organic reactions.

Chapter 2 deals with the relationship between activity and acid-base properties of La-based catalysts. La_2O_3 and $LaOCl$ were extensively characterized, making use of X-ray diffraction, X-ray photoelectron spectroscopy, Raman spectroscopy and IR spectroscopy, while their acid-base properties were probed with CO , CO_2 and methanol. As a result, it was possible to explain the difference in the reactivity of the catalysts towards CCl_4 in terms of difference in Lewis acid strength and density.

Chapter 3 provides a general reaction scheme for the destructive adsorption of the CHC_1 series, namely CCl_4 , $CHCl_3$, CH_2Cl_2 and CH_3Cl . In addition, the relationship between the composition of the catalyst and the observed activity and selectivity is discussed. In situ IR spectroscopy and GC analysis were used to monitor the reaction. As a result, fundamental insight is obtained into the intermediates of destructive adsorption when applying La_2O_3 -based materials to convert mixtures of CHC_1 . This is of high relevance when destroying the light ends in industrial waste streams.

In **Chapter 4**, it is shown that La_2O_3 -based materials are also a catalyst for the dehydrochlorination of chlorinated ethanes. Elimination of HCl over the catalyst materials results in the formation of a $C=C$ bond. The dehydrochlorination of several chlorinated ethanes, namely C_2H_5Cl , $1,2-C_2H_4Cl_2$ and $1,1,2-C_2H_3Cl_3$, was performed as a function of time and temperature. The reactor effluent in flow-gas experiments was continuously analyzed with GC. Moreover, before and after reaction, the catalytic surface and bulk phase of the catalyst material was characterized using XPS and XRD, respectively. The dehydrochlorination of $1,1,2-C_2H_3Cl_3$ was also performed as a function of temperature, while the gas phase was analyzed using IR. The results illustrate how the chlorination degree of the catalyst material directly influences the selectivity in the dehydrochlorination reaction. This reaction is not only interesting for the conversion of chlorinated ethanes in waste streams, but could also be applied to enable selective cracking of $1,2-C_2H_4Cl_2$ into C_2H_3Cl under less costly conditions.

Chapter 5 discusses $LaCl_3$ as a catalyst for the hydrogen-chlorine exchange reaction between CH_2Cl_2 and CCl_4 into $CHCl_3$. This is the first time that the activation of $C-Cl$ and $C-H$ bonds is performed catalytically without the presence of oxygen atoms. In this reaction, the reactants are run over a fully chlorinated catalyst in order to prevent destructive adsorp-

Chapter 1

tion. Both bulk phase and carbon nanofiber-supported LaCl_3 catalysts are used. The reaction was monitored in a flow-gas experiment as a function of temperature and time using GC. In addition, DFT calculations were performed on the H-Cl exchange reaction between CCl_4 and CH_2Cl_2 to gain insight into the reaction steps. The exchange of H and Cl between CHCs under oxygen-free conditions is a new catalytic process and may be applicable for the selective conversion of chlorinated waste compounds, but it could also be used for the selective activation of hydrocarbons, such as methane or ethane.

In **Chapter 6**, the potential of the La-based materials for the conversion of CHC_{1-2} is explored in a series of flow-gas experiments. A mixture of chlorinated methanes and ethanes are converted over La_2O_3 -based materials to verify whether the dehydrochlorination and destructive adsorption can occur simultaneously in one reactor, as would be case for the light ends waste mixtures. Also, CCl_4 is tested as an alternative chlorinating agent for HCl in the conversion of methane into CH_3Cl . The low economic value of CCl_4 in comparison to HCl would make the process economically more favourable and serve as a route for the disposal of the undesirable CCl_4 . Finally, a combination of La_2O_3 and SAPO-34 material was used as a test-case for the one-pot conversion of chlorinated waste compounds into products, such as fuel or chemical intermediates. CH_2Cl_2 was used as reactant and was converted via destructive adsorption over La_2O_3 into CH_3OH , which is consecutively converted into hydrocarbons via the methanol-to-olefin reaction over SAPO-34.

Chapter 7 consists of a summary of this PhD thesis and a look into the future. It provides the main conclusions as well as some comments with respect to future research on this topic.

Conversion of Chlorinated Waste Streams from the Production of Polyvinyl Chloride
over La-Based Catalysts

Destructive Adsorption of CCl_4 over La-Based Solids: Linking Activity to Acid-Base Properties

In previous research it was found that La_2O_3 -based catalysts offer the best combination of activity and stability for the catalytic destruction of chlorinated C_1 (CHC_1). In this chapter, the synthesis and physicochemical properties of La_2O_3 , LaOCl and LaCl_3 are discussed. The chapter starts with an introduction and hypothesis regarding the link between acid-base properties and activity of La_2O_3 -based materials for the destructive adsorption of CHC_1 . Next, the experimental method of catalyst preparation and characterization using X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS), scanning electron microscopy (SEM), N_2 -physisorption, temperature programmed desorption (TPD) of CO_2 , infrared (IR) and Raman spectroscopy are provided. Also, the experimental setups for the activity measurements and the IR probing experiments used throughout this PhD thesis are presented. Two factors were found to be of influence on the activity of La_2O_3 -based materials for the destructive adsorption of CCl_4 ; the strength of the Lewis acid site and the availability of lattice oxygen. A higher degree of chlorination results in stronger Lewis acid sites and hence, higher intrinsic activity. However, a certain number of O atoms is needed to maintain activity. Therefore, an optimum combination of the acid-base pair is expected to exist in a suitable catalytic material.

Introduction

As discussed in Chapter 1, in previous work it has been shown that of all basic oxides, La_2O_3 -based catalysts possess the optimal combination of activity and regeneration for the destructive adsorption and catalytic destruction of chlorinated hydrocarbons.¹⁻⁴ La_2O_3 is not the most basic of the metal oxides, so basicity is not only of influence. The activity for destructive adsorption is higher, for example, in BaO . In fact, the high destructive capacity of La_2O_3 lies in the regeneration potential with steam. This reaction relies heavily on the mobility of lattice oxygen atoms.

La_2O_3 -based materials have high oxygen mobility and La^{3+} has been used as a dopant to increase oxygen mobility in catalysts.⁵ This mobility is important for the regeneration of lattice oxygen. Oxygen atoms from water are converted into lattice oxygen at the catalytic surface of the solid under formation of HCl . Bulk phase conversion from LaCl_3 into LaOCl was detected, however, indicating that the diffusion of oxygen in the lattice is significant.^{1-3, 4} Therefore, destructive adsorption, which results in chlorination of the catalyst, should be investigated in order to gain fundamental understanding on the conversion of CHCs over La-based catalysts.

It was found that La_2O_3 and LaOCl are active for the destructive adsorption of CCl_4 , although the latter is the more active phase.⁶ From previous density functional theory (DFT) calculations, in combination with IR probing experiments, a general trend was observed: surface basicity decreases in the order $\text{La}_2\text{O}_3 > \text{LaOCl} > \text{LaCl}_3$.^{6, 7} However, a real connection between CHC_1 destruction activity and the acid-base properties of the La-based catalysts is still missing. Therefore, in this chapter we focus on the physicochemical properties of La_2O_3 -based materials in relation to the activity for the destructive adsorption of CCl_4 . The goal of this chapter is to establish the link between acid-base properties of La-based solids and their destructive adsorption capacity behaviour for CCl_4 . For this purpose, two distinct LaOCl materials have been prepared and characterized in detail, making use of X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS), temperature programmed desorption (TPD) of CO_2 , Raman spectroscopy, scanning electron microscopy (SEM) and IR spectroscopy (IR), while their acid-base properties were probed with CO , CO_2 and CH_3OH . As a result, it was possible to explain the difference in the reactivity of both solids in terms of difference in Lewis acid strength. This fundamental information provides guidelines for designing new catalyst materials with improved activity for the destruction of CHCs.

Destructive adsorption of CCl₄ over La-based solids

Experimental

Materials synthesis

Commercial samples of La₂O₃ (Acros Organics, 99.99 %, surface area of 1 m²/g and pore volume of 0.004 mL/g) and LaCl₃·7H₂O (Acros Organics, 99.99 %, surface area of 6 m²/g and pore volume of 0.03 mL/g) were used without additional purification. Two LaOCl materials were synthesized and are further denoted as LaOCl-S (S = solid state) and LaOCl-P (P = precipitation), with the labels indicating the preparation method.

LaOCl-S was synthesized by a solid-state reaction according to Reaction Eq. (1). An equimolar mixture of La₂O₃ (Acros Organics, 99.99 %) and LaCl₃·7H₂O (Acros Organics, 99.99 %) was exposed to a 20 mL/min flow of O₂ (Hoekloos, 99.995 %) at 700 °C.⁸

LaOCl-P was prepared by a precipitation process using LaCl₃·7H₂O (Acros Organics, 99.99 %) as a precursor and an aqueous NH₄OH (Acros Organics, 28-30 wt% in H₂O, p.a.) solution (Reaction Eq. (2) and (3)). The obtained gel was filtered, washed, dried at 120 °C and subsequently heated at 550 °C in pure N₂ (Hoekloos, 99.9 %) for 6 h.⁹

Experimental setups

This section provides information on the IR cell combined with a vacuum system and the setup used for the activity experiments with online GC analysis. These home-built setups are discussed in detail because they are also used for experiments described in other chapters of this PhD thesis.

The quartz IR static vacuum cell is schematically shown in Figure 1. The lower part (Figure 1a) is built up from an oven region and the region where the IR beam passes through two KBr windows. The sample holder (Figure 1c) is placed inside the lower part of the cell, after which the upper part (Figure 1b) is connected. The sample holder, which has a piece of soft-iron incorporated, can be placed in two positions using a magnet: the sample is in the pathway of the IR beam, or the sample is hanging in the oven region. When it is in the IR beam, the sample holder is supported by the bottom of the cell. It is suspended in the oven region by using a second magnet to move a glass pin, also with soft iron incorporated, into the ring of the sample holder. In this manner, the sample can be heated, but this also enables measurement of a gas phase spectrum independent of the wafer. The oven region

Chapter 2

can be heated to a maximum temperature of 550 °C.

The IR cell is connected to a vacuum system, which makes pre-treatment under vacuum conditions possible and is used to introduce reactants and probing compounds into the cell (Figure 2). A turbo pump enables pre-treatment of the sample at low pressure (mini-

Destructive adsorption of CCl₄ over La-based solids

mum = 10^{-6} mbar). A membrane pump is connected to create a pre-vacuum for the turbo pump (minimum = 10^{-3} mbar) and to remove reactants and probing compounds from the cell. Liquid reactants and probing compounds are evaporated by injection via a septum into an evacuated flask under static vacuum, which was connected to the vacuum system. Gas phase reactants are led into the system by connecting gas cylinders to the vacuum systems via a pressure reducer. The system also contains two digital pressure meters to monitor the pressure of the reactants and probing compounds independently of the pressure in the vacuum cell.

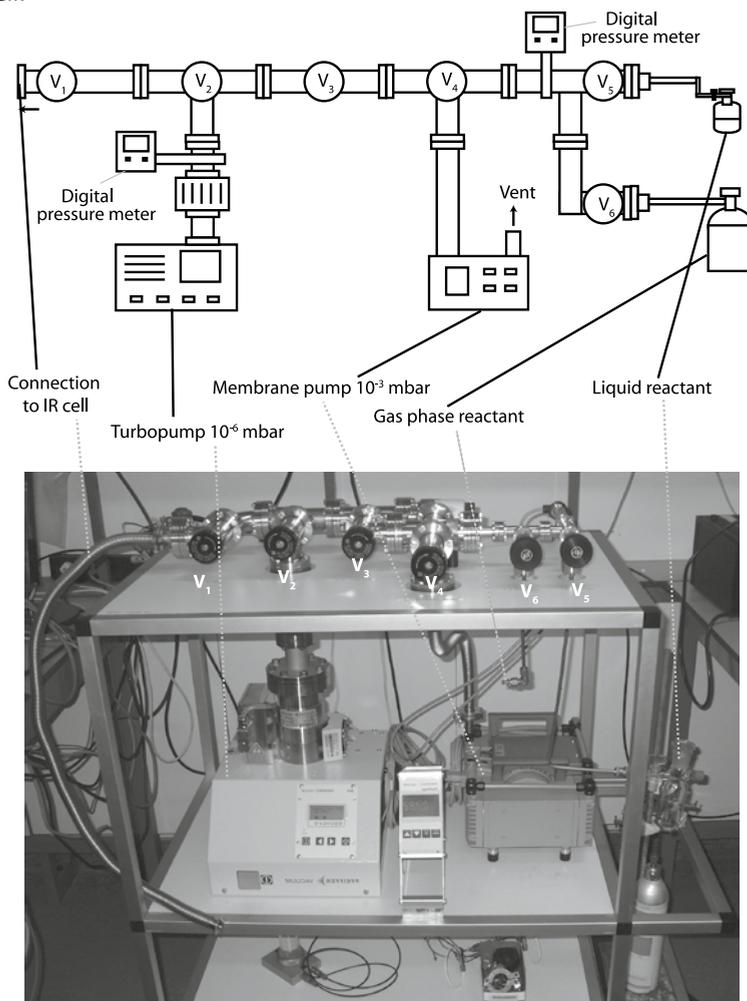

Figure 2. Schematic drawing and picture of the vacuum system connected to IR cell in Figure 1. V₁₋₆ indicate open/close volumes which are used to regulate pressure in the cell and the vacuum system.

Chapter 2

The experimental setup used for the activity experiments is shown in Figure 3. The setup consists of three main parts: the automatic mass flow controller (MFC) system for the generation of the reactant feed, the oven containing the reactor and catalyst bed, and the online gas chromatograph (GC). The MFCs (Brooks 0-100 mL) and the oven are controlled by Labview and the GC is controlled by EZChrom 3.2.

The reactant flow is generated by running He through a bubbler containing a volatile liquid compound. The bubbler can be placed in an ice bath to keep the vapour pressure, and consequently the reactant concentration, constant. The concentration resulting from the He and CHCl_{1-2} vapour ranges between 0 and 10 vol% CHCl_{1-2} in He. In this manner, two flows can be generated based on volatile liquid CHCl_{1-2} (MFC 1 and 2). MFC 3 is a MFC which can be used for various gas phase reactants. The gas phase reactant is then diluted to the desired concentration with He provided by MFC 1 or 2 without a bubbler. The flow is led to

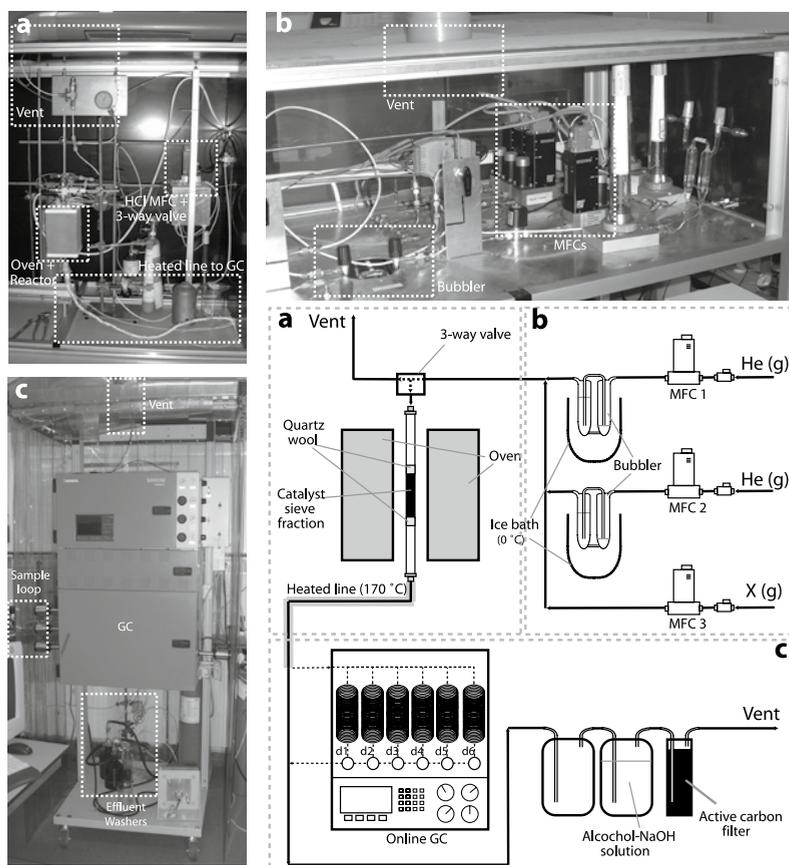

Figure 3. Schematic drawing and pictures of the setup used for catalytic activity experiments for reactions with CHCl_{1-2} . (a) MFC system, (b) Oven and reactor, and (c) GC and effluent purification. X represents any gas different from He.

Destructive adsorption of CCl₄ over La-based solids

the reactor via a three-way valve, which is also connected to the vent. The three-way valve can be switched to the vent to stabilize the reactant flow concentration before contact with the catalyst and to release over-pressure. The catalyst sieve fraction is fixed between two quartz wool wads in a quartz tubular fixed bed reactor, which is positioned vertically in a tubular oven with the gas inlet at the top. The flow runs from the reactor through a heated line (170 °C) to prevent condensation of the reactants and products. This line is made of stainless steel of which the inside is fused with silica to prevent corrosion as a result of reaction products.

The composition of the reactor effluent was analyzed by a custom-built Siemens Maxum Edition 2 gas chromatograph with a sampling time of 240 s connected via a sample loop. The connectors and valves in the GC are made out of corrosion-resistant Hastelloy-C alloy. The GC contains four separate columns and detectors, which are each calibrated for a different group of compounds. All detectors are thermal conductivity detectors (TCD) using He as carrier gas. The chromatograph columns are positioned into two separate oven parts, which are kept by at 80 and 120 °C means of an air bath. The different groups of chemicals that are analyzed by each column are shown in Table 1. The gas flow finally passes through an alcohol-NaOH solution and an active carbon filter to remove acidic products and volatile organics, respectively, before it is released into the vent. The entire GC was positioned under ventilation surrounded by transparent plastic sheets to optimize the suction of the vent (Figure 3c). Both the reactor (Figure 3a) and the mass-flow controller system (Figure 3b) were positioned in closed compartments with separate connections to the ventilation.

Table 1. Siemens Maxum GC columns and the respective compounds for which each column was calibrated.

Column Name	Column T (°C)	Detected compounds
RR1 T1	80	O ₂ , N ₂ , Ar, CH ₄ and CO
RR2 T2	80	CH ₄ , CO ₂ , C ₂ H ₄ and C ₂ H ₆
RR3 T3a	80	CH ₄ , CO ₂ , C ₂ H ₄ , C ₂ H ₆ and HCl
RL2 T5a	120	CCl ₄ , CHCl ₃ , CH ₂ Cl ₂ , CH ₃ Cl, CH ₃ OH, 1,1,2-C ₂ H ₃ Cl ₃ , 1,2-C ₂ H ₄ Cl ₂ , C ₂ H ₅ Cl, 1,1-C ₂ H ₂ Cl ₂ , cis-1,2-C ₂ H ₂ Cl ₂ , trans-1,2-C ₂ H ₂ Cl ₂ , C ₂ H ₃ Cl and C ₂ HCl not calibrated: CH ₄ , H ₂ O, CO, CO ₂ and HCl

Characterization

The phase purity of the La-based materials was checked with XRD. The XRD measurements were collected at ambient conditions with a Bruker-Nonius PDS 120 powder diffractometer system, equipped with a position-sensitive gas-filled detector of 120° 2θ, using Co K_{α1} radiation (λ = 1.78897). A Phillips XL-30 field emission gun (FEG) scanning electron

Chapter 2

microscope was used to obtain SEM images. XPS spectra were acquired using a Perkin-Elmer (PHI) model 5500 spectrometer. All spectra were obtained using samples in the form of pressed wafers. XPS data were obtained for LaOCl-S and LaOCl-P, before and after (only for LaOCl-S) reaction with CCl_4 . Raman spectra were recorded with a Holoprobe Kaiser Optical spectro-meter equipped with a holographic notch filter, CCD camera, and 532 nm laser. All spectra were measured under ambient conditions. The specific surface area and pore volume have been determined by N_2 sorption measurements with a Micromeritics accelerated surface area and porosimetry ASAP 2400 instrument. Surface areas were calculated by using the BET model with micro- and macropores described by the Horvath-Kawazoe and BJH models, respectively.

IR spectra of the probing measurements with CH_3OH and CO_2 were collected using a Nicolet 550 spectrometer with a resolution of 4 cm^{-1} . The IR quartz cell described in the previous section was used at room temperature (RT). The samples, were pressed into self-supported 2 cm^2 disks and activated in situ prior to IR measurements in vacuum ($\sim 1 \cdot 10^{-4}\text{ Pa}$) at $550\text{ }^\circ\text{C}$. CH_3OH (Sigma-Aldrich, 99.9+ %) was initially dosed to an equilibrium pressure of 1.3 mbar. The gas was then progressively evacuated at RT and then at increasing temperatures up to $200\text{ }^\circ\text{C}$. CO_2 (Air Liquide, Inc., 99.99+ %) was dosed in steps to equilibrium pressures up to 6.5 mbar.

For CO sorption, a stainless steel IR cell was equipped with crystalline ZnSe inner windows, which, in combination with the outer KBr windows, allowed it to collect spectra in the region of $4000\text{-}500\text{ cm}^{-1}$, while the temperature increased from -195 to $25\text{ }^\circ\text{C}$. The samples were pressed into self-supported 2 cm^2 wafers and activated in situ prior to IR measurements in a vacuum at 550°C for 2-3 h. Before CO introduction, the samples were cooled to the corresponding experimental temperatures ($-195\text{ }^\circ\text{C}$) under a vacuum of $5 \cdot 10^{-5}$ mbar. It is important to note that the cell should be cooled below $0\text{ }^\circ\text{C}$, keeping the sample in the upper part of the cell to prevent the humidity absorbed on the cell walls to reach the sample surface. CO was dosed at $-195\text{ }^\circ\text{C}$ to ~ 6 mbar equilibrium pressure of CO and progressively desorbed in a closed cell by raising the temperature in the range from -195 to $25\text{ }^\circ\text{C}$. In this case, the pressure inside the cell rose to 10-12 mbar because of desorption and cell heating. The low temperature IR spectra were recorded using a Bruker IFS166 spectrometer with 3 cm^{-1} spectral resolution.

TPD experiments with CO_2 were performed in a tubular reactor under a He flow with the effluent analyzed by a Micromeritics Autochem II chemisorption analyzer. The heating rate was $5\text{ }^\circ\text{C}/\text{min}$. Atmospheric CO_2 was adsorbed after long-term exposure to air at ambient conditions. No pre-treatment was used for these experiments.

Activity experiments

The activity measurements for the destructive adsorption of CCl_4 were performed with the experimental setup shown in Figure 3. The catalyst bed consisted of 1.0 g of sample

Destructive adsorption of CCl₄ over La-based solids

pressed in a 150-500 μm sieve fraction, pretreated in a 10 mL/min He flow at 550 $^{\circ}\text{C}$. In the case of La_2O_3 , the pretreatment was under O_2 flow instead of He. To find the initial reaction temperature, the reaction was carried out from 50 to 400 $^{\circ}\text{C}$ using a 20 mL/min 6 vol % CCl_4/He flow. This flow was generated by bubbling He through a bubbler containing CCl_4 for 30 min out through a vent. Once stabilized, the flow was led over the reactor bed. The temperature of the reactor was raised from 50 to 400 $^{\circ}\text{C}$ in steps of 10 $^{\circ}\text{C}$. The heating ramp was 3 $^{\circ}\text{C}/\text{min}$, and after each step of 10 $^{\circ}\text{C}$, the temperature was held constant for 5 min. In the case of LaOCl-S and LaOCl-P , the reactions were also performed at a constant temperature of 200 $^{\circ}\text{C}$. The flow was stabilized as described above and led over the pre-treated reactor bed at 200 $^{\circ}\text{C}$. The composition of the reaction mixture was analyzed with time by GC.

Results and Discussion

Materials synthesis and characterization

Table 2 summarizes the physicochemical properties of the La-based materials under study. The N_2 sorption results show that LaOCl-P has a relatively large surface area and pore volume. La_2O_3 possesses a lower surface area, pore volume and average pore size than LaOCl-S and LaOCl-P . LaOCl-P shows a more open structure compared to LaOCl-S and La_2O_3 . More importantly, the high surface area means that there will be more reaction sites available for LaOCl-P than for LaOCl-S and La_2O_3 . The XRD patterns of LaOCl-S and LaOCl-P are shown in Figure 4 and resemble those of tetragonal LaOCl .¹⁰ As a reference, the diffractogram of La_2O_3 is included in Figure 4, and the XRD 2θ positions and intensities for LaOCl ,¹⁰ LaCl_3 ,¹¹ and $\text{La}_2\text{O}(\text{CO}_3)_2$ ¹² are summarized in Table 3.

However, both the reflection intensities and the background level clearly vary with the preparation method. Intense and sharp reflection peaks associated with a very weak back-

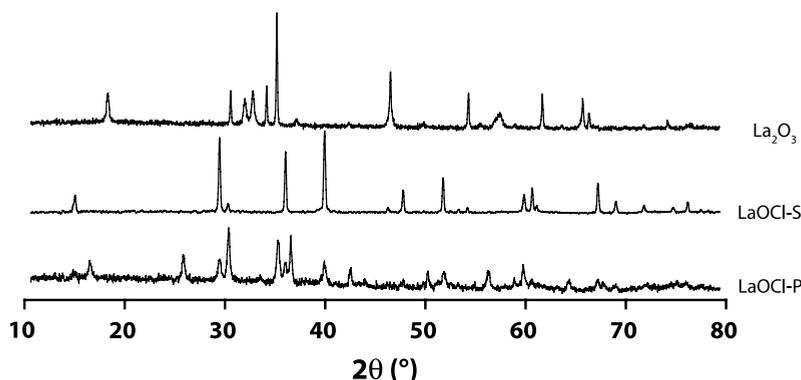

Figure 4. X-ray diffractogram of La_2O_3 , LaOCl-S , and LaOCl-P materials measured under ambient conditions.

Chapter 2

ground are observed for LaOCl-S, pointing out the high crystallinity of this sample. In contrast, the XRD patterns of LaOCl-P features broad reflections of very low intensity compared to LaOCl-S, while the background level is particularly high.

Table 2. Physicochemical properties of the La-based catalyst materials under study, together with the surface composition and phase purity as determined with XPS, XRD and Raman (na = not applicable).

Sample name	Surface area (m ² /g)	Pore volume (mL/g)	Average pore size (nm)	Surface composition as determined with XPS		Phases as determined with Raman	Phases as determined with XRD
				O/La	O/Cl		
La ₂ O ₃	1	0.001	14.3	0.34	na	La ₂ O ₃	La ₂ O ₃ La carbonates
LaOCl-S	6	0.040	23.6	0.17	2.78	LaOCl	LaOCl
LaOCl-P	36	0.300	34.0	0.14	1.80	LaOCl	LaOCl LaCl ₃ La carbonates
LaCl ₃	6	0.030	22.4	na	na	LaCl ₃	LaCl ₃

This indicates that LaOCl-P contains a small number of LaOCl crystallites embedded in an amorphous phase. Also, additional peaks are present in the XRD of LaOCl-P. When compared to reference materials,^{11, 12} a large amount of La₂O(CO₃)₂ was found to be present in LaOCl-P. The lanthanum carbonates are most likely formed with CO₂ from the water or the air during precipitation. The carbonates are very stable and remain in the material up to a temperature of 750 °C.⁶ SEM photographs of LaOCl-S and LaOCl-P are presented in Figure 5. LaOCl-S shows a very homogeneous distribution of polycrystallites with lengths of ca. 4 μm and thicknesses of < 1 μm. This particular shape of grains reflects well the layered crystal-line structure of LaOCl. The SEM picture of LaOCl-P sample shows polycrystallites of small size having a rodlike shape. The difference in morphology as concluded from the XRD data is therefore confirmed by these SEM images.

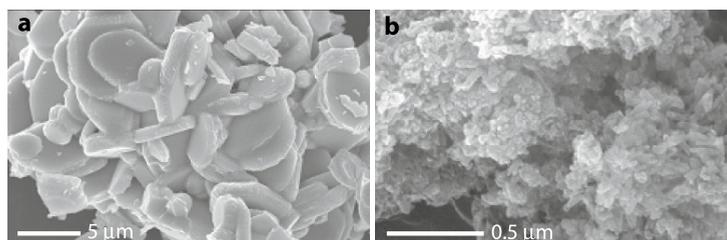

Figure 5. Scanning electron micrographs of (a) LaOCl-S and (b) LaOCl-P materials.

Destructive adsorption of CCl₄ over La-based solids

The Raman spectra presented in Figure 6 both show that the main phase of LaOCl-S and LaOCl-P is LaOCl, as evidenced by the bands at 331 and 437 cm⁻¹.^{13, 14} Especially, the Raman spectrum of LaOCl-P shows other bands at 413, 392, 363, 302, 243 and 224 cm⁻¹. No reference was found with respect to these bands, but they possibly result from bulk lanthanum carbonate. However, the Raman band indicative of carbonates around 1000 cm⁻¹ is not observed in the spectrum, and it is presently unclear why these differences occur between

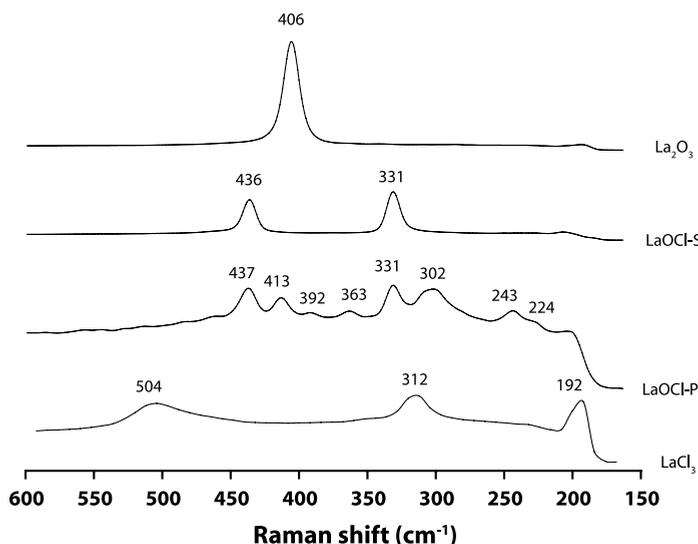

Figure 6. Raman spectra of La₂O₃, LaOCl-S, LaOCl-P and LaCl₃ materials measured under ambient conditions.

Table 3. XRD positions and relative intensities for LaCl₃, LaOCl, and La₂O(CO₃)₂.¹⁰⁻¹²

LaOCl		LaCl ₃		La ₂ O(CO ₃) ₂	
2θ (°)	Relative intensity	2θ (°)	Relative intensity	2θ (°)	Relative intensity
25.9	326	15.9	999	14.9	400
29.3	290	27.7	315	29.3	1000
30.0	747	28.6	520	35.8	1000

		71.0	130	86.9	500

Chapter 2

XRD and Raman. The bands at 413, 363, 302, 243 and 224 cm^{-1} may therefore result from the background and have become visible because of the low intensity of the LaOCl bands. XPS also provides information regarding the phase purity of LaOCl-S and LaOCl-P. According to Table 1, the O/La surface ratio for La_2O_3 is 0.34 and for LaCl_3 is 0. For LaOCl-S, the value of 0.17 again shows that it is a very pure LaOCl phase. LaOCl-P has a slightly lower O/La ratio and should therefore be more chlorinated.

Activity Experiments

In a first series of experiments, we have studied the destructive adsorption of CCl_4 over La_2O_3 , LaOCl-S, and LaOCl-P and LaCl_3 as a function of the reaction temperature. Figure 7 only shows the conversion of CCl_4 to CO_2 for three materials, because no significant activity was observed for LaCl_3 . The first CO_2 is detected at 300 °C for La_2O_3 , and a sharp increase in the amount of CO_2 is observed at higher temperatures. The formation of carbonates by re-adsorption of CO_2 might delay the detection of CO_2 . However, in previous TPD measurements¹⁵ CO_2 was already released at 230 °C from La_2O_3 which contained carbonates. Since, during the experiment, CO_2 is not detected until 300 °C, the interference of carbonate formation with our experiments is not likely. The initial reaction temperature is at approximately 170 °C for both lanthanum oxychloride materials. This is at a much lower temperature than

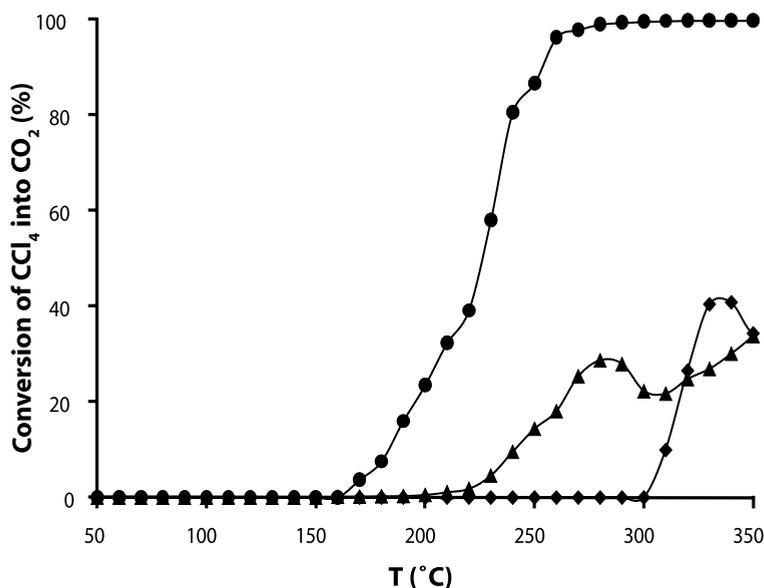

Figure 7. Conversion of CCl_4 to CO_2 measured at 200 °C for samples La_2O_3 (♦), LaOCl-S (▲) and LaOCl-P (●) as a function of temperature.

Destructive adsorption of CCl_4 over La-based solids

for La_2O_3 , indicating that both LaOCl materials are more active than La_2O_3 .

Since the samples become chlorinated during the reaction, the initial temperature of reaction is the only information available from these measurements. To be able to compare LaOCl-S and LaOCl-P, the materials were tested for the CCl_4 destruction reaction at constant temperature of 200 °C as well. The results are shown in Figure 8. In the first part of the measurement, the conversion is constant and controlled by the transformation of CCl_4 into the products. It should be noted that for LaOCl-P, the conversion is 100% in the first part of the curve and that its destruction capacity may be higher than indicated by these results. Then, as the rate of conversion decreases, bulk diffusion limitations take effect. After this, the conversion stabilizes and reaches a steady state, where the reaction is controlled by diffusion of oxygen to the surface and chlorine to the bulk. In the case of LaOCl-S, the steady-state conversion as a result of solid-state O/Cl diffusion is close to zero due to its low surface area. Eventually, the materials will become deactivated, and the conversion drops to zero.

After reaction at constant temperature, resulting in deactivation, XPS and Raman were performed on the deactivated LaOCl-S sample. LaOCl-P was not measured in this way, since it took very long to deactivate. The Raman spectra before and after reaction did not show any change in band positions or intensity. Apparently, no change in the bulk phase was observed as a result of the reaction. The XPS results tabulated in Table 4 show a relative decrease in oxygen and an increase of chlorine at the surface. Even though LaOCl-S has become deactivated, oxygen is still present at the surface. The final chlorine content increases with the reaction temperature. Higher temperatures result in a prolonged O/Cl bulk/surface diffusion and bulk diffusion decreases as the chlorine content increases. However, an increased temperature facilitates O/Cl diffusion, allowing it to continue even at higher chlorine content.

Chapter 2

LaOCl-P has a much higher destruction activity, which was expected in view of the high surface area of LaOCl-P. Therefore, the conversion has to be normalized to enable a fair comparison between the activities of LaOCl-S and LaOCl-P. The conversion, 8% for LaOCl-S and 100% for LaOCl-P, is divided by the surface area to get the activity per square meter of material. During the reaction, the surface area that was calculated with N₂ physisorption changes as a result of the chlorination. For the first area of the curves, the change in surface area is assumed not to be significant. For LaOCl-S and LaOCl-P, respectively, the destructive capacities were 4.2·10⁻⁷ and 8.7·10⁻⁷ mol CO₂ formed per square meter of material per minute. However, for LaOCl-P, the obtained destructive adsorption is a lower limit. So, after normalization, LaOCl-P is over twice as active as LaOCl-S. The key factor in the activity is the strength of the acid-base couple responsible for the reaction.¹⁶ The Lewis acid site initiates the reaction by splitting off a chlorine atom. Therefore, the trend in activity, La₂O₃ < LaOCl-S < LaOCl-P, parallels the trend in surface acidity. However, LaCl₃ is not active for the destructive adsorption of CCl₄, even though it is more acidic than the other materials. This is because of the absence of basic oxygen sites, which stabilize the CCl₃ fragment remaining after the initial split of a chlorine atom by the acid site. Moreover, the absence of oxygen simply implies that no stoichiometric reagent is available for CO₂ formation. The difference in destructive capacity between LaOCl-S and LaOCl-P is expected to be linked to a difference in acid-base properties between them, in particular to the strength of the Lewis acid sites. Therefore, the LaOCl materials were further studied with probe molecules in combination with IR spectroscopy.

Table 4. O/Cl ratio measured by XPS of sample LaOCl-S before and after reaction with CCl₄ until deactivation at various temperatures.

Sample	O/Cl
• Before reaction	• 2.8
• Deactivated after reaction at 200 °C	• 1.7
• Deactivated after reaction at 210 °C	• 1.6
• Deactivated after reaction at 220 °C	• 1.4

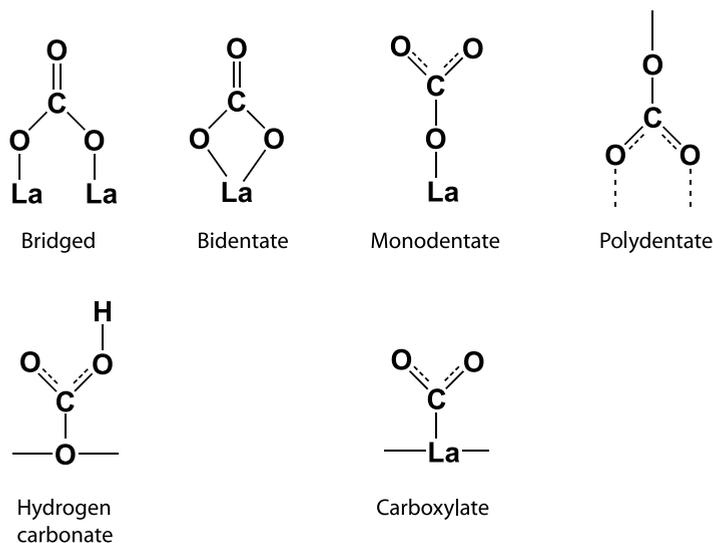

Materials acid-base properties

CO₂ was adsorbed to probe the basicity of the materials under study. CO₂ can act as a Lewis acid toward either O²⁻ surface ions resulting in the formation of carbonate species, or residual basic OH surface species resulting in the formation of hydrogen carbonates. Furthermore, CO₂ can act as a Lewis base and form carboxylates. The possible compounds resulting from CO₂ coordination are described in Scheme 1.¹⁵ For the carbonates, the principal anchoring structures are included in this scheme. The IR spectra after CO₂ adsorption for LaOCl-S and LaOCl-P are shown in Figure 9. The spectra were obtained by subtraction of the spectrum measured directly after pre-treatment. In all spectra, the spectrum of gas phase

Destructive adsorption of CCl₄ over La-based solids

CO₂ was subtracted in order to display only the surface species. They were also normalized for the amount of sample and the surface area.

The band around 1450 cm⁻¹ in the spectrum of LaOCI-P appeared as a result of the subtraction. For LaOCI-S, three main bands were observed at 1589, 1423, and 1266 cm⁻¹. Smaller bands were present at 2349, 1523, 1326, and 1200 cm⁻¹. Bands, which are not shown here, were also detected at 1036, 845, 826, 729, 708, and 669 cm⁻¹. The latter is

Chapter 2

a bending mode of molecular CO₂. The band at 2349 cm⁻¹ was only observed at high equilibrium pressures. This band is generated by the coordination of CO₂ on Lewis acid sites of the surface. The main band at 1423 cm⁻¹ has been attributed to the doubly degenerated asymmetric ν_3 stretch of the free carbonate ion.¹⁷ In the present case, it corresponds to a polydentate carbonate, having a strong ionic character. In the adsorbed state, the symmetry of the carbonate ion is lowered, and the species generally present two split $\nu(\text{CO})$ bands at either side of the band at 1423 cm⁻¹.¹⁸ This is the case for the other two main bands at 1589 and 1266 cm⁻¹, which are both at 166 cm⁻¹ from this band. The bands at 1523 and 1326 cm⁻¹ are also coupled with a $\Delta\nu_3 = 100$ cm⁻¹, where $\Delta\nu_3$ is the difference in frequency between the ν_3 stretch of the free carbonate ion and the split bands. It has been shown that bidentate carbonate species generally present a $\Delta\nu_3$ split between 150 and 300 cm⁻¹, and bridging carbonate species have a $\Delta\nu_3$ split above 300 cm⁻¹.¹⁸ The bands with $\Delta\nu_3 = 100$ cm⁻¹ are indicative of either monodentate or polydentate carbonates.

Using these considerations, we can unfortunately not distinguish between monodentate and polydentate carbonates, except for their thermal stability, with the former being less stable at higher temperature. The relative intensities of the bands in the spectrum of LaOCl-S would then be attributed to a low concentration of monodentate or polydentate carbonates and a high concentration of bidentate carbonate. Also, the band at 845 cm⁻¹ is attributed to the $\nu(\text{CO}_3)$ of bidentate carbonate,¹⁸ and the band at 1036 cm⁻¹ has been attributed to the symmetric C-O stretching of bidentate carbonate.¹⁷ The presence of a weak, but sharp band at 1201 cm⁻¹ could be indicative of the presence of hydrogen carbonates ($\partial(\text{OH})$ mode).¹⁸ In such case, the corresponding stretching modes will be found at around 1600 cm⁻¹ (a shoulder in the high-wavenumber tail of the bidentate carbonate band) and below the 1266 cm⁻¹ peak. The corresponding $\nu(\text{OH})$ mode could be guessed at around 3624 cm⁻¹, but that region is however very noisy. If confirmed, the presence of hydrogen carbonate species will be indicative of the basicity of hydroxyl groups.

In the spectra of LaOCl-P, the band of weakly adsorbed CO₂ is also present, but the band is present in all spectra and not just at a high equilibrium pressure. This indicates that these species are more strongly adsorbed and that the Lewis sites are more acidic. In fact, the band is also slightly shifted to lower wavenumbers. The IR spectra are very different from those of LaOCl-S in the carbonate region. A broad set of bands is present even at low equilibrium pressure. A similar spectrum was obtained for CO₂ adsorption on La₂O₃ as reported by Manoilova et al.⁶ Also, the IR spectrum of La₂(CO₃)₃ is characterized by these absorption bands between 1650 and 1250 cm⁻¹ with two peaks at 1494 and 1390 cm⁻¹.¹⁹ The bands at 1654, 1612, and 1275 cm⁻¹ were also observed by Manoilova et al. in the spectra of LaOCl and were attributed to bridged carbonate. In that case, however, these bands appeared simultaneously with another band due to bridged species on two different O adsorption sites. In the case of LaOCl-P, they are not coupled, indicating that the two O adsorption sites of these bridged species are not different. Another interpretation is that the band at 1612 cm⁻¹ would be assigned to hydrogen carbonates, which are confirmed for LaOCl-P by the modes at 1211 and 3624 cm⁻¹. So, only the bands at 1654 and 1275 cm⁻¹ are likely to be assigned

Destructive adsorption of CCl₄ over La-based solids

to a single species of bridged carbonates. Previously, the IR frequencies for monodentate, bridged, and polydentate carbonates have been calculated by DFT,⁷ but the geometries for the bridged type tended to converge into the polydentate structure. This may explain the observed difference between the calculated⁷ and experimentally observed frequencies.

To discriminate between the presence of either polycarbonate or monodentate carbonate on LaOCl-S, TPD with CO₂ was performed. Similar experiments were also done for LaOCl-P to verify the type of carbonates detected on the surface. The results are given in Figure 10. In Table 5, reference compounds and their respective desorption temperatures are tabulated.⁶ For LaOCl-S, the first signal on the thermal conductivity detector (TCD) is measured at 25-170 °C. At this temperature, water is desorbed from the surface. A small shoulder is also present around 160 °C, which has been assigned to physisorbed CO₂. Another peak becomes visible at 240-430 °C, which also possesses a low-intensity shoulder. The main band can be assigned to either bidentate or bridged carbonate species. However, in the case of bridged species, polydentate carbonates would be formed as a result of the CO₂ desorption. Since no signal is detected above 370 °C and polydentate carbonates desorb around 620 °C, the signal is most likely indicative of bidentate carbonates. No references were found regarding the low-intensity shoulder at 400 °C. IR spectroscopy was unable to discriminate between polydentate carbonates and monodentate carbonates before, but as stated above,

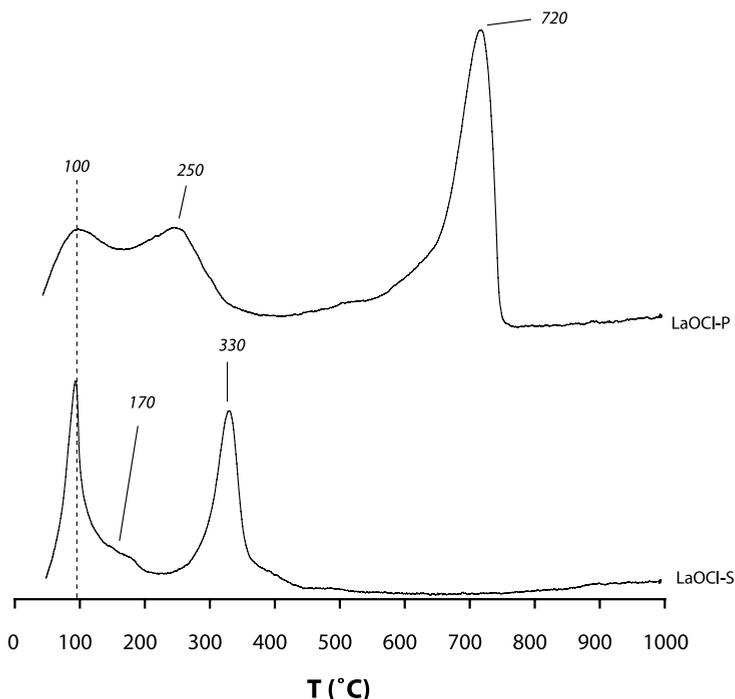

Figure 10. TPD of CO₂ adsorbed from the air under ambient conditions on LaOCl-S and LaOCl-P.

Chapter 2

Table 5. Desorption temperatures for La-based reference compounds.⁶

Reference compound	Structure / Reaction	Desorption Temperature (°C)
La ₂ O ₃	La ₂ (CO ₃) ₃ → La ₂ O ₃ ·xCO ₂ + (3-x) CO ₂	300-400
	La ₂ O ₃ ·xCO ₂ → La ₂ O ₃ + x CO ₂	500-730
LaOCl	physisorbed CO ₂ → CO ₂	100
	bridged carbonates → polydentate carbonates + CO ₂	290 620
	polydentate carbonates → CO ₂	
LaCl ₃	physisorbed CO ₂ → CO ₂	100

no polydentate carbonates were detected by TPD. The band for monodentate carbonates is usually measured around 25 °C, but is hard to distinguish since physisorbed CO₂ and water also desorb in this region. However, according to the IR results, monodentate carbonates are formed upon adsorption of CO₂ on LaOCl-S. Therefore, on LaOCl-S, a low concentration of monodentate species and a high concentration of bidentate carbonates is expected to be present after adsorption of CO₂.

For LaOCl-P, two TCD peaks are visible in the region between 25 and 380 °C. One possesses a maximum at 75 °C and the other at 230 °C. As for sample LaOCl-S, the former is assigned to water and physisorbed CO₂, while the latter is indicative of either bidentate or bridged carbonate species. Another option is the decomposition of bulk carbonates. A peak between 500 and 730 °C would then also be visible, and this is in fact the case. In the case of bridged species, formation of polydentate carbonates would be the result of CO₂ desorption. IR results indicated the presence of bridged carbonates and bulk carbonates. This is certainly a possibility, but the TPD results cannot discriminate between bridged carbonates and bulk carbonates, since they possess desorption peaks in the same temperature regions. On the basis of both the IR results and the TPD results, the formation of bridged and bulk carbonates takes place upon adsorption of CO₂ on LaOCl-P.

CO adsorption can be used to probe Lewis acidity. Absorption bands located at high wavenumbers are related to strong M-CO bonds, which is a consequence of a strong Lewis acid site. On the basis of IR spectra during adsorption and desorption of CO, a distribution of the strengths of the Lewis acid sites can be obtained. Figure 11 shows the IR spectra for sample LaOCl-S obtained after CO adsorption and consecutive desorption for increasing measurement temperature. Because of the low surface area and relatively high activation temperature, no IR bands due to hydroxyl groups could be discovered. As a consequence, we concentrate our analysis on the ν(CO) region. After CO adsorption at -195 °C, a strong band at 2165 cm⁻¹ was observed with a weak shoulder at 2155 cm⁻¹, likely witnessing the presence of Brønsted acid sites. After CO desorption, the band at 2155 cm⁻¹ disappears quickly, and the band at 2165 cm⁻¹ decreases in intensity and shifts to 2172 cm⁻¹. The CO adsorption band and the consecutive desorption of CO show the distribution in strength of the Lewis acid sites at the surface of LaOCl-S. The strongest Lewis acid sites on LaOCl-S are

Destructive adsorption of CCl₄ over La-based solids

therefore represented by the band that remains after CO desorption at 2172 cm⁻¹.

In the IR spectrum of LaOCl-P presented in Figure 12, a weak band of the hydroxyl groups was observed at 3651 cm⁻¹, so confirming the presence of small amounts of Brønsted acid sites. After CO adsorption at -195 °C, the free OH band disappeared completely, and a perturbed one becomes visible at 3615 cm⁻¹. In the CO region of the IR spectra, the strong

Destructive adsorption of CCl₄ over La-based solids

band at 2165 cm⁻¹ and a weak and broad one at 2155 cm⁻¹ were observed. After CO desorption, the band at 2155 cm⁻¹ decreases in intensity. At the same time, a free hydroxyl band reappears, and the perturbed one at 3615 cm⁻¹ diminishes. In other words, the band at 2155 cm⁻¹ can be assigned to H-bonded CO. After CO desorption, the band at 2165 cm⁻¹ shifts toward higher wavenumber at 2171 cm⁻¹. As with LaOCl-S, the distribution of the strengths of the Lewis acid sites is reflected in the spectra upon desorption. In the case of LaOCl-P, the strongest Lewis acid site is represented by the band at 2171 cm⁻¹. So, LaOCl-S and LaOCl-P have identical Lewis acid sites and also show no large differences in the distribution of the Lewis acid sites. Thus, the type of sites available on samples LaOCl-S and LaOCl-P cannot be distinguished by CO adsorption using IR spectroscopy. To discriminate between the different sites, another more powerful probe molecule is needed. In our opinion, this is CH₃OH.

Two types of irreversibly adsorbed species (species which are not removed by a relatively short evacuation at RT) can be formed as a result of adsorption of alcohols on metal oxides: alkoxy species, resulting from dissociative chemisorption on a very weak Lewis acid site located near a very basic one, and undissociated species, coordinated on a strong Lewis acid site.²⁰ This is schematically represented in Scheme 2. Adsorption of CH₃OH is, however, much less specific, since it could also occur on couples having a predominantly Lewis acid character. The respective dissociation processes of an acid/base couple with predominant Lewis acid and base character can be envisaged as in Scheme 3.⁴ Dissociation of CH₃OH on an acid-base couple is similar to the first reaction step for the destruction of CCl₄. DFT calculations have shown that CCl₄ is split into two fragments: Cl^{δ-}, coordinated toward the Lewis acid site, and CCl₃^{δ+}, stabilized on the basic oxygen.⁷ CH₃OH is also split into two fragments: methoxy species coordinated toward the Lewis acid site and a hydrogen atom, which is transferred to the basic oxygen site. Since the same acid-base couple is needed for both processes, the CH₃OH adsorption results are very likely to give information on the active site for the destructive adsorption of CCl₄ over La-based materials as well. The comparison between CCl₄ and CH₃OH dissociation on a La-O acid-base couple is shown in Scheme 4. Because, compared to oxygen, the chlorine atom is more electronegative, the La-Cl bond formed during the dissociation is stronger than the La-OCH₃ bond, and the Cl is more difficult to desorb.

The IR results of the adsorption of CH₃OH on LaOCl-S and LaOCl-P are shown in Figure 13. For the spectra at 1.3 mbar of CH₃OH in equilibrium at RT, the spectrum of gas phase CH₃OH was subtracted. The spectra were also normalized for the amount of sample and the surface area. The IR spectrum of LaOCl-S at equilibrium shows a main band at 1033 cm⁻¹. This band was also visible in the gas phase spectrum of CH₃OH and is attributed to physisorbed species. A small band is present at 1104 cm⁻¹, which is attributed to an on-top coordinated methoxy species on a La³⁺ site.²¹ After 15 min of evacuation at RT, the weakly adsorbed species have been removed. Also, the band of linearly adsorbed methoxy species has decreased in intensity, and two small bands have become better resolved at 1062 and 1012 cm⁻¹. These bands are attributed to doubly bridged and three-fold coordinated methoxy species, respectively.²¹ Upon further evacuation, these bands also disappear, and a band

Chapter 2

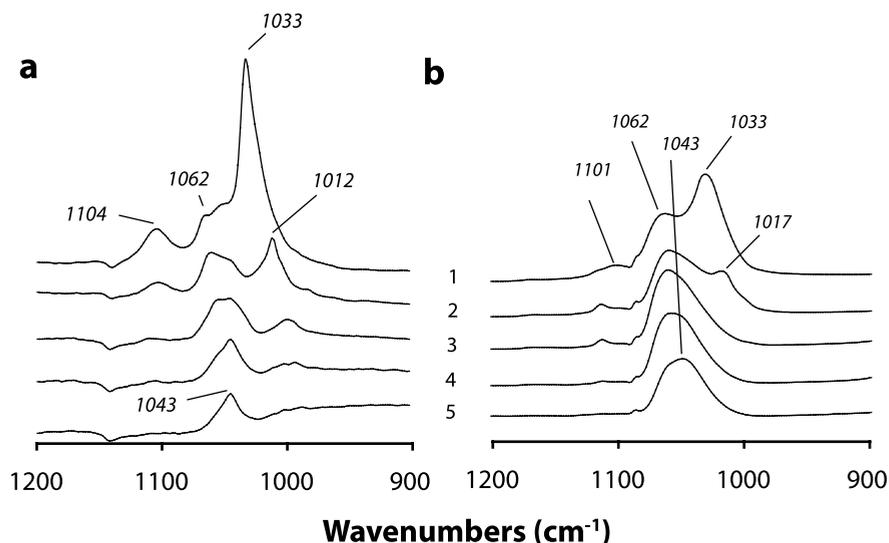

Figure 13. FTIR spectra of CH_3OH adsorbed on (a) LaOCl-S and (b) LaOCl-P at (1) 1.3 mbar equilibrium pressure and the consecutive desorption by (2) evacuation at RT, (3) evacuation at 100 °C, (4) evacuation at 150 °C, and (5) evacuation at 200 °C.

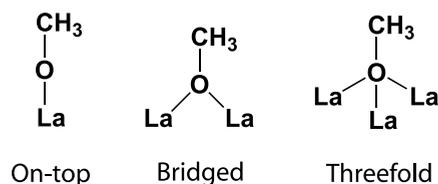

becomes visible at 1043 cm^{-1} , which is also caused by the twofold coordination of adsorbed methoxy species.²¹ It has been proposed that the two bridging species are differing from the coordinative unsaturation of the cations constituting the site.²¹ The possible coordinated methoxy species can be envisaged as in Scheme 5.

As with LaOCl-S , a strong band resulting from a weakly adsorbed species is visible on LaOCl-P at 1033 cm^{-1} , which is removed by evacuation at RT. Again, bands become visible after evacuation at RT at 1017 , 1062 , and 1101 cm^{-1} , attributed to three-fold coordinated, doubly bridged, and linearly adsorbed methoxy species, respectively. The bands of three-fold coordinated and linearly adsorbed methoxy species have disappeared after evacuation at 100 °C. After evacuation at 150 and 200 °C, the broad bands of the doubly bridged species show a different behaviour for its two components, with the doubly bridged species in the presence of defects (those at lower wavenumber) being less susceptible to evacuation. It seems that at higher loading the methoxy species prefer a doubly bridged coordination, where at lower loading three-fold coordination is preferred. Also, the methoxy species remain adsorbed at much higher temperatures than on LaOCl-S , which indicates the presence of relatively more acidic Lewis sites on LaOCl-P .

To verify this hypothesis, we have integrated the area under the adsorption bands for the adsorbed methoxy groups. The results are summarized in Table 6. It is clear that the integrated area is larger for LaOCl-S for spectra 1, 2 and 3. These spectra are, however, dominated by the physisorbed CH_3OH and the weakly adsorbed methoxy species, such as the three-fold and linearly adsorbed species. The bridged methoxy species are adsorbed more strongly and remain on the surface the longest. In spectra 4 and 5, the bridged methoxy

Destructive adsorption of CCl₄ over La-based solids

species are the only species remaining on the surface of LaOCl-S and LaOCl-P. In these spectra, however, LaOCl-P has a larger integrated area than LaOCl-S. This indicates that LaOCl-S might contain more Lewis acid sites, but LaOCl-P possesses the strongest Lewis acid sites. The main difference between LaOCl-S and LaOCl-P was the amount of chlorine present at the surface, as was determined by XPS. Apparently, the higher amount of chlorine is not reflected in the strength of the Lewis acid sites, but in the number of specific sites that are present. For LaOCl-P, the sites to which the methoxy species were most strongly adsorbed, namely, the sites forming bridged methoxy species, are more abundant than for LaOCl-S.

Scheme 5. Possible coordinated methoxy species to La-based materials.

Table 6. Relative integrated areas (error margin = ± 0.1) under spectra of Figure 8 at different stages of CH₃OH adsorption/desorption on samples LaOCl-S and LaOCl-P.

Conditions	Species present	LaOCl-S	LaOCl-P
CH ₃ OH at equilibrium pressure of 1.3 mbar	Physisorbed CH ₃ OH Linear, bridged and three-fold methoxy species	17.2	6.0
Evacuation at RT	Linear, bridged and three-fold methoxy species	7.6	4.1
Evacuation at 100 °C	Bridged and three-fold methoxy species	4.3	3.6
Evacuation at 150 °C	Bridged and three-fold methoxy species	2.8	3.1
Evacuation at 200 °C	Bridged methoxy species	1.8	2.5

Conclusions

It was found that the synthesis method of the LaOCl materials has a dramatic influence on the bulk as well as on the surface properties. LaOCl-S, prepared via a solid-state reaction, is highly crystalline and a pure LaOCl phase. The high crystallinity is also reflected by its low surface area and pore volume. LaOCl-P, prepared via a sol-gel reaction, is characterized by a relatively high surface area and pore volume. LaOCl-P mainly consists of LaOCl crystallites

Chapter 2

embedded in an amorphous phase. Moreover, LaOCl-P contains bulk lanthanum carbonate.

Furthermore, IR spectroscopy, in combination with probe molecules such as CO₂, CO, and CH₃OH, is a powerful method to assess the acid-base properties of LaOCl materials. Lewis acidity has been probed with CO and CH₃OH. The CO adsorption experiments have shown that LaOCl-S and LaOCl-P do possess similar Lewis acid sites. On the other hand, CH₃OH probing shows that LaOCl-P contains a larger number of strong adsorption sites than LaOCl-S, more specifically sites that are likely used for the destructive adsorption of CCl₄. The larger amount of chlorine at the surface that was observed with XPS appears to increase the number of active Lewis acid sites at the surface of LaOCl-P. Basicity has been assessed via CO₂ adsorption, and these experiments show that the type of carbonate formed on LaOCl-S and LaOCl-P differs. In the case of LaOCl-S, a high amount of bidentate carbonates and a low amount of monodentate carbonates are observed. For LaOCl-P, bulk carbonates are formed together with some bridged carbonates.

Finally, La-based materials are active in the destructive adsorption of CCl₄, and the following activity trend was observed: LaCl₃ << La₂O₃ < LaOCl-S < LaOCl-P. The difference in Lewis acidity between La₂O₃ and LaOCl is reflected by the lower initial reaction temperature of LaOCl. The higher activity of LaOCl-P is caused by its higher density of strong Lewis acid sites in comparison with LaOCl-S. These conclusions are in line with the observation of XPS that the surface of LaOCl-S contains more chlorine than that of LaOCl-P. Because chlorine is more electronegative than oxygen, more strong Lewis acid sites are available on LaOCl-P. However, these differences in strength cannot be revealed by CO IR adsorption measurements. Nevertheless, we believe that the strength of the Lewis acid sites remains a key factor for activity and that stronger Lewis acid sites result in a higher intrinsic activity for CCl₄ destruction. However, basic oxygen sites remain necessary to enable the conversion of CCl₄ to CO₂. In other words, the appropriate acid-base pair should be available at the catalyst surface to have an active material. These observations also suggest that novel catalyst materials can be synthesized by modifying the surface composition of basic oxides. In this context, addition / removal of chlorine can be used as a way to tune the acid-base pair in a basic oxide.

Conversion of Chlorinated Waste Streams from the Production of Polyvinyl Chloride
over La-Based Catalysts

Intermediates in the Destruction of Chlorinated C₁ Hydrocarbons on La-based Materials: Mechanistic Implications

The reaction steps for the destructive adsorption of CHCl₃, CH₂Cl₂ and CH₃Cl over a LaOCl-P catalyst material were investigated to gain more insight into the reaction network of the destructive adsorption of chlorinated C₁ (CHC₁). The activity and selectivity for the destructive adsorption of the CHC₁ series was tested over LaOCl-P in flow-gas experiments. Surface intermediates on LaOCl-P and related gas phase products were studied using in situ infrared spectroscopy (IR). The IR results show that during reaction, LaOCl-P is covered with carbonate, formate and methoxy groups. The relative amount of each of these surface intermediates depends on the Cl/H ratio of the reactant. The decomposition of the surface species leads to the formation of the reaction products. This is influenced by the temperature and the relative amount of Cl present on the surface. Effluent analysis results show that the activity for the destructive adsorption of H-containing CHC₁ decreases with increasing hydrogen content of the reactant. The influence of the chlorination degree of the material on selectivity and activity could be used to tune the catalyst for optimal conversion of a specific mixture: the chlorination degree of the material largely determines what type of surface groups are formed and into which gas phase products they dissociate.

Chapter 3

Introduction

The destructive adsorption and catalytic destruction of CCl_4 over La_2O_3 -based materials has been studied extensively and the reactivity of C-Cl bonds towards these catalysts is well-understood.¹⁻⁶ However, the light ends mixtures formed during the production of $\text{C}_2\text{H}_3\text{Cl}$ also contain H-containing CHC_1 , namely CHCl_3 , CH_2Cl_2 and CH_3Cl . Preliminary research on the catalytic destruction of H-containing chlorinated C_1 (CHC_1) over supported and unsupported La_2O_3 catalysts indicates that all CHC_1 follow a similar reaction path.^{2, 5} However, as opposed to the case of CCl_4 , CO was found to be the main product in the catalytic destruction of CHCl_3 and CH_2Cl_2 .

The reactant molecule is thought to first exchange two chlorine atoms with one lattice oxygen atom from the catalyst, as illustrated by Reaction Eq. (1), similarly to the reaction of CCl_4 . The resulting reaction intermediate consecutively dissociates into CO and HCl/H_2 . However, since HCl was already present as a result of the dechlorination reaction with water, the presence of either H_2 or HCl could not be confirmed.^{2, 5} Therefore, further studies on the reaction mechanism is needed to gain understanding of the role and behaviour of the C-H bond in the destructive adsorption of CHC_1 . Also, the influence of the acid-base properties of the catalyst with respect to activity and selectivity should be investigated to achieve control of the reaction towards re-usable products.

In this chapter, we report on a general reaction scheme for the destructive adsorption of CHC_1 and the relationship between the composition of the catalyst and the observed activity and selectivity. In situ infrared (IR) spectroscopy and gas chromatography (GC) analysis were used to monitor the reaction of CHCl_3 , CH_2Cl_2 and CH_3Cl over the LaOCl-P catalyst material. As a result, fundamental insight is obtained into the intermediates of destructive adsorption when applying La-based materials to convert mixtures of CHC_1 . This is of high relevance when destroying the light ends in industrial waste streams. Moreover, the results demonstrate that several products, formed during the reactions described in this chapter, are potentially re-usable as fuel or feed-stock.

Experimental

Materials

For this chapter, the LaOCl-P sample was used for the activity and in situ IR experiments. The preparation method and physicochemical properties of this sample have been described in detail in Chapter 2.

Intermediates in the destruction of chlorinated C₁ on La-based Materials

In Situ IR Temperature-Programmed Reaction

Due to interference of the bands of bulk carbonates on La₂O₃ with the adsorbed species, only LaOCl-P was used for the IR measurements. For these IR measurements, the quartz cell was used, which was discussed in Chapter 2. All IR spectra were measured using a Perkin Elmer 2000 spectrometer with a resolution of 4 cm⁻¹. LaOCl-P was pressed into self-supporting wafers (2 cm²), and activated in situ prior to the IR measurements in dynamic vacuum at 550 °C for 30 min. After pre-treatment, the reactant (50 mbar) was introduced to the cell after which the cell was closed. The reactant was equilibrated with the sample at room temperature and, subsequently, spectra of the solid and the gas phase were measured. The temperature of the sample was raised to 300 °C in steps of 50 °C. After each step, spectra were recorded. Spectra were measured for the adsorption of 50 mbar of HCOOH (Acros Organics, 98+ %) and CH₃OH (Acros Organics, 99.8 %) on LaOCl-P to use as a reference for the assignment of formate and methoxy groups, respectively.

Flow-Gas Activity Experiments

The activity measurements for the destructive adsorption of CCl₄ (Acros Organics, 99.8 %), CHCl₃ (Acros Organics, 99.9 %), CH₂Cl₂ (Acros Organics, 99.9 %) and CH₃Cl (Fluka, ≥ 99.8 %) were performed in a tubular fixed bed quartz reactor. The catalyst bed consisted of LaOCl-P (1.0 g) pressed in a sieve fraction (150-500 μm), pre-treated in a He (Hoekloos, ≥99.996 %) flow (10 ml/min) at 550 °C. The reactions were performed at constant temperature of 400 °C. The total flow rate of the reactant feed was 20 ml/min 4-6 vol% CHC₁ in He (Hoekloos, ≥99.996 %). Details of the setup can be found in Chapter 2.

Results and Discussion

IR Spectroscopic Studies

When CHC₁ adsorb on La₂O₃-based materials, C-Cl bonds are broken and C-O bonds are formed resulting in chemisorption of the CHC₁. Both bonds are related to IR active vibrations and therefore IR enables characterization of the surface species and chemisorbed reaction intermediates. IR spectra of the gas phase and catalyst wafer were measured separately during the reaction of LaOCl-P with CHCl₃, CH₂Cl₂ and CH₃Cl and are shown in Figure 1 and 2. Unfortunately, small fluctuations in the concentration of ambient CO₂ and H₂O prevented the accurate detection of these species as reaction products. Consequently, CO₂ and H₂O are not included in the spectra and in the discussion of the IR results.

For the reactions with CHCl₃, several bands are observed in the gas phase spectra at

Intermediates in the destruction of chlorinated C₁ on La-based Materials

RT, shown in Figure 1a. The band at 1269 cm⁻¹ is indicative of CH₂Cl₂ that was present as a contaminant in the reactant.⁷ The remainder of the bands is assigned to CHCl₃.⁷ At 150 °C a band arises at 2143 cm⁻¹, which is characteristic for CO.⁷ The intensity of the CO band increases with increasing reaction temperature. At 200 °C, the rotation-vibration pattern of HCl is observed at 2886 cm⁻¹.⁷ As the temperature increases, the intensity of the HCl band increases also. A low intensity band at 1832 cm⁻¹ is visible at 300 °C and is accompanied by a broadening of the band at 856 cm⁻¹. The bands are due to the formation of COCl₂ and regarding the relatively low intensity, a small amount is formed.⁷ In addition, a band arises at 922 cm⁻¹, which is assigned to C₂Cl₄.⁷

To elucidate the surface reaction steps of the conversion of CHCl₃, spectra of the wafer were also measured. In Figure 2a, each spectrum is shown after subtraction of the corresponding gas phase spectrum and the spectrum of the wafer prior to reaction. The bands at 3020 and 1223 cm⁻¹ are assigned to physisorbed CHCl₃. In addition, immediately after introduction of CHCl₃, a broad band at 3579 cm⁻¹ is visible, characteristic of surface hydroxyl groups. Simultaneously with the OH bands at RT, bands appear at 1402, 1496 and 1597 cm⁻¹. These bands are also visible in the spectrum of LaOCl-P under ambient conditions and are attributed to the presence of bulk carbonate (1402 and 1496 cm⁻¹) and bidentate carbonate (1597 cm⁻¹). As a result of the high basicity of La₂O₃-based materials, carbonates and hydroxyl groups are formed readily at RT by reaction with CO₂ and H₂O from air.

In a blank experiment, LaOCl-P was kept under static vacuum in the reaction cell to verify whether the observed bands are a result of the presence of air, or of destructive adsorption of CHCl₃. The intensity of the carbonate bands in the blank experiment was of the same order of magnitude as observed in the spectrum at RT for the experiment with CHCl₃. The carbonate bands at RT in Figure 2a are therefore a result of residual air in the reaction cell. During the blank experiment surface hydroxyl groups were also formed, but after 4 h the intensity of the ν(OH) band was still significantly lower in comparison with the band observed after 15 min at RT with CHCl₃ in the cell. This implies that the hydroxyl groups are formed as a result of the interaction of CHCl₃ with the LaOCl-P surface.

Table 1. Measured vibrational frequencies and mode assignment of methoxy and formate groups after adsorption of CH₃OH and HCOOH, respectively, on LaOCl-P at RT after evacuation.

CH ₃ OH on LaOCl-P (cm ⁻¹)	Methoxy Mode	HCOOH on LaOCl-P (cm ⁻¹)	Formate Mode
1017	ν(CO) 3-fold	1261	ν(OCO) _s Monodentate

Intermediates in the destruction of chlorinated C_1 on La-based Materials

The abstraction of the proton from CHCl_3 by strong basic O sites initiates the reaction, which was also proposed by Koper et al. from experiments on the destructive adsorption of CHCl_3 on CaO (Scheme 1, Species 1b to 2b).⁸ This proton abstraction is expected to be accompanied by the removal of a chlorine atom from the reactant resulting in the formation of a carbene-like intermediate. The formation of dichlorocarbene (CCl_2) on a metal oxide surface has been proven by adsorption of CCl_4 on Fe_3O_4 studied using Scanning Tunnelling Microscopy (STM).⁹ Moreover, it was found that the CCl_2 fragment is mobile on the surface at RT. Koper et al. found from pulse experiments that CHCl_3 is initially converted on CaO into CO exclusively, whereas addition of larger amounts resulted in the formation of COCl_2 and C_2Cl_4 .⁸ Hydration of CaO already led to formation of COCl_2 and C_2Cl_4 after introduction of lower amounts of CHCl_3 . Since both chlorination and hydration of the surface result in the decrease of O availability, the formation of COCl_2 and C_2Cl_4 is indicative of O deficiency. The formation of C_2Cl_4 and COCl_2 is confirmed in the gas phase IR spectrum for destructive adsorption of CHCl_3 at 300 °C (Figure 1a).

At 100 °C, bands are visible at 1346, 1371 and 1562 cm^{-1} , which are characteristic for chemisorbed formate groups (Table 1). The intensity of the formate bands has decreased in the spectrum measured at 150 °C, and simultaneously CO is formed (Figure 1a). The formation of formate groups is the result of a Cl abstraction rather than proton abstraction as the initial reaction step. Initially, COHCl , an intermediate similar to COCl_2 , is formed after exchange of two Cl atoms for an O atom (Scheme 1, Species 1a to 2a). This intermediate is known to thermally dissociate into CO and HCl (Scheme 1, Species 3a to 3a'). However, when COHCl is formed at the surface, rapid re-adsorption is possible, resulting in the formation of formate groups (Scheme 1, Species 4a to 5a). During the increase of temperature

Chapter 3

from RT to 150 °C, the OH-band at 3579 cm⁻¹ also increases in intensity and shifts to 3529 cm⁻¹. The broadening and perturbation of the OH-band can be explained by the interaction between OH groups and CHCl₃.¹⁰

At 200 °C, the formate bands have disappeared and the intensity of the OH-bands has decreased. Moreover, three distinct maxima are visible in the ν(OH) region and a low-intensity band appears at 3180 cm⁻¹, which may be the result of hydrogen bonding between chloroform and surface hydroxyl groups. The three OH bands have previously been linked to the occurrence of different phases in La₂O₃ powders based on XRD.¹¹ The bands at 3491, 3597 and 3666 cm⁻¹ are assigned to LaOOH, La(OH)₃ and isolated La-OH, respectively.¹¹ The different bands are related to the degree of hydration of the sample. Initially, through proton abstraction the surface becomes saturated with OH groups and at higher chlorination degree, the OH groups react with Cl to form HCl and regenerate basic O sites. The thermal dissociation of COHCl (Scheme 1, Species 3a to 3a') may be more favourable at 200 °C than the re-adsorption and consecutive formation of formate groups, since bands related to formate groups are not found in the spectrum. An alternative interpretation is that the formate groups are formed, which immediately dissociate to CO and surface hydroxyl groups (Scheme 1, Species 6a to 6a'). The decrease of the formate bands parallels the increase of the carbonate band at 1597 cm⁻¹. This implies that the formate groups convert into bidentate carbonates (Scheme 1, Species 5a to 5a').¹² Above 200 °C, the intensity of the carbonate band at 1597 cm⁻¹ decreases, which leads to CO₂ formation. As previously mentioned, however, CO₂ could not be detected due to experimental limitations. The bands at 999 and 1032 cm⁻¹ are assigned to La-O vibrations. The broadness of the bands is most likely due to the rearrangement of the LaOCl-P structure as a result of chlorination of the catalytic surface. The band at 1140 cm⁻¹ appears simultaneously with bidentate carbonate, however, no reference was found with respect to this band.

Bands, which are all assigned to CH₂Cl₂, are observed at RT in the gas phase spectra (Figure 1b) during the destructive adsorption of CH₂Cl₂ over LaOCl-P.⁷ At 150 °C, a small shoulder arises at 1227 cm⁻¹, which can be assigned to CHCl₃.⁷ At 200 °C, CO is formed and the intensity of the CO band increases as the temperature increases. At 300 °C, several bands arise at 1034 and 1745 cm⁻¹. In addition, bands are visible between 2700 and 3000 cm⁻¹. The bands at 1034 and 1745 cm⁻¹ are characteristic for CH₃OH and CH₂O, respectively.⁷ The pattern of bands in the 2700-3000 cm⁻¹ region confirms the formation of CH₂O and CH₃OH.⁷ The bands may in addition be indicative of HCl formation.⁷

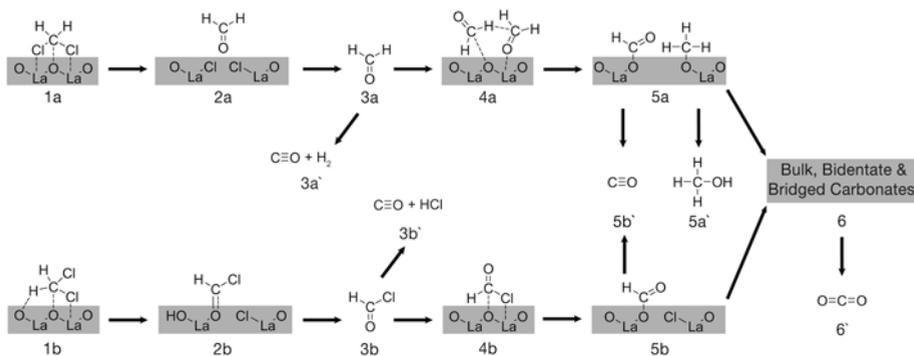

The spectra of the catalyst, measured during the destructive adsorption of CH₂Cl₂, are shown in Figure 2b. At RT, bands are observed at 3064, 2993 and 1273 cm⁻¹, assigned to physisorbed CH₂Cl₂. Also, a low intensity hydroxyl band is observed at 3591 cm⁻¹, indicating proton abstraction similar to the destructive adsorption of CHCl₃ (Scheme 2, Species 1b to 2b). The recombination of CHCl to C₂H₂Cl₂ is not observed at high temperature, however. Apparently, the surface reaction involving CHCl is limited to lattice O extraction resulting in the formation of COHCl. As the temperature increases, the hydroxyl band broadens and at 300 °C, three maxima are visible at 3507, 3591 and 3642 cm⁻¹. This is similar to the hydroxyl

Intermediates in the destruction of chlorinated C_1 on La-based Materials

bands observed during the experiment CHCl_3 (Figure 2a). Even though no products are observed in the gas phase below 250 °C, the wafer spectra show bands at 1566, 1375, 1336 and 2858 cm^{-1} at 100 °C, indicating formation of formate groups. This can be explained by the previously discussed consecutive re-adsorption and formation of formate groups from COHCl (Scheme 2, Species 4b to 5b).

At 200 °C, a broad set of bands is present at 1600-1300 cm^{-1} , which increases in intensity at 250 °C. The broad bands between the two maxima at 1566 and 1375 cm^{-1} are assigned to bulk carbonates. At 150 °C and higher temperatures, bands are also present around 1011 cm^{-1} and 2800-3100 cm^{-1} as a result of methoxy group formation. In previous IR experiments of CH_3OH probing on LaOCl-P , different types of methoxy species have been identified based on the vibrational frequencies in the low wavenumber region (Table 1). These experiments were discussed in Chapter 2.3.2. The bands observed at 1097, 1045 and 1011 cm^{-1} have been assigned to on-top, bridged and three-fold methoxy species, respectively. The methoxy species are predominantly in the three-fold adsorbed state and are stable up to 300 °C. The intensity of the bands at 2956 and 2858 cm^{-1} in the $\nu(\text{CH})$ region parallels the intensity of the $\nu(\text{CO})$ band of three-fold adsorbed methoxy. The decrease in intensity at 300 °C of the band at 2858 cm^{-1} is caused by the overlap between the $\nu(\text{CH})$ bands of formate and methoxy groups, since the formate species dissociate at 300 °C. In addition to three-fold methoxy species, a relatively low concentration of bridged and on-top adsorbed methoxy species is formed at the surface. Similar to the reaction with CHCl_3 , a reaction pathway initiated by Cl abstraction may explain the formation of methoxy species. Analogous to CHCl_3 , CH_2Cl_2 produces CH_2O after Cl removal (Scheme 2, Species 1a to 2a).

CH_2O is known to form dioxymethylene (O_2CH_2) and polyoxymethylene species on the surface of ionic solids, which can convert further into formate and methoxy groups.¹² However, the bands characteristic for dioxymethylene and polyoxymethylene are not observed in the spectra. Moreover, the formation of dioxymethylene requires reduction of a metal site,

Scheme 2. Proposed reaction scheme for the destructive adsorption of CH_2Cl_2 on LaOCl-P . To illustrate the difference between adsorbed species and gas phase species, the catalyst surface is highlighted grey.

Chapter 3

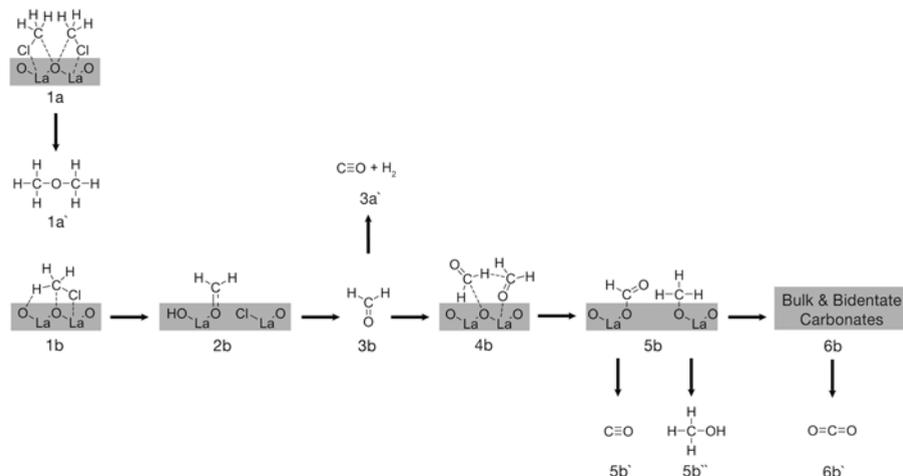

which is highly unlikely in the case of lanthanum.¹³ On the other hand, it has been shown recently that even though La^{3+} is unable to change oxidation state, oxidation of OCl is possible.^{14, 15} A more likely explanation, however, is that CH_2O reacts via a Cannizzaro-like reaction to form a methoxy and formate group (Scheme 2, species 4a to 5a)). At 250 °C, CH_3OH is formed in the gas phase. The formation of CH_3OH is linked to the increased concentration of methoxy species and hydroxyl groups at the surface. As a result, basic O sites are regenerated by CH_3OH desorption (Scheme 2). The fact that CH_2O is observed in the gas phase spectrum at 300 °C indicates that re-adsorption is becoming less favourable, or that more CH_2O is formed at the surface (Scheme 2).

At 300 °C, bands are visible at 1689, 1597, 1527 and 1333 cm^{-1} . The band at 1689 cm^{-1} is ascribed to monodentate formate (Table 1), which means that compared to the CHCl_3 experiment, the formate groups remain on the surface up to higher temperatures. Therefore, temperature is not the only factor influencing dissociation. Chlorination of the catalytic surface is likely to be an additional parameter. The bands at 1597, 1523 and 1333 cm^{-1} are assigned to carbonates remaining on the surface after dissociation of bulk carbonates. The bands at 1523 and 1333 cm^{-1} have previously been assigned to polycarbonates (Chapter 2.3.2).

For CH_3Cl on LaOCl-P at RT, the observed bands are all assigned to gas phase CH_3Cl (Figure 1c). At 250 °C, a strong band arises at 1178 cm^{-1} assigned to $(\text{CH}_3)_2\text{O}$. At 300 °C, other bands indicative of $(\text{CH}_3)_2\text{O}$ arise at 931, 1101, 2817 and 2925 cm^{-1} . A band is also observed at 1033 cm^{-1} as a result of CH_3OH formation. Moreover, gas phase C=O at 2143 cm^{-1} is visible in the spectrum at 300 °C.

During the experiment with CH_3Cl on LaOCl-P, bands assigned to physisorbed CH_3Cl are observed at 2965, 2937 and 2865 cm^{-1} (Figure 2c). The intensity of the surface species bands is significantly lower than for the experiments with CHCl_3 and CH_2Cl_2 , making the spectra rather noisy after subtraction. At room temperature, the $\nu(\text{OH})$ band is visible at 3552 cm^{-1} . The intensity of this band is relatively constant throughout the experiment. This indicates that hydrogen abstraction is not favourable in the case of CH_3Cl (Scheme 3, Species 1b to 2b). At 150 °C, the previously assigned bands of methoxy groups are observed at 2954, 2852 and 2808 cm^{-1} . Broad bands are also observed in the low wavenumber region, confirming the presence of methoxy species. The position of the band at 1020 cm^{-1} is indicative of three-fold adsorbed methoxy species (Table 1). The bands at 1038, 1066 and 1103 cm^{-1} show that a relatively small amount of two-fold and on-top adsorbed methoxy groups is also present at the surface. The formation of methoxy groups is accompanied by gas phase $(\text{CH}_3)_2\text{O}$.

Two possible pathways can lead to the formation of $(\text{CH}_3)_2\text{O}$; 1) recombination of two surface methoxy species, resulting in the regeneration of an O site. However, due to the low intensity of the methoxy bands compared to the experiment with CH_2Cl_2 on LaOCl-P, it appears unlikely that $(\text{CH}_3)_2\text{O}$ is not formed for CH_2Cl_2 . 2) a more probable pathway is the exchange of two Cl atoms from two CH_3Cl molecules for one O atom (Scheme 3, Species 1a to 1a'). The CH_3Cl molecule is relatively small compared to the molecules containing more

Intermediates in the destruction of chlorinated C_1 on La-based Materials

Scheme 3. Proposed reaction scheme for the destructive adsorption of CH_3Cl on $LaOCl$ -P. To illustrate the difference between adsorbed species and gas phase species, the catalyst surface is highlighted grey.

of the large Cl atoms. Therefore, the conversion of CH_3Cl into $(CH_3)_2O$ is able to occur without the formation of large amounts of surface species.

At 300 °C, the methoxy groups have dissociated simultaneously with the formation of CH_3OH as was observed for the destructive adsorption of CH_2Cl_2 . In addition to methoxy species, broad bands are visible at 1700-1200 cm^{-1} . These bands are similar in position and intensity for the carbonate bands that are observed for the experiments at RT with $CHCl_3$ and CH_2Cl_2 (Figure 2a and 2b). These bands were ascribed to residual air in the vacuum cell and, consequently, the formation of carbonates. The intensity of the carbonates is relatively constant in all spectra. However, at 300 °C the carbonate band is broader and two low intensity bands arise at 1782 and 1730 cm^{-1} . No reference has been found for the assignment of these bands. The broadening of the carbonate bands at 300 °C may indicate the formation of formate groups. The dissociation of formate groups would consequently explain the gaseous CO that is observed at 300 °C (Figure 1c).

GC Activity Experiments

To evaluate activity and selectivity, flow gas experiments were performed. The region in the chromatogram where $COCl_2$ is observed contains other peaks and $COCl_2$ is therefore difficult to detect. As a result, both the assignment and the quantification of $COCl_2$ may be susceptible to a rather large error. Therefore, $COCl_2$ has been omitted from the GC results, since it is generally formed together with CO_2 . Another point of discussion is the fact that CH_3Cl and CH_3OH are co-eluting. Fortunately, the IR results complement the GC results. In the IR experiments, the formation of CH_3OH was observed, whereas CH_3Cl

Chapter 3

formation was not observed. The product formed during the GC experiments is therefore assigned to CH_3OH . This also means that the formation of CH_3OH could not be confirmed during the GC experiments with CH_3Cl . $(\text{CH}_3)_2\text{O}$ was also not detected by GC and consequently the conversion of this reaction is actually higher than experimentally determined.

To enable comparison of selectivity, the reactions were performed on LaOCl-P at 400 °C. The overall conversion is shown in Figure 3. It is defined as the sum of flow concentrations of the C-containing products, divided by the sum of the flow concentrations of the reactant and the C-containing products, multiplied by 100 %. The overall conversion at 400 °C shows the following trend: the conversion of destructive adsorption of $\text{CH}_x\text{Cl}_{4-x}$ decreases as x increases. A trend is observed in the conversion as a function of time. Initially, the conversion is relatively high. This may not seem the case for CH_3Cl ; nevertheless, because of the co-elution of CH_3Cl and CH_3OH , the conversion is likely to be significantly higher than measured by the GC analysis. After some time a sharp decrease in conversion is observed. The decrease in activity is caused by the complete chlorination of the catalyst surface. Once the surface is fully chlorinated, the reaction becomes controlled by the diffusion of lattice O to the surface and lattice Cl to the bulk.

In Figure 4, the conversion of the products is shown for the destructive adsorption of CHCl_3 , CH_2Cl_2 and CH_3Cl on LaOCl-P at 400 °C as a function of time. The conversion was defined as the flow concentration of a product, divided by the sum of the flow concentrations of the reactant and the products, multiplied by 100 %. As the reaction time increases, the surface becomes more chlorinated. Therefore, the timescale can be translated into a chemical parameter, namely surface chlorination. The conversion curves have similar shapes;

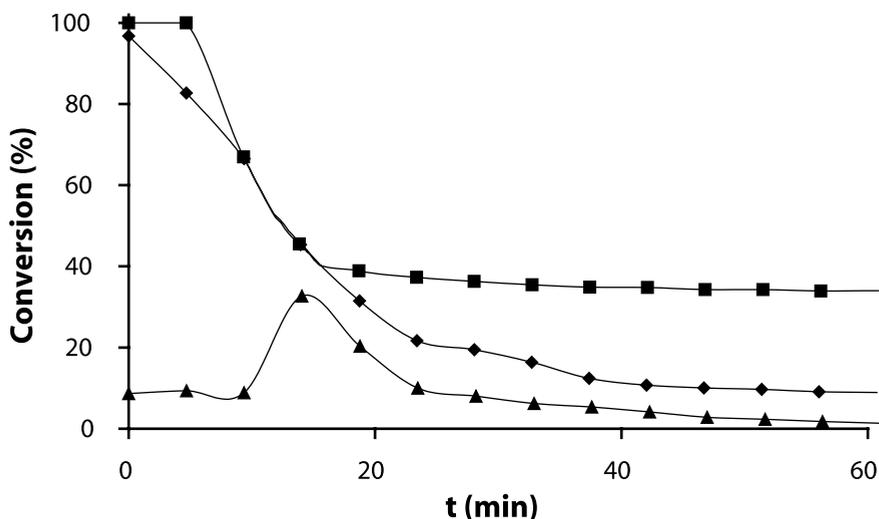

Figure 3. Overall conversion for the destructive adsorption of 6-7 vol% of CHCl_3 (■), CH_2Cl_2 (◆) and CH_3Cl (▲) in He on LaOCl-P at 400 °C as a function of time.

Intermediates in the destruction of chlorinated C_1 on La-based Materials

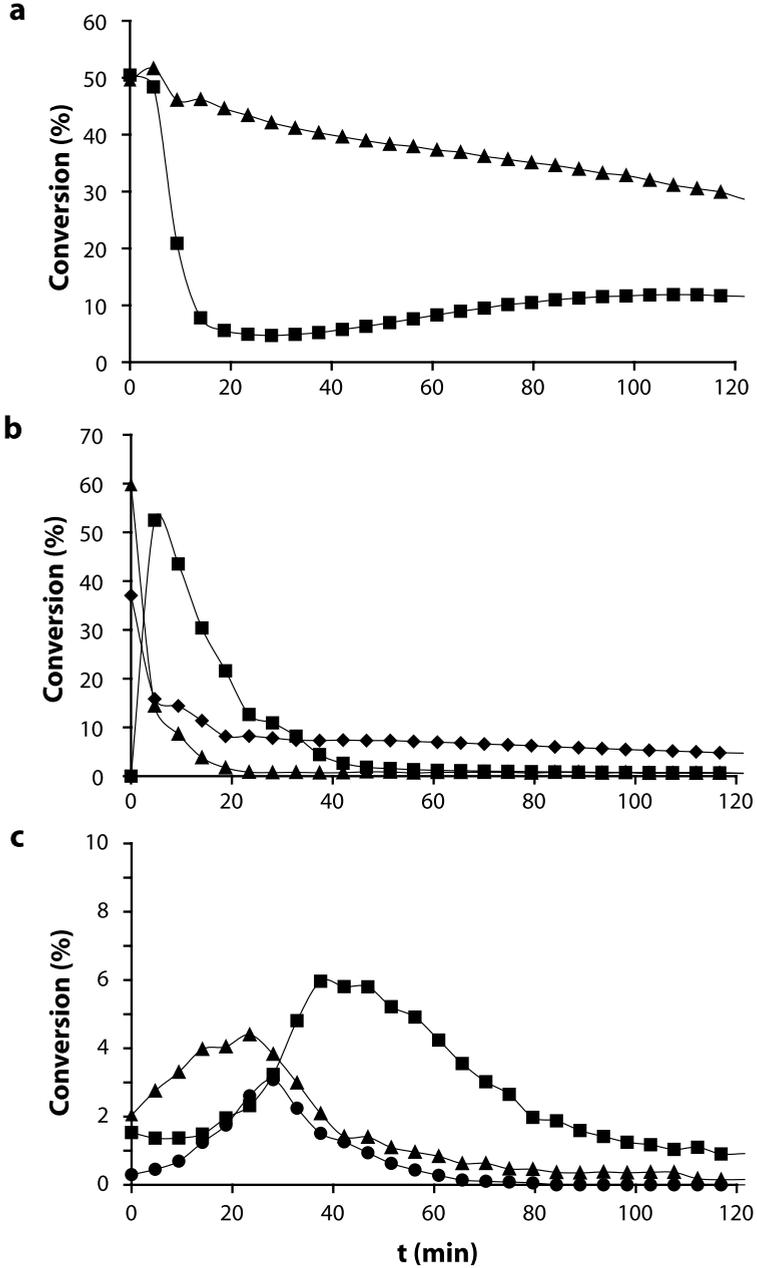

Figure 4. Conversion to each product for the destructive adsorption of CHCl_3 (a), CH_2Cl_2 (b) and CH_3Cl (c) on LaOCl-P as a function of time at 400 °C. The symbols in the graphs refer to the products: CO (▲), CO_2 (■), CH_3OH (◆) and CH_4 (●).

Chapter 3

an increase, followed by a maximum value, ending in a decrease. The maximum conversion indicates that a certain degree of chlorination increases conversion. This is in agreement with the experiments mentioned in Chapter 2 for CCl_4 on LaOCl-P, where higher intrinsic activity was observed for a more chlorinated surface. An increase in chlorination leads to stronger Lewis acid sites, which are important for the initial reaction step. Once a C-Cl bond has been broken, basic O sites are needed to stabilize the remaining fragment and to convert it into O-containing products. Therefore, an optimum combination of strong Lewis acid sites with sufficient basic O sites exists, which is controlled by the surface chlorination degree. In the experiments on LaOCl-P, a maximum was not observed in some cases. The chlorination degree of the surface has probably exceeded the optimum value. Therefore, the measurements only show the decrease in conversion following the maximum. In all experiments, the formation of CO_2 follows the formation of other products, such as CO, CH_3OH and CH_4 . Also, the maximum conversion of CO_2 is observed later in the reaction as the H-content of the reactant increases. This indicates that the chlorination of the surface results in the formation of CO_2 . Either it promotes the formation of CO_2 as a reaction product, or carbonates are formed in an earlier stage of the reaction and desorb as CO_2 as a result of surface chlorination. The latter is regarded the most likely scenario.

General Discussion

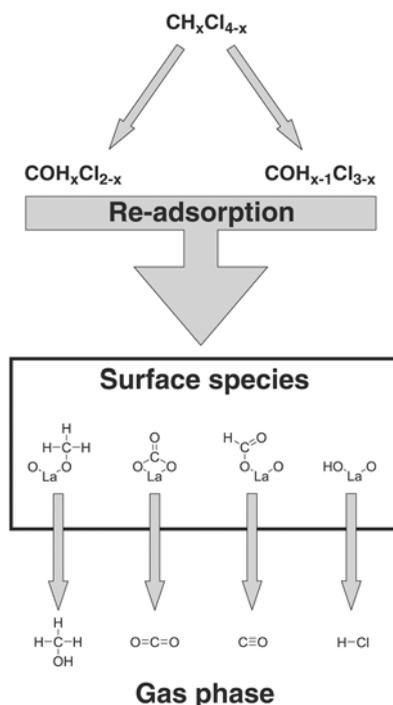

The results of the IR analysis are summarized in Table 2. Even though different products are formed for each reaction, the reaction pathways described in Schemes 1-3 can be summarized by a general reaction scheme (Scheme 4). Two initial pathways are proposed for the destructive adsorption of the CHC_1 series, i.e. CCl_4 , CHCl_3 , CH_2Cl_2 and CH_3Cl . The first reaction pathway is known from the destructive adsorption of CCl_4 and is similar for the other CHC_1 . Two Cl atoms of the reactant are exchanged for a lattice O atom, which leads to the formation of a gas phase intermediate, namely $\text{COH}_x\text{Cl}_{2-x}$. In the case of CH_3Cl , another reaction may occur which resembles this pathway, since this molecule possesses only one Cl atom. Two CH_3Cl molecules both donate one Cl atom and an O atom is exchanged in return. As a result, $(\text{CH}_3)_2\text{O}$ is formed as a gas phase product. For the destructive adsorption of CCl_4 , it was found in Chapter 2 that an optimum combination of Lewis acidity/basicity exists for the active sites. The C-Cl bond becomes elongated when the Cl-atom is attracted by a La^{3+} Lewis acid site resulting in the breaking of the C-Cl bond and the formation of a La-Cl bond. The basic O sites are necessary to stabilize the remaining CCl_3 fragment and enable the conversion of CCl_4 into CO_2 . The strength of the Lewis acid site therefore is a key factor for activity and this is also applicable to the other CHC_1 .

The second pathway results in the formation of an adsorbed $\text{CH}_{x-1}\text{Cl}_{3-x}$ fragment after removal of an H and Cl atom from the reactant (Scheme 4). Obviously, CCl_4 is unable to react via this reaction pathway due to the absence of H atoms. However, for the other CHC_1 the O site is able to abstract a H atom. A hydroxyl group is formed as a result of the

Intermediates in the destruction of chlorinated C₁ on La-based Materials

removal of the H atom and the Cl atom forms a bond with the La atom. Based on these results, it is not possible to determine whether the formation of the hydroxyl group precedes or follows the formation of the La-Cl bond. Nevertheless, the strength of the basic O atom directly influences the initial step of the reaction pathway. The CH_{x-1}Cl_{3-x} fragment is able to migrate across the surface and remove a lattice O atom to form the gas phase intermediate COH_{x-1}Cl_{3-x}. The removed O atom is not replaced by another anion and this would result in an overall positive charge on the catalyst material. However, La₂O₃-based materials are able to incorporate additional O atoms and reconstruct the catalytic surface.¹⁶ Moreover, carbonates which are on the catalyst surface can change coordination to compensate for the loss of O. This means that removal of H/Cl from the CHC₁ is dependent on the number of additional O atoms that is incorporated into the material and the amount and type of carbonates present on the catalytic surface.

Two initial pathways result in the formation of two similar intermediate products (Scheme 4). The rapid re-adsorption of the two intermediates, COH_xCl_{2-x} and COH_{x-1}Cl_{3-x}, results in the formation of hydroxyls, formates, carbonates or methoxy groups. The formed surface species can further interconvert or dissociate into gas phase products, depending on the chlorination degree of the surface and the reaction temperature. COCl₂ is converted into

Scheme 4. Proposed general reaction scheme for the destructive adsorption of CH_xCl_{4-x} on LaOCl-P.

Chapter 3

CO₂ after re-adsorption, which may re-adsorb again resulting in carbonate formation. In the case of COHCl, a formate group is formed when re-adsorption occurs. Via a Cannizzaro-like reaction COH₂ is re-adsorbed leading to the formation of a methoxy and formate group.¹³ In some cases, the intermediates are observed in the gas phase spectra, i.e. CH₂O and COCl₂ for CH₂Cl₂ and CHCl₃, respectively.

The constant temperature experiments show that the conversion of H-containing CHC₁ decreases as the H-content of the reactant increases. This trend can be explained by the change in polarization in the bonds of the CH_xCl_{4-x} molecule. The polarization of the reactant molecule is linked to the electronegativities (EN) of the atoms.¹⁷ The difference in EN between the C atom and the Cl atom results in a polarization between the central atom and the substituents. Since the EN of the H atom is relatively the same as for the C atom, a C-H bond is less polarized than the C-Cl bond. Even though the direction of the polarization of the C-H is opposite to that of the C-Cl bond, the influence of the C-H bond on the polarization of the molecule is negligible. According to the proposed reaction scheme, the initial steps involve the lengthening and consecutive breaking of the C-H bond and/or C-Cl bond. Loss of polarization as a result of decreasing Cl content stabilizes the reactant molecule, and hence reduces the susceptibility to H or Cl abstraction, resulting in lower activity. In addition to the reactant, the chlorination of the catalyst is also found to be of influence on the conversion. After a certain reaction time, a maximum conversion is reached. This shows that a specific chlorination degree represents the optimum combination of Lewis acidity and basicity.

Table 2. Overview of gas phase and surface species detected on LaOCl-P with IR for the destructive adsorption of CHCl₃, CH₂Cl₂ and CH₃Cl at RT, 100, 150, 200, 250 and 300 °C (diss. = dissociation, form. = formation).

Intermediates in the destruction of chlorinated C₁ on La-based Materials

The IR studies on the destructive adsorption of the H-containing CHC₁ series revealed different products and surface species. In general, higher H-content of the reactant results in more hydrogenated reaction products. The surface species follow the same trend. The GC experiments at constant temperature show that CO₂ is formed after an initial period of chlorination. The conversion into CO₂ parallels the trend in activity for the reactants; the time of maximum conversion to CO₂ is longer as the reactant becomes more hydrogenated. The IR experiments have shown that carbonates are formed in all reactions discussed here. Therefore, it is concluded that carbonates are retained on the surface of the catalyst as long as sufficient O is available. As the surface becomes chlorinated, CO₂ is released from the surface. The exclusive formation of CH₃OH from CH₂Cl₂ was observed on LaOCl-P after an induction period. This illustrates how the chlorination degree of the surface influences the selectivity. The two proposed reaction pathways based on the IR results yield different products for each reactant. A sharp decrease in the conversion into CO₂ and CO is observed for CHCl₃ and CH₂Cl₂, respectively. These are products resulting from the proposed pathway proceeding via H/Cl abstraction. Since the surface is O-rich at the beginning of the experiment, the abstraction by the Lewis basic site is favourable. As the catalyst surface becomes more chlorinated, the material is becoming less basic. This results in a decreased conversion of CO₂ and CO for the experiment with CHCl₃ and CH₂Cl₂, respectively. The second pathway is also dependent on the availability of O atoms to enable the exchange of two Cl atoms for one O atom between the reactant and the catalytic material. However, the strength of the basic O site is not of direct influence as it is in the H/Cl abstraction pathway. This explains why a more gradual decrease in conversion is observed for the formation of CO and CH₃OH in the experiments with CHCl₃ and CH₂Cl₂, respectively.

Conclusions

For the destructive adsorption of CHCl₃, CH₂Cl₂ and CH₃Cl on La₂O₃-based materials, two reaction pathways are established that lead to the formation of gas phase intermediates (Scheme 4). It was found that a basic O site is able to abstract a H atom from the gas phase molecule, which is a new aspect for the destructive adsorption in comparison to the previous experiments with CCl₄. The intermediates can rapidly re-adsorb on the catalyst surface and form surface species. The surface species can interconvert and/or dissociate into gas phase products. The dissociation of the surface species is dependent on the reaction temperature and the degree of surface chlorination.

With respect to activity, the same result is found as for the catalytic destruction of the same compounds found in the PhD thesis of Van der Avert.^{2, 5} As the number of hydrogen atoms in the molecule increases, the initial temperature of reaction increases. Conversion of the CHC₁ at constant temperature decreases with an increasing number of hydrogen atoms. This trend is believed to be a result of the decreasing polarization of the bonds in the CHC₁ molecule as a consequence of more hydrogen atoms. The H and Cl abstraction that initiates

Chapter 3

the reaction is therefore less favourable with increasing H-content. A second factor which influences conversion is the chlorination degree of the LaOCl surface. An optimum degree of surface chlorination exists, which translates to an optimal combination of Lewis acidic and basic surface sites. Therefore, control of the chlorination degree of the surface is important when steam is added to the system to make the reaction catalytic.

The selectivity for the destructive adsorption of H-containing CHC_1 largely depends on the reactant. It implies that the relative concentrations of the reactant will directly influence the product distribution when mixtures of CHC_1 are converted. In order to use the catalytic conversion of CHC_1 for the production of re-usable chemicals, the selectivity has to be directed towards products containing C-H bonds, such as CH_3OH , $(\text{CH}_3)_2\text{O}$ and CH_2O . Also, the formation of CO , COCl_2 , CO_2 and C_2Cl_4 needs to be minimized. A way to tune the reaction towards more desirable products may be the combination of waste streams with a hydrogen and carbon rich source. The surface chlorination is, in view of the proposed reaction scheme, of direct influence on the selectivity. A catalyst with ample O promotes the reaction pathway involving H/Cl removal. The removal of H results in less hydrogenated, and hence less desirable, surface intermediates and gas phase products. The surface chlorination also inhibits the formation of carbonates, which reduces the formation of CO_2 . Therefore, a chlorinated catalyst is more selective than, for example, pure La_2O_3 . This is important when applying steam to make the reaction catalytic, because the chlorination degree of the steady state catalyst can be tuned for optimal conversion.

Acknowledgements

Maria Garcia Ramos (Utrecht University) is thanked for performing the GC activity experiments. Marco Daturi (University of Caen, France) and Ad Mens (Utrecht University) are thanked for their contribution to the design of the IR vacuum setup used in these experiments. We also thank Tom Visser (Utrecht University) for his input regarding the IR results. This work was supported by the National Research School Combination Catalysis (NRSC-C) and the Dutch Science Foundation (VICI/NWO-CW grant).

Conversion of Chlorinated Waste Streams from the Production of Polyvinyl Chloride
over La-Based Catalysts

4

Dehydrochlorination of Intermediates in the Production of Vinyl Chloride over La_2O_3 -Based Catalysts

Light ends waste mixtures contain both chlorinated C_1 (CHCl_1) and C_2 (CHCl_2). In this chapter, the dehydrochlorination of CHCl_2 over La_2O_3 and LaOCl catalyst materials is studied. This reaction is important for the conversion of the CHCl_2 in the light ends mixtures into more desirable chlorinated ethenes, such as 1,1- $\text{C}_2\text{H}_2\text{Cl}_2$ and $\text{C}_2\text{H}_3\text{Cl}$. Moreover, the dehydrochlorination of 1,2- $\text{C}_2\text{H}_4\text{Cl}_2$ into $\text{C}_2\text{H}_3\text{Cl}$ is a key step in the production of polyvinyl chloride (PVC), which is performed uncatalyzed in industry. Therefore, the conversion of chlorinated ethanes over La_2O_3 -based catalysts is not only interesting from a waste conversion point of view, but also as a potential process in the production of PVC. It was found both La_2O_3 and LaOCl are active for the elimination of HCl under formation of chlorinated ethenes. When a catalytic surface is oxygen-rich, side-reactions occur resulting in chlorination of the catalyst material and the formation of oxygenated products, such as CO and CO_2 . Instead, when a catalytic surface is chlorine-rich, a stable product distribution and surface composition is achieved with 100 % selectivity towards the formation of chlorinated ethenes.

Chapter 4

Introduction

1,1-C₂H₂Cl₂, which is the monomer for the production of polyvinylidene chloride (PVDC), is prepared from the dehydrochlorination of 1,1,2-C₂H₃Cl₃ using alkaline solutions.¹ Actually, in most cases 1,1,2-C₂H₃Cl₃ is used to produce 1,1-C₂H₂Cl₂, since sufficient quantities are formed during the production of C₂H₃Cl. Also, the cracking of 1,2-C₂H₄Cl₂ to C₂H₃Cl is a non-catalytic dehydrochlorination reaction. Not many heterogeneous catalysts are known for the dehydrochlorination of chlorinated ethanes, mainly because of low selectivity and chlorine poisoning. In fact, alumina is active for this reaction and has been studied because dehydrochlorination is an undesirable side-reaction in the oxychlorination of ethene into 1,2-C₂H₄Cl₂, which is catalyzed by CuCl₂/γ-Al₂O₃.^{2,3} Therefore, dehydrochlorination of chlorinated ethanes is not only interesting from a waste conversion point of view as an active dehydrochlorination catalyst could be used in the preparation steps towards C₂H₃Cl as well.

The goal of this Chapter is to investigate the relation between the La₂O₃-based catalyst composition and its activity and selectivity in the dehydrochlorination of chlorinated ethanes. C₂H₅Cl and 1,1,2-C₂H₃Cl₃ were chosen as reactants because they are the main C₂ byproducts found in the light ends mixtures, as was shown in Chapter 1. 1,2-C₂H₄Cl₂ was selected to test the catalyst for the conversion of into C₂H₃Cl, which is a commercially important reaction. Flow-gas experiments over LaOCl as a function of temperature were performed with C₂H₅Cl, 1,2-C₂H₄Cl₂, 1,1,2-C₂H₃Cl₃, C₂H₃Cl and C₂HCl₃ with online gas chromatography (GC) analysis. The latter two reactants were chosen to evaluate the catalyst activity towards unsaturated chlorinated C₂. Also, the conversion of 1,1,2-C₂H₃Cl₃ as a function of temperature was monitored in a static vacuum cell using gas phase infrared spectroscopy (IR) to complement the GC results. The stability and selectivity of La₂O₃ and LaOCl were evaluated in a flow-gas experiment at constant temperature with 1,1,2-C₂H₃Cl₃ as reactant. In addition, the catalyst composition before and after this experiment was characterized with X-ray photoelectron spectroscopy (XPS) and X-ray diffraction (XRD).

Experimental

Materials and Characterization

For this chapter, the LaOCl-P sample was used for the temperature-programmed and constant temperature activity experiments. The method of preparation and physicochemical properties of this sample have been described in detail in Chapter 2. The experiments with 1,1,2-C₂H₃Cl₃ were repeated with La₂O₃ (Acros Organics, 99.99 %). The phase composition of La₂O₃ and LaOCl-P after reaction as a function of time with 1,1,2-C₂H₃Cl₃ was determined using XRD and XPS. XRD measurements were performed at ambient conditions with a Bruker-AXS D8 diffractometer equipped with a Co_{Kα1,2} source. The XPS spectra were acquired

Dehydrochlorination of chlorinated ethanes over La₂O₃-Based materials

using a Perkin-Elmer (PHI) model 5500 spectrometer. All XPS spectra were obtained using samples in the form of pressed wafers.

Flow Gas Experiments

The activity experiments for the dehydrochlorination of C₂H₅Cl (Aldrich, ≥99.7 %), 1,2-C₂H₄Cl₂ (Acros Organics, 98+ %) and 1,1,2-C₂H₃Cl₃ (Acros Organics, 98 %) were performed in a tubular fixed-bed quartz reactor. The catalyst bed consisted of 0.5 g LaOCl-P or La₂O₃ pressed in a 200-500 μm sieve fraction, pretreated in 10 mL/min He (Hoekloos, ≥99.996 %) at 550 °C. To find the initial reaction temperature, the reaction was carried out from 50 to 400 °C using a 25 mL/min 3-4 vol% reactant/He flow. In the case of 1,1,2-C₂H₃Cl₃, the reactions were also performed at 400 °C over La₂O₃ and LaOCl-P. Details of the setup can be found in Chapter 2.

IR Experiments

During the flow gas experiments with 1,1,2-trichloroethane over La₂O₃, several products were detected which could not be assigned by GC. To complement the GC data, the reaction of 1,1,2-trichloroethane on La₂O₃ was monitored in situ by IR. For these IR measurements, the quartz cell was used, which was discussed in Chapter 2. All IR spectra were recorded using a Perkin Elmer 2000 spectrometer with a resolution of 4 cm⁻¹. La₂O₃ (Acros Organics, 99.99 %) was pressed into a self-supporting wafer (2 cm²), and activated in situ prior to the IR measurements in dynamic vacuum at 550 °C overnight. After pretreatment, 1,1,2-C₂H₃Cl₃ (Acros Organics, 98 %) (30 mbar) was introduced into the cell and the wafer was placed in the oven position of the cell, enabling the measurement of gas phase IR spectra. The temperature was raised from 100 to 400 °C in steps of 50 °C. After each step the temperature was held constant during which gas phase spectra were recorded.

Results and Discussion

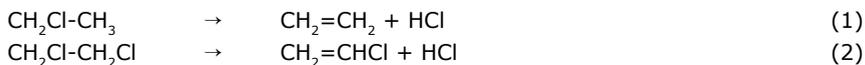

Temperature Programmed Reaction Experiments

The effluent composition of the temperature programmed dehydrochlorination reactions over LaOCl is shown in Figure 1. In the case of C₂H₅Cl and 1,2-C₂H₄Cl₂, 100 % selectivity is observed towards C₂H₄ and C₂H₃Cl, respectively (Reaction Eqs. (1) and (2)). 1,1,2-C₂H₃Cl₃ is converted into several products. A significantly lower initial reaction temperature is observed for chloroethane compared to 1,2-C₂H₄Cl₂ and 1,1,2-C₂H₃Cl₃. It has been established that the

Chapter 4

cleavage of the C-Cl bond typically precedes the removal of a H atom.^{4,5} Furthermore, it has been shown that the initial reaction rate for the dehydrochlorination of chlorinated ethanes increases with an increasing number of chlorine atoms.⁶ It should be noted, however, that this trend was established based on mono-, di- and tri-substituted chloroethanes with all chlorine atoms on the same carbon atom. With more C-Cl bonds on the same carbon atom in a chlorinated ethane molecule, the C-Cl bonds become more polarized. As a result, the C-Cl bonds are more susceptible to cleavage. Instead, C-Cl bonds on both carbon atoms may stabilize the polarization of the C-Cl bonds, which explains the higher initial temperature of reaction of 1,2-C₂H₄Cl₂ and 1,1,2-C₂H₃Cl₃ with respect to C₂H₅Cl.

The main product for the dehydrochlorination of 1,1,2-C₂H₃Cl₃ is 1,1-C₂H₂Cl₂ and in addition C₂H₃Cl and cis-1,2-C₂H₂Cl₂ are formed. The formation of C₂H₃Cl implies that Cl₂ elimination occurs. This reaction is, however, energetically highly unfavourable and is not expected to proceed. A possible explanation would be that a different product is co-eluting with C₂H₃Cl. Therefore, the product assigned by the GC as C₂H₃Cl has been labelled as X in Figure 1 and 2. Chlorine and hydrogen atoms can be removed from the reactant molecule via two pathways of HCl elimination, shown in Reaction Scheme 1. The formation of 1,1-C₂H₂Cl₂ (Scheme 1, Reaction a) is favoured over the reaction towards 1,2-C₂H₂Cl₂ (Scheme 1, Reaction b). In addition, no formation of trans-1,2-C₂H₂Cl₂ (Scheme 1, Reaction c) was detected. At 400 °C, trace amounts of CO and CO₂ were detected. Blank experiments were also performed and no significant product formation was observed, which rules out non-catalytic gas phase reactions. Based on these results, it is concluded that LaOCl is an active catalyst for the dehydrochlorination of chlorinated ethanes.

The dehydrochlorination of chlorinated ethanes over heterogeneous catalysts is catalyzed by three types of active sites: acidic, basic or dual sites.⁷ It has been shown that for the dehydrochlorination of 1,1,2-trichloroethane, the selectivity towards the 1,1- and 1,2-product are influenced by the acid-base properties of the catalyst.⁷ Control of the chlorination degree of the catalyst is crucial to tune the acid-base properties and optimize the performance of the catalyst when converting mixtures of chlorinated C₁ and C₂. In Chapters 2 and 3, it was shown that the acid-base properties of La₂O₃-based catalysts are a key factor for the activation of C-Cl and C-H bonds in chlorinated C₁. Hence, the degree of chlorination may also be of influence on the selectivity of the dehydrochlorination of chlorinated C₂. Therefore, the reaction with 1,1,2-C₂H₃Cl₃ was repeated with La₂O₃, which contains weaker La³⁺ Lewis acid sites. The reactor effluent composition was analyzed throughout the experiment, as shown in Figure 2. In addition to the products observed over LaOCl, trans-1,2-C₂H₂Cl₂ is detected. However, as the temperature increases the selectivity towards 1,1-C₂H₂Cl₂ increases, while it decreases towards the other products. Low concentrations of CO and CO₂ were detected as in the case of LaOCl. Also, small amounts of two products were detected

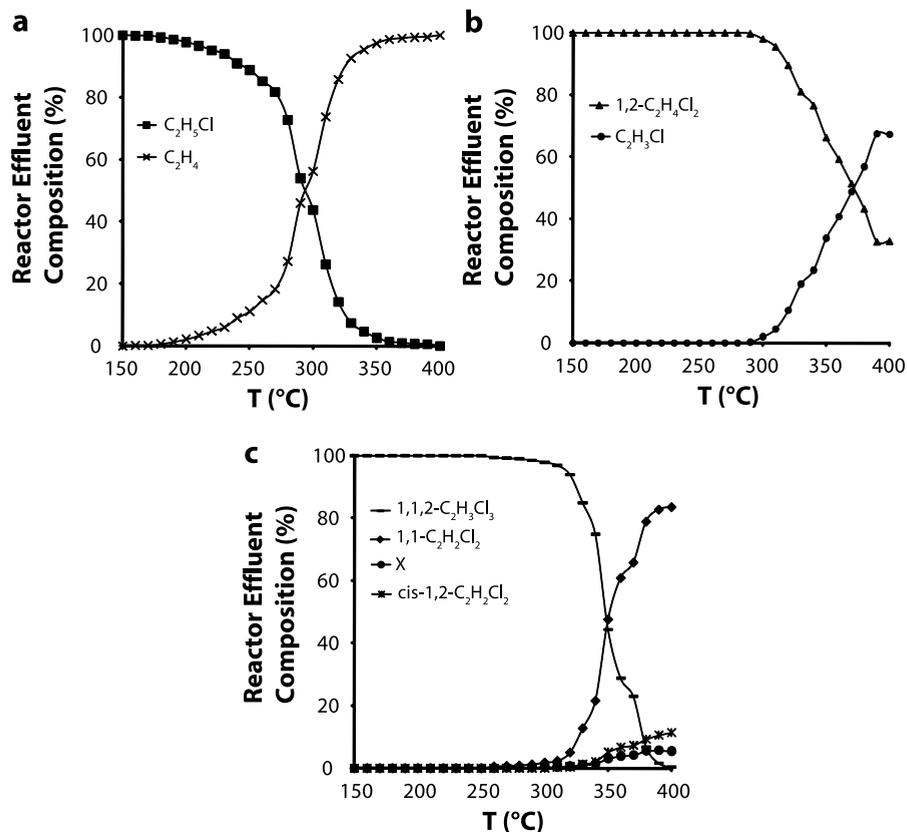

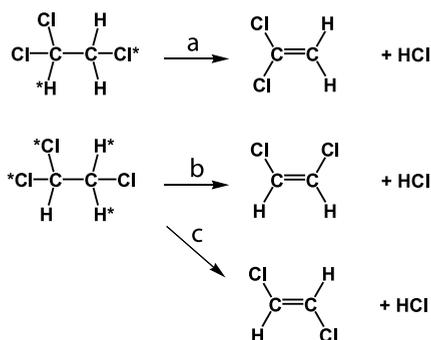

Dehydrochlorination of chlorinated ethanes over La_2O_3 -Based materials

which could not be assigned based on the GC results. Even though these products could not be identified, the retention times indicate that these compounds are chlorinated hydrocarbons (CHCs). Therefore, the same response factor as for the other CHCs is assumed to be valid for these unknown products.

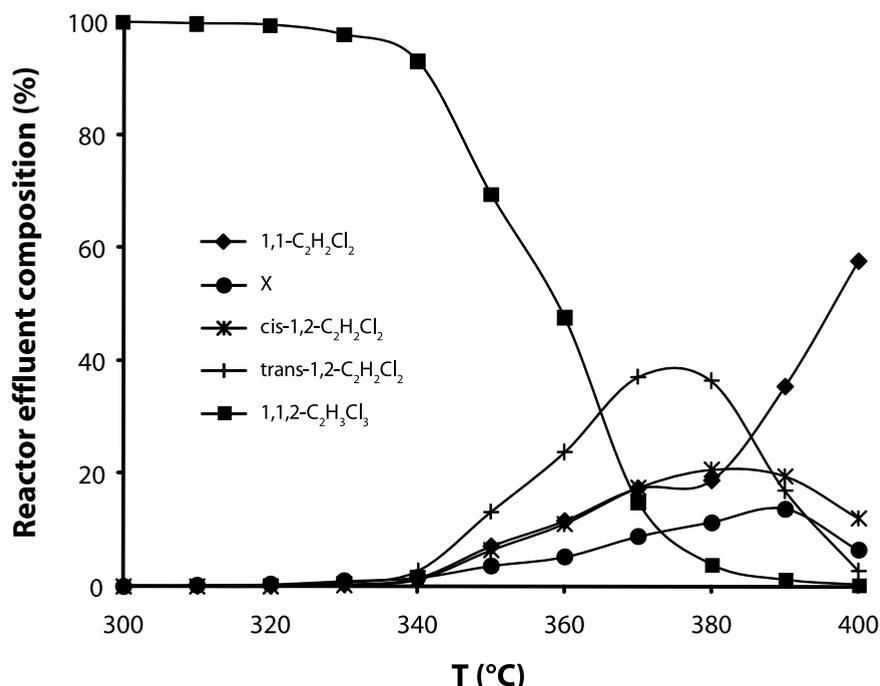

Figure 2. Effluent composition for the dehydrochlorination of 1,1,2-C₂H₃Cl₃ over La₂O₃ as a function of temperature (GHSV = 2000 h⁻¹, inlet concentration: [1,1,2-C₂H₃Cl₃] = 3.2 vol%, X = product unassigned based on GC).

In Situ IR Reaction Experiments

The flow-gas experiments indicate that La₂O₃ and LaOCl catalyze the dehydrochlorination of chlorinated ethanes and that the acid-base properties of the catalyst directly influence the selectivity. However, the assignment of the products is difficult with gas chromatography only. Therefore, the gas phase composition of the temperature programmed reaction on La₂O₃ in a vacuum cell was monitored using IR spectroscopy to complement the GC results. The recorded spectra are shown in Figure 3. In the spectral regions 2250-2400 and 1350-1900 cm⁻¹, the strong bands of ambient CO₂ and H₂O, respectively, were removed by spectroscopic software. Figure 3a illustrates the increase and decrease of the bands in the gas phase spectra as a function of temperature during the experiment. In Figure 3b, the spectrum of the reactant at room temperature (RT) is shown together with that of Spectrum

Dehydrochlorination of chlorinated ethanes over La_2O_3 -Based materials

Chapter 4

11 from Figure 3a. Spectrum 11 was chosen for the assignment of the bands of the products, because all the bands which are observed during the experiment are present in this spectrum.

The assignment of the bands based on reference spectra is shown in Table 1.⁸ The products that are formed throughout the experiment are 1,1-C₂H₂Cl₂, cis-1,2-C₂H₂Cl₂, trans-1,2-C₂H₂Cl₂, C₂HCl, CO and CO₂. Specific bands were chosen, which possesses high intensity and minimal overlap with other bands, to derive the relative ratios of the products as a function of temperature as shown in Figure 3a. The spectra show that C₂H₂Cl₂ derivatives are formed simultaneously at 200 °C (Figure 3a, spectrum 4).

3340				3340 (vs)		

As the temperature increases (Figure 3a, spectrum 5-9), the intensity of the chlorinated ethene bands increases with maximum intensity at 250 °C (Figure 3a, spectrum 9). Further increase of the temperature results in a decrease in intensity of the bands assigned to cis/trans-1,2-C₂H₂Cl₂. The intensity of the 1,1-C₂H₂Cl₂ band, however, remains constant. The decrease in intensity of the bands of the 1,2-derivatives is accompanied by the formation of CO, CO₂ and C₂HCl (Figure 3a, spectrum 10). The formation of C₂HCl indicates that a second dehydrochlorination reaction may occur resulting in the formation of a C=C bond. At 350 °C, a band becomes visible at 730 cm⁻¹, for which a reference could not be found. Strong

Dehydrochlorination of chlorinated ethanes over La₂O₃-Based materials

absorption at this position is characteristic for C-Cl stretch vibrations. When the temperature reaches 400 °C, the bands of C₂HCl and 1,1-C₂H₂Cl₂ also decrease and a strong increase in intensity of the CO₂ band is observed. The formation of CO and CO₂ is characteristic for destructive adsorption of CHCs. After more than 1 h of reaction, only CO and CO₂ are detected. These results show that high temperatures should be avoided to prevent undesirable secondary reactions.

No bands indicative of C₂H₃Cl were observed in the spectra. The other products which were detected during the temperature programmed flow-gas experiment over La₂O₃ (Figure 2), namely 1,1-C₂H₂Cl₂ and cis/trans-1,2-C₂H₂Cl₂, were also observed in the in situ IR experiment. Therefore, based on these spectra it is proposed that the product which co-elutes with C₂H₃Cl is C₂HCl. The dehydrochlorination of 1,1,2-C₂H₃Cl₃ proceeds at relatively low temperature. At higher temperature, two secondary reactions of the chlorinated ethenes are favorable; a second elimination of HCl or destructive adsorption. The former results in the formation of C₂HCl. The latter leads to the breaking of the C-C bond and formation of CO and CO₂ via exchange of oxygen and chlorine atoms. The 1,2-C₂H₂Cl₂ derivatives are more susceptible to the secondary reactions than 1,1-C₂H₂Cl₂. It should be noted that no significant amounts of CO and CO₂ were detected during the flow-gas experiments. A possible reason for this may be the different nature of the experiments; the IR experiments are in a closed cell as opposed to the flow-gas experiment in which the reactant has a limited residence time.

Catalyst Behaviour

The temperature programmed flow-gas experiment over La₂O₃ suggests there is an induction period during which the selectivity changes. This is supported by the in situ IR experiments. Moreover, no bands indicative of HCl were found in the gas phase spectra. It is known that La₂O₃ and LaOCl can be chlorinated into a pure LaCl₃ phase using HCl. The HCl reacts with the basic oxygen sites according to Reaction Eq. (3). During the dehydrochlorination of chlorinated ethanes, HCl may either be re-adsorbed or the H and Cl atom are abstracted directly by the La-O couple and remain on the surface. Either way, the catalytic surface will change which may affect the activity and selectivity. The stability of LaOCl and La₂O₃ materials for the dehydrochlorination of 1,1,2-C₂H₃Cl₃ was tested in a flow-gas experiment at 400 °C. The reactor effluent composition as a function of time is shown in Figure 4. The experiment over La₂O₃ was stopped prematurely because the reactor became plugged.

The experiments show that over La₂O₃, an induction period precedes a stable conversion and product distribution. The same products which were detected during the temperature programmed reactions are formed. The two unknown products, labelled x1 and x2, are

Chapter 4

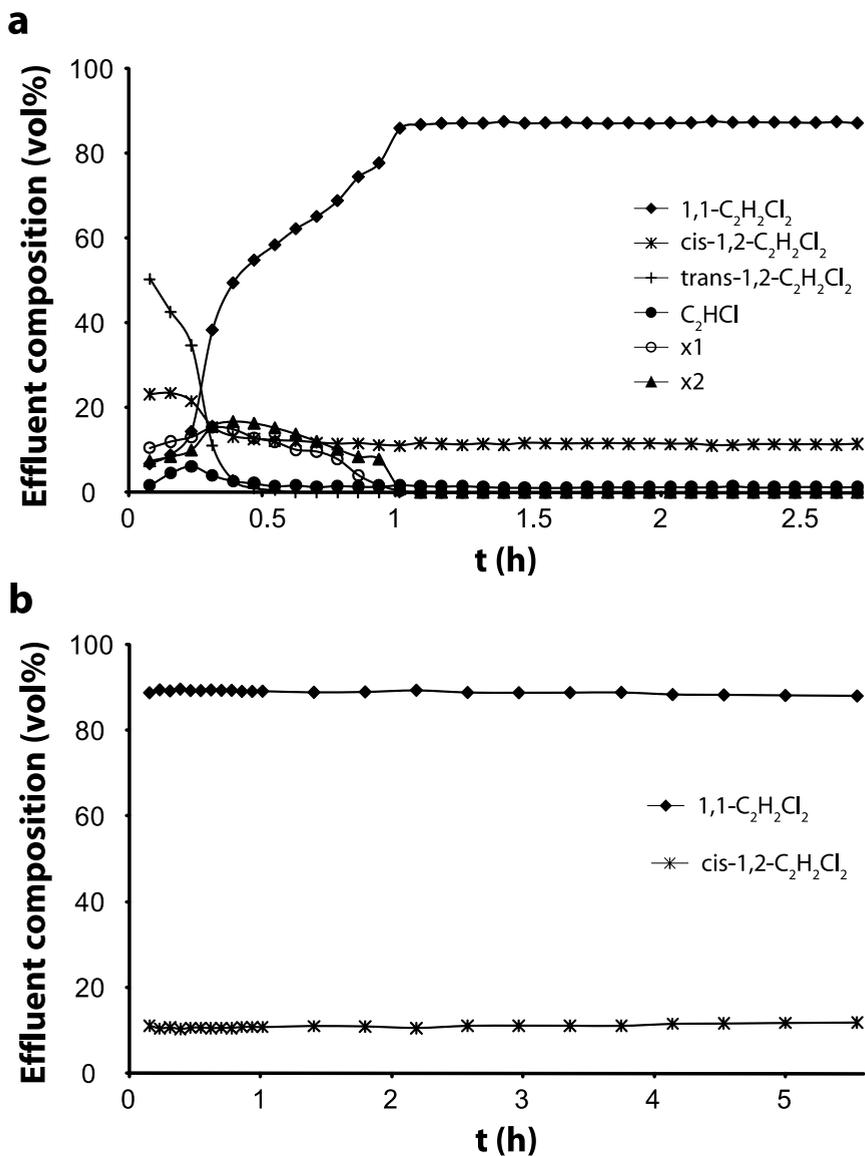

Figure 4. Effluent composition for the dehydrochlorination of 1,1,2-C₂H₃Cl₃ over (a) La₂O₃ and (b) LaOCl at 400 °C as a function of time (GHSV = 2000 h⁻¹, inlet concentration: [1,1,2-C₂H₃Cl₃] = 3.2 vol%, x_n = product unassigned based on GC and IR).

Dehydrochlorination of chlorinated ethanes over La₂O₃-Based materials

formed at higher concentrations than during the temperature programmed experiments and are therefore included in Figure 4. In the case of LaOCl, the induction period is not observed. After the induction period, the product distribution in the constant temperature experiments is similar for both LaOCl and La₂O₃. Although coke formation was observed, no significant loss of activity occurs in the experiments. LaOCl has proven to be a more stable catalyst with high selectivity towards chlorinated ethenes.

Even though the GC is not calibrated for HCl and H₂O, these products are visible in the chromatogram at low retention times. The intensities of the peaks assigned to HCl and H₂O are shown in Figure 5 as a function of time. The hydroxyl groups formed after HCl elimination can react into both HCl and H₂O. Initially, H₂O is eliminated from the oxygen-rich catalytic surface according to Reaction Equation (4). As the reaction proceeds, less hydroxyl groups are available and more chlorine is present on the surface. As a result, elimination of HCl from the surface becomes more favourable. The reaction time at which HCl formation becomes more dominant than H₂O formation, is also when the product distribution becomes stable. Therefore, it is proposed that a specific degree of chlorination of the catalyst material results in steady-state conversion of chlorinated ethanes. It should be noted that a small amount of H₂O is probably still formed together with HCl once the product distribution has stabilized, but due to overlap of the H₂O and HCl peak, the intensity of the H₂O peak is considered zero.

If a specific chlorination degree is needed for steady-state conversion, the catalyst materials used in the constant temperature experiments should possess similar surface compositions. To verify this, the LaOCl and La₂O₃ catalyst were characterized before and after reaction with 1,1,2-trichloroethane using XPS and XRD. The XRD results, as shown in Figure 6, provide information on the bulk phase composition of the catalyst materials. Before reaction, the characteristic diffraction patterns of LaOCl and La₂O₃ are observed (Figure

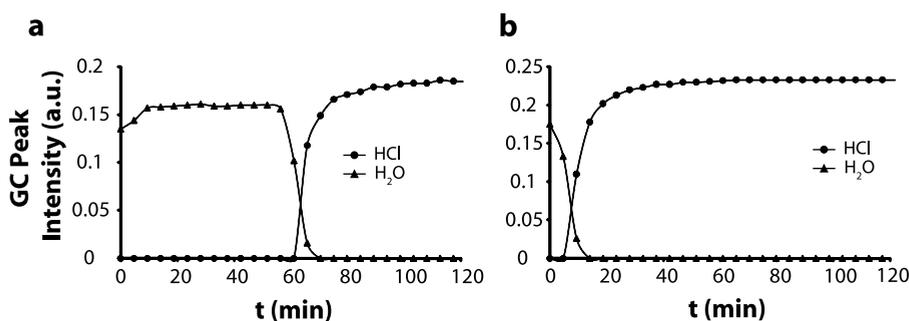

Figure 5. Intensity of H₂O and HCl peak in the chromatograms for the dehydrochlorination of 1,1,2-C₂H₃Cl₃ over (a) La₂O₃ and (b) LaOCl at 400 °C as a function of time as shown in Figure 4 (GHSV = 2000 h⁻¹, inlet concentration: [1,1,2-C₂H₃Cl₃] = 3.2 vol%, x_n = product unassigned based on GC and IR).

Chapter 4

6a and 6c, respectively). The diffractogram of La_2O_3 after approximately 3 h of reaction at 400 °C is shown in Figure 6b. The peaks observed after reaction show that during reaction the crystalline La_2O_3 phase has been converted into a pure crystalline LaOCl phase. Even though the peaks are much broader in the amorphous LaOCl catalyst material, the similarity is straightforward. The dehydrochlorination of 1,1,2-trichloroethane at 400 °C over LaOCl was performed for ca. 6 h, which is over two times as long as in the case of La_2O_3 . The pattern of the LaOCl phase is partially preserved after reaction. However, a second phase is present, which was assigned as $\text{LaCl}_3 \cdot 3\text{H}_2\text{O}$. The peaks at $2\theta = 17.3, 29.2, 38.5, 42.5$ and 46.9° and their relative intensities are characteristic of $\text{LaCl}_3 \cdot 3\text{H}_2\text{O}$. It is uncertain whether LaOCl is converted into $\text{LaCl}_3 \cdot 3\text{H}_2\text{O}$ directly or into LaCl_3 , which becomes hydrated when it is exposed to air prior to the XRD measurement. Either way, the bulk phase of both La_2O_3 and LaOCl has become chlorinated during the constant temperature reactions. Chlorination of the bulk phase is also observed during the destructive adsorption and catalytic destruction of chlorinated C_1 . This is caused by the solid-state diffusion of oxygen and chlorine atoms between the catalytic surface and the bulk. As the surface becomes chlorinated, the chlorine atoms diffuse into the bulk and surface oxygen is regenerated. It is therefore viable to assume that the same process occurs when the surface becomes chlorinated as a result of the dehydrochlorination reaction.

The surface composition of LaOCl and La_2O_3 before and after reaction was determined with XPS. All spectra were normalized to the La3d bands. Because La_2O_3 -based materials strongly adsorb CO_2 and H_2O , the exposure to air may influence the characterization of O atoms. The intensity of the Cl2p band was therefore chosen as a measure of surface chlo-

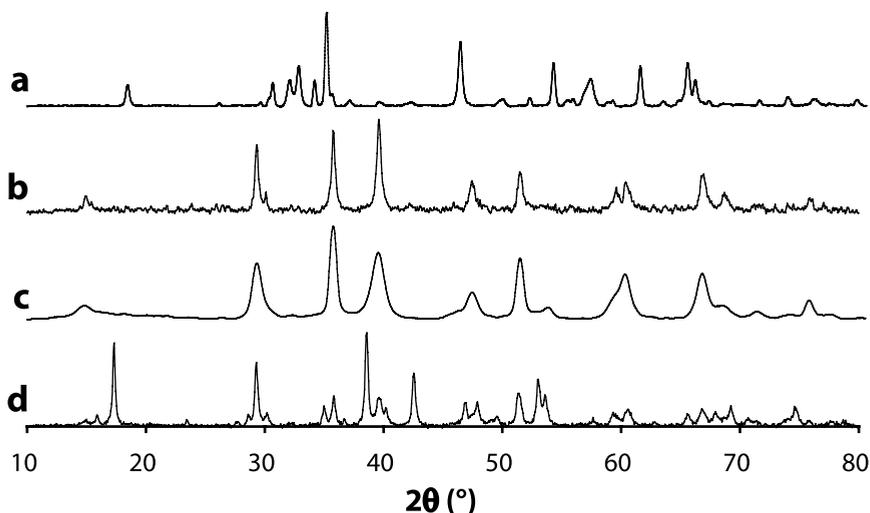

Figure 6. X-ray diffractograms of La_2O_3 and LaOCl before (a and c, respectively) and after (b and d, respectively) the dehydrochlorination of 1,1,2- $\text{C}_2\text{H}_3\text{Cl}_3$ at 400 °C, as shown in Figure 4.

Dehydrochlorination of chlorinated ethanes over La₂O₃-Based materials

mination. Figure 7 shows the Cl2p band for LaOCl and La₂O₃ before and after reaction. The Cl2p band is obviously not observed in the spectrum of La₂O₃ before reaction (Figure 7a). However, the La4p band is observed in the same region at 197 eV. Both these XPS bands are known to possess a shoulder at higher energy than the maximum, which is also observed here. The La4p band appears as a shoulder of the Cl2p band in the spectra of the materials containing chlorine. The Cl2p band positioned at 200 eV is observed in Figure 7b-d. The spectra show that the surface chlorination of the materials after reaction is approximately the same and in both cases higher than before reaction. This result confirms the hypothesis that a specific degree of chlorination is required to reach steady-state conversion.

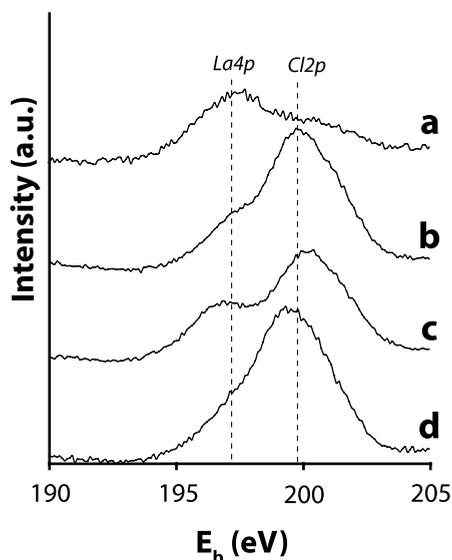

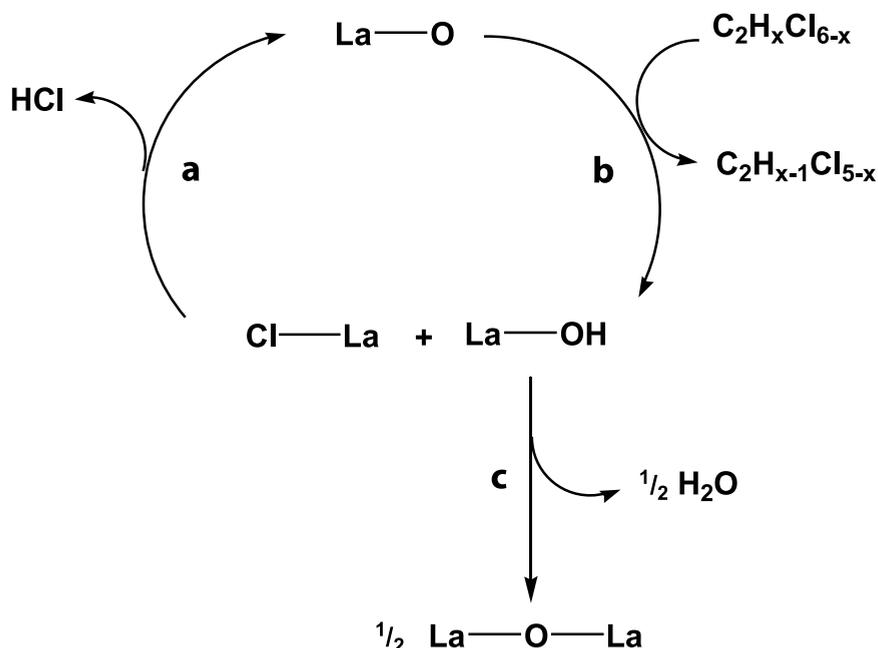

Figure 7. X-ray photoelectron spectra of La₂O₃ and LaOCl before (a and c, respectively) and after (b and d, respectively) the dehydrochlorination of 1,1,2-C₂H₃Cl₃ at 400 °C, as shown in Figure 4.

Conclusions

La₂O₃-based materials are active catalysts for the dehydrochlorination of chlorinated ethanes. The reaction scheme for the dehydrochlorination of chlorinated ethanes over La₂O₃-based catalyst materials is schematically shown in Scheme 2. A hydrogen and chlorine atom is abstracted from the chlorinated ethane, resulting in the formation of a hydroxyl group and a lattice chloride (Reaction b). In the case of an O-rich surface, such as La₂O₃, the hydroxyl groups will react with other hydroxyl groups under formation of H₂O (Reaction c). However, when a specific degree of chlorination of the catalytic surface is reached, the elimination of H₂O becomes less pronounced and HCl is formed (Reaction a). After the induction period

Chapter 4

Scheme 2. Catalytic cycle for the dehydrochlorination of chlorinated ethanes over La_2O_3 -based materials: (a) desorption of HCl from the catalyst material, (b) H + Cl abstraction by catalytic surface and (c) desorption of H_2O from the catalyst material

characterized by the formation of H_2O , the product distribution and conversion become stable and the chlorination degree of the catalyst surface also remains constant.

The in situ IR experiment has shown that at relatively high temperature, secondary reactions may occur, such as a second dehydrochlorination step resulting in the formation of an ethyne, or destructive adsorption leading to the formation of CO and CO_2 . This indicates that the reaction temperature and chlorination degree are key factors to achieve optimal selectivity towards the formation of ethenes. Because the chlorination degree of the catalyst is of influence on both activity and selectivity for the conversion of chlorinated C_1 and C_2 , it may be used to tune the catalytic properties of the La_2O_3 -based catalyst.

Conversion of Chlorinated Waste Streams from the Production of Polyvinyl Chloride
over La-Based Catalysts

Hydrogen-Chlorine Exchange between Chlorinated Waste Compounds over LaCl_3 -based Catalysts under Oxygen-Free Conditions

CCl_4 has been banned from commercial uses and is currently only produced in chemical industries as a by-product. The combination of its low economic value and environmental regulation makes this compound undesirable and its conversion into more valuable products advantageous. In this chapter, the H-Cl exchange reaction of CCl_4 with other chlorinated hydrocarbons (CHCs), specifically CH_2Cl_2 , over unsupported and carbon nanofiber (CNF)-supported LaCl_3 catalysts is studied. The chapter starts with an introduction on the potential of LaCl_3 as a catalyst material for the H-Cl exchange reaction. Next, thermodynamic calculations, the synthesis of the LaCl_3 materials, density functional theory (DFT) calculations and activity experiments are discussed. It will be shown that LaCl_3 is an active catalyst for the H-Cl exchange reaction between CCl_4 and CH_2Cl_2 with 100 % selectivity towards CHCl_3 and 45 % conversion per g LaCl_3 at 450 °C. Unsupported LaCl_3 catalysts show low conversion due to their low surface area. In contrast, CNF-supported LaCl_3 catalysts are found to be significantly more active than the unsupported catalysts based on both weight and volume. DFT calculations indicate that weakly adsorbed hydride and chloride species are present on the catalytic surface and are exchanged with H and Cl atoms from the gas phase reactant. To the best of our knowledge, this is the first catalyst for the exchange of H and Cl between gas phase reactants without the presence of either lattice or gas phase oxygen atoms.

Chapter 5

Introduction

CCl_4 is one of the most hazardous chlorinated compounds and has been banned from commercial use in many countries. As a result, the production of CCl_4 has been decreasing and will continue to phase out.¹ Hence, the economic value of this chemical is low and it is considered a waste product. However, CCl_4 is still produced in chemical industries as a by-product. Therefore, both the production and disposal of CCl_4 are heavily regulated.^{1, 2} H-Cl exchange with other chlorinated hydrocarbons (CHCs) would be advantageous to make more valuable CHCs, which could be recycled in the production process.

Reaction thermodynamics are favorable for using CCl_4 as a Cl source with CH_4 or another chloromethane. The best known way for running these reactions is thermal gas phase radical chemistry.³ The disadvantage of radical chemistry is its low selectivity due to the formation of various chlorinated C_1 (CHC_1) and C_1 (CHC_2) coupling products.³ In addition, coke formation at the temperatures that are required for radical generation is severely hampering the process. As a result, commercial application of this reaction is currently not feasible and incineration is commonly used as a route for the destruction of CCl_4 .

La_2O_3 -based catalysts are known to be active for the catalytic conversion of CHC_1 ⁴⁻⁹ as well as the activation of hydrocarbons, such as CH_4 and C_2H_6 .¹⁰⁻¹² In other words, these catalyst materials are able to activate both C-H and C-Cl bonds. Here, we report for the first time that LaCl_3 can be used as a highly active and stable catalyst for the H-Cl exchange between CHC_1 ; i.e. a mixture of CH_2Cl_2 and CCl_4 . Catalytic H-Cl exchange of CCl_4 with CH_4 has been studied before, focusing on supported Pt/Mn systems in combination with O_2 . This catalytic system is, however, markedly different from the materials described here. So far, all catalytic systems involving the exchange of H and Cl between gas phase reactants require the presence of O atoms, either as lattice oxygen or in gas phase molecules, such as O_2 and H_2O . In this case, the La-based catalysts were synthesized by chlorination of a precursor to LaCl_3 to exclude the presence of lattice oxygen in the catalyst. This is necessary to prevent the destructive adsorption processes of the reactant molecules. A catalyst for this type of reaction without O atoms is novel and offers new possibilities for the conversion of CHCs, in particular CCl_4 .

Experimental

Calculations with HSC Chemistry 4.1

The equilibrium composition of an equimolar mixture of CCl_4 and CH_2Cl_2 was calculated as a function of temperature. Three sets of input data were used for the calculations and are summarized in Table 1. Data set 1 consists of all CHC_{1-2} , HCl, Cl_2 and C. In data set 2, C was omitted to exclude dissociation of the reactants into coke. Data set 3 only consists of

O-free H-Cl exchange over LaCl₃-based Catalysts

the CHC₁₋₂ to prevent HCl elimination reactions. The temperature range was 0 to 600 °C at ambient pressure and 101 data points were calculated. In addition, the free Gibbs energy change was calculated for several reactions that resulted from data sets 1-3 as a function of temperature.

Catalyst Preparation

Three LaCl₃-based catalyst materials were investigated; two bulk catalysts and one supported on CNF. The precursors used for the bulk materials were synthesized LaOCl and commercial LaCl₃•7H₂O. The preparation of LaOCl-P has been described in Chapter 2. LaCl₃•7H₂O

Chapter 5

was dried at 60 °C overnight, which resulted in dehydration into $\text{LaCl}_3 \cdot 3\text{H}_2\text{O}$ as determined by X-ray diffraction (XRD) (not shown). The carbon-supported catalyst was synthesized by the incipient wetness impregnation method making use of an aqueous LaCl_3 solution on synthesized carbon nanofibers (CNF). In this manner, 20 wt% LaCl_3 was loaded on the CNF material. CNF were grown as described by Toebes et al.¹³ Supported Ni/ SiO_2 catalyst with a metal loading of 5 wt% was used to grow low density CNF (140 m^2/g), prepared by homogeneous deposition precipitation.¹⁴ After impregnation the catalyst was dried at 60 °C overnight. Before chlorination, sieve fractions of the pre-treated precursors were heated at 500 °C in He for 6 h. Next, the precursors were chlorinated in situ using the setup described in Chapter 2.2.2. $\text{LaCl}_3 \cdot 3\text{H}_2\text{O}$ was chlorinated with 6 vol% CCl_4/He for 30 h at 460 °C, and was labelled $\text{LaCl}_3\text{-H}$. LaOCl-P and the CNF-supported catalyst were chlorinated with 10 vol% HCl/He at 460 °C for 20 and 4 h, respectively. They were labelled $\text{LaCl}_3\text{-P}$ and $\text{LaCl}_3\text{-C}$, respectively. In Table 2, an overview of the catalysts and preparation methods is provided.

Table 2. Overview of preparation and nomenclature of LaCl_3 catalyst materials.

Name	Precursor	Precursor pre-treatment	Method of chlorination	Precursor BET surface area (m^2/g)
$\text{LaCl}_3\text{-H}$	$\text{LaCl}_3 \cdot 3\text{H}_2\text{O}$	Dried in air at 60 °C Heated in He at 500 °C	6 vol% CCl_4/He at 460 °C	1

$\text{LaCl}_3\text{-C}$	$\text{LaCl}_3 \cdot 7\text{H}_2\text{O}$ CNF	CNF impregnated with 20 wt% $\text{LaCl}_3 \cdot 7\text{H}_2\text{O}$ Dried in air at 60 °C Heated in He at 500 °C	10 vol% HCl at 460 °C	120

Activity Experiments

The catalytic experiments were performed in the setup described in Chapter 2.2.2. Equimolar mixtures of either CH_2Cl_2 with CCl_4 of 4-6 vol% each in He were led over the catalyst with a flow rate of 5 ml/min ($\text{GHSV} = 400 \text{ h}^{-1}$). As the catalysts materials were synthesized by in situ synthesis, the amount of LaOCl and $\text{LaCl}_3 \cdot 7\text{H}_2\text{O}$ was pre-calculated for 1 g of LaCl_3 . In the case of the carbon supported catalyst, the reactor was filled with approximately the same volume as in the case of the bulk catalyst. For the bulk materials, blank experiments were performed with quartz pellets. For the supported catalyst, CNF were used for a blank experiment. During the temperature programmed experiments, the reactor temperature was raised from 300 to 460 °C in steps of 20 °C, and the effluent was continuously analyzed by GC. In addition, the H-Cl exchange of $\text{CCl}_4/\text{CH}_2\text{Cl}_2$ was performed over the CNF supported catalyst at 400 °C for 36 h.

O-free H-Cl exchange over LaCl₃-based Catalysts

Density Functional Theory (DFT) Calculations

Gradient-corrected spin-polarized periodic DFT calculations using DMol3 code in Materials Studio 3.2 by Accelrys were performed with a LaCl₃(100) model surface based on a 2x2 periodic unit cell with 16 layers (total of 64 atoms), similarly to calculations reported previously.^{6, 9, 11} The 6 bottom layers were constrained during the calculations to simulate bulk properties, and the remaining top layers were optimized with an adsorbate. A vacuum spacing of 1.5 nm was used in all surface models. The calculations used the double numerical with polarization (DNP) basis set and the generalized gradient-corrected Perdew-Wang (GGA PW91) functional. Tightly bound core electrons for La were represented with semi-core pseudopotentials. Reciprocal-space integration over the Brillouin zone was approximated through k-point sampling with a separation of 0.5 nm⁻¹ using the Monkhorst-Pack grid (1x2x1). Convergence with respect to the number of k-points was tested by decreasing the k-point separation distance to 0.4 nm⁻¹ for representative structures. An orbital cutoff distance of 0.5 nm was used for all atoms. All adsorption and surface reaction energies were calculated at 0 K without zero-energy corrections.

Results and Discussion

Thermodynamic Calculations

The calculations were performed by creating several datasets. The software consists of a database with the thermodynamic properties of chemicals. The reactant input amounts were chosen as 0.5 mol of CCl₄ and 0.5 mol of CH₂Cl₂. The computer program calculates equilibrium compositions based on these input amounts as a function of temperature. Apart from the reactants, the data set also consists of the products which are permitted. When a product is not included in the dataset, the program will not allow it as a product. It should be noted that these equilibria are based on thermodynamics and do not provide information on the kinetics. The equilibrium mixtures found for each data set are shown in Figure 1.

In data set 1, all likely products are included, namely CH_xCl_{4-x}, C₂H_xCl_{6-x}, C₂H_xCl_{4-x}, HCl, Cl₂ and C. Figure 1a shows that in the whole temperature range, CH₂Cl₂ is not present in the equilibrium mixture. Up to 200 °C, no reaction of CCl₄ occurs and CH₂Cl₂ fully dissociates according to Reaction Eq. (1) At higher temperatures, CCl₄ dissociates into C and Cl₂ (Reaction Eq. (2)). Based on this result, dissociation of CH₂Cl₂ into carbon and HCl is expected to be more favourable than in the case of CCl₄. Overall, this means that catalyst coking may occur during reaction.

Chapter 5

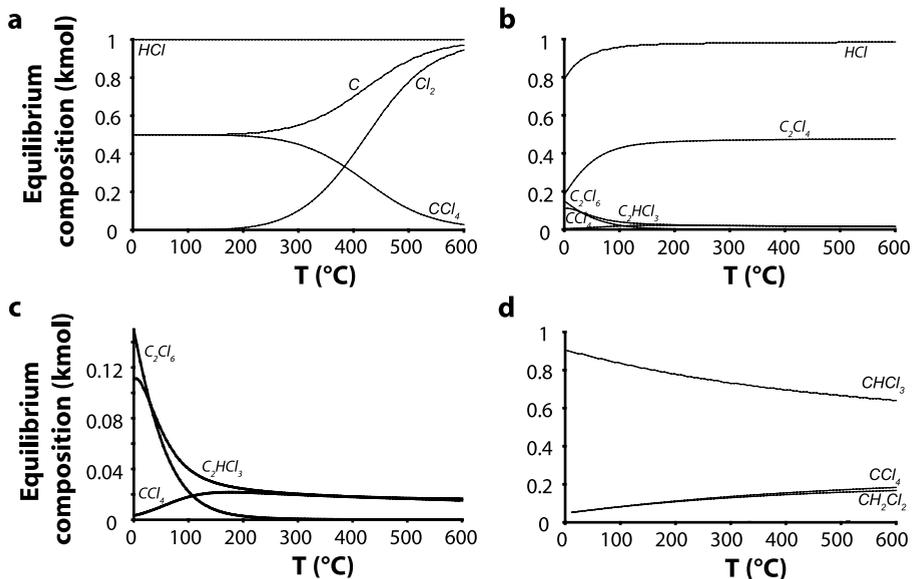

Figure 1. Equilibrium composition calculations of an equimolar mixture of CCl_4 and CH_2Cl_2 as a function of temperature using Data set 1 (a), Data set 2 (b, c) and Data set 3 (d).

In Data set 2, carbon was omitted from the products. In other words, the formation of coke was excluded from the equilibrium calculations. This translates into formation of CHC_2 via elimination of HCl . The main product in the equilibrium mixture is expected to be C_2Cl_4 and HCl (Reaction Eq. (3)). The formation of C_2Cl_4 has been observed experimentally, indicating that the reaction is also kinetically favourable.³ At low temperature, C_2Cl_6 and C_2HCl_3 are formed.

In the third data set, the formation of HCl and Cl_2 was excluded in addition to carbon. This set was used to evaluate the reactions yielding CHC_{1-2} only. It is found that CCl_4 and CH_2Cl_2 are equilibrated with CHCl_3 by H-Cl exchange (Reaction Eq. (4)). The calculations show that the reaction mixture cannot be fully converted into CHCl_3 in this temperature range.

The free Gibbs energy change for the main reactions found in the equilibrium composition calculations were determined (Figure 2), namely: 1) the dissociation of CCl_4 , 2) the dissociation of CH_2Cl_2 , 3) the formation of C_2Cl_4 via HCl elimination and 4) formation of CHCl_3 via

O-free H-Cl exchange over LaCl_3 -based Catalysts

H-Cl exchange (Reaction Eqs. (1), (2), (3) and (6), respectively). Based on thermodynamics, the following trend was observed going from most favourable to least favourable: dissociation of $\text{CH}_2\text{Cl}_2 >$ the formation of C_2Cl_4 via HCl elimination $>$ formation of CHCl_3 via H-Cl exchange $>$ the dissociation of CCl_4 . In gas phase experiments at relatively high temperatures ($>500\text{ }^\circ\text{C}$), three reactions were observed: the formation of coke, C_2Cl_4 and CHCl_3 . Both the formation of C_2Cl_4 and coke are undesirable reactions. Therefore, a catalyst for the selective exchange of H and Cl atoms, such as for CCl_4 and CH_2Cl_2 , would be advantageous.

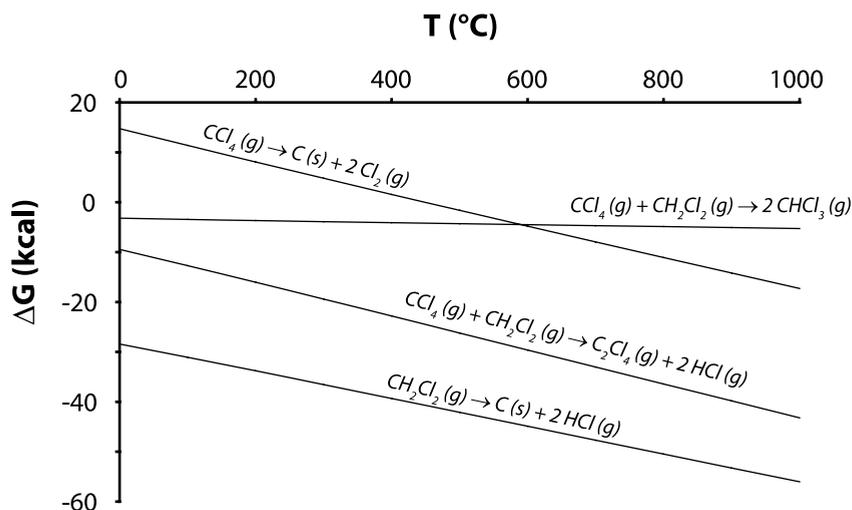

Figure 2. Free Gibbs energy change for reactions involving CCl_4 and CH_2Cl_2 as a function of temperature.

Catalyst Activity and Stability

The reaction between CH_2Cl_2 and CCl_4 over LaCl_3 yielded CHCl_3 exclusively according to Reaction Eq. (4). Unfortunately, coke formation was observed and may hamper the long-term application of the catalyst material. Figure 1a shows that $\text{LaCl}_3\text{-H}$ has a low, but appreciable activity. Although determination of the catalyst surface area is impracticable due to the hygroscopic nature of LaCl_3 , the low conversion is most likely a result of the low surface area of the $\text{LaCl}_3 \cdot 7\text{H}_2\text{O}$ precursor. Therefore, LaOCl-P with a relatively high surface area (Table 2) was used as a precursor and was chlorinated with HCl. This resulted only in a slight increase in catalytic conversion as shown in Figure 3a. The higher surface area of the LaOCl-P precursor is most likely lost by the chlorination pre-treatment with HCl. To efficiently increase the catalyst surface area, LaCl_3 was impregnated onto CNF. This support was selected because of its relative inertness to the chlorination of the precursor with HCl and the absence of lattice oxygen, which may lead to destructive adsorption of the reactants.

Chapter 5

In addition, the deposition of non-metals on carbon supports has been proven successful.¹⁵ Figure 3a clearly shows that this catalyst exhibits the highest conversion on a weight basis. Also on a volume basis, $\text{LaCl}_3\text{-C}$ is almost two factors more active compared to the unsupported materials (Figure 3b).

To evaluate the stability of $\text{LaCl}_3\text{-C}$, the reaction was run for 36 h at 400 °C. The results are shown in Figure 4 and indicate the presence of an induction period in the first hour of reaction. In that period a significant amount of coke is formed together with HCl and Cl_2 (Reaction Eqs. (1) and (2)). The conversion into coke was calculated based on the difference be-

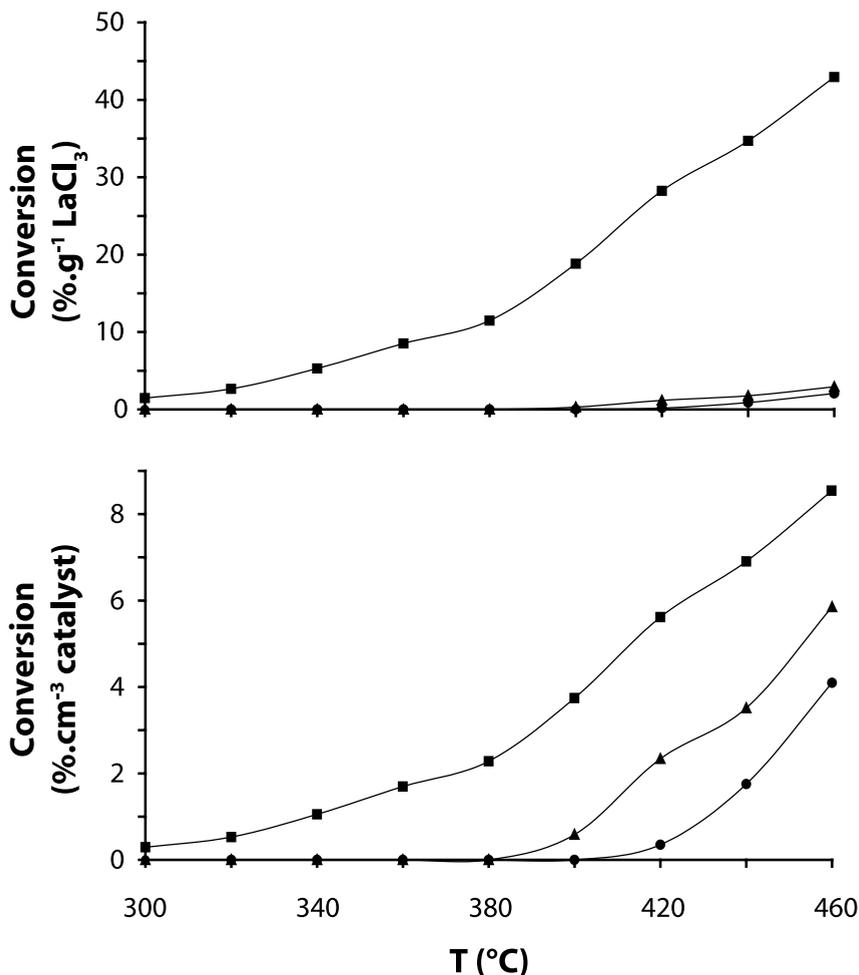

Figure 3. Conversion of a mixture of CH_2Cl_2 and CCl_4 into CHCl_3 based on weight (a) and volume (b) of the catalyst material over $\text{LaCl}_3\text{-H}$ (●), $\text{LaCl}_3\text{-P}$ (▲) and $\text{LaCl}_3\text{-C}$ (■). O-free H-Cl exchange over LaCl_3 -based Catalysts

tween the reactant concentration and the product concentrations. The carbon deficit in the reactor effluent was assumed to be a result of coke formation. It should be noted that the H-Cl exchange reaction also proceeds at relatively low conversion in the gas phase. Therefore, the product formation of the blank experiment has been subtracted in Figures 3 and 4. Despite the coke formation, the selectivity to CHCl_3 remains constant. A possible explanation for the induction period is that Ni remaining from the CNF growth catalyzes the conversion of CCl_4 into coke. CNF are grown on a Ni/SiO_2 catalyst. After CNF have been grown, Ni and SiO_2 are removed by washing steps. However, a trace amount of Ni is encapsulated in the CNF and can therefore not be removed by washing. During the H-Cl exchange experiments it may become accessible as a result of thermal expansion and the severe chlorination treatment needed for the synthesis of LaCl_3 . In that case, the induction period is a result of the Ni catalyzed dissociation of the reactants. Especially CCl_4 is dissociating during this period as shown in Figure 2. Another explanation could be that CHC_2 species are formed and are not detected by GC. This would account for the carbon deficit in the reactor effluent and is supported by the thermodynamics and previous experiments, when C_2Cl_4 was detected in the gas phase reaction.³

The H-Cl exchange reaction proceeds via net exchange of a H and Cl atom between CCl_4 and CH_2Cl_2 (Reaction Eq. (4)). The catalytic reaction can be envisaged as two separate H/Cl exchange reactions between the catalyst surface and a gas phase reactant (Reaction Eqs. (5) and (6)).

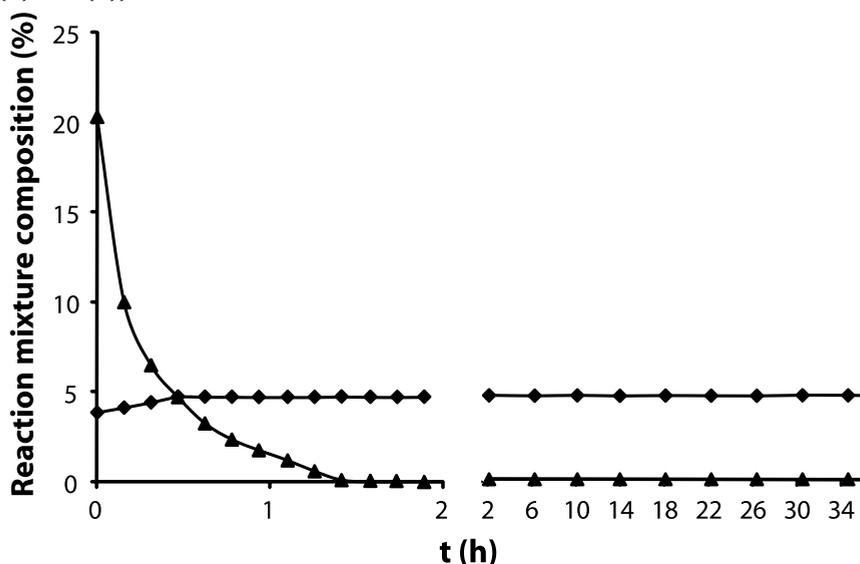

Figure 4. Reaction mixture composition for the H-Cl exchange between CCl_4 and CH_2Cl_2 at 400 °C over LaCl_3 -C as a function of time. Only C-containing products are shown, namely CHCl_3 (◆) and C (▲). The formation of carbon was calculated based on the concentration of the gas phase products. Chapter 5

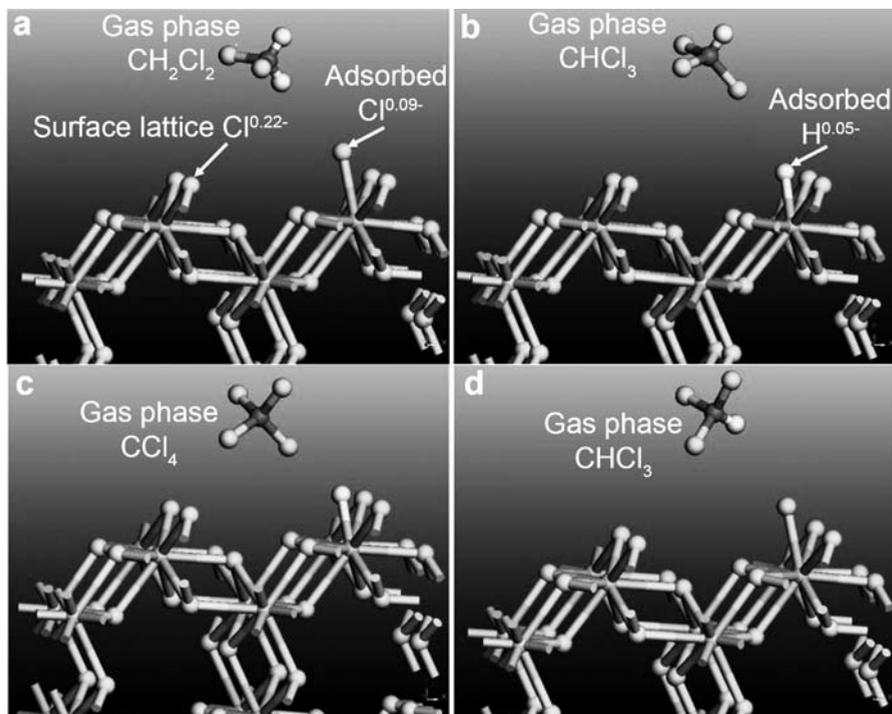

Figure 5. Proposed reaction mechanism for H-Cl exchange between CCl_4 and CH_2Cl_2 over LaCl_3 catalyst based on DFT calculations: a) gas phase CH_2Cl_2 above LaCl_3 catalyst, b) gas phase CHCl_3 formed after Cl for H exchange with the surface, c) gas phase CCl_4 above LaCl_3 catalyst and d) gas phase CHCl_3 formed after H for Cl exchange with the surface. Atomic charges were calculated with the Hirshfeld method.

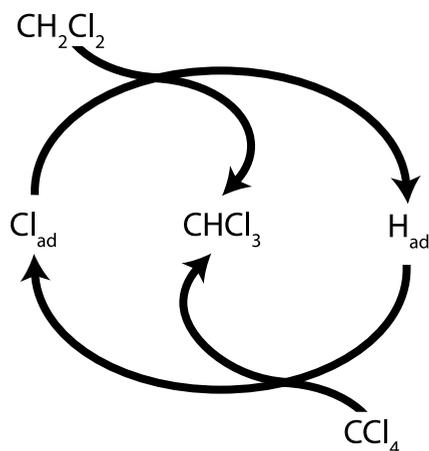

Figure 6. Schematic representation of the H-Cl exchange reaction between CCl_4 and CH_2Cl_2 over LaCl_3 -based catalysts.

O-free H-Cl exchange over LaCl₃-based Catalysts

To verify whether this mechanism is viable, DFT calculations were performed on the H-Cl exchange between CCl₄ and CH₂Cl₂. It was found that regardless of the position of the exchanged lattice Cl anions and presence of any neighbouring defects, the H/Cl exchange reaction is estimated to be highly endothermic at 310-324 kJ/mol. The calculations, therefore, suggest that gas phase moieties, such as CH₂Cl₂, are unlikely to exchange their H with Cl anions from the LaCl₃ lattice. However, the calculations also suggest that adsorbed Cl atoms can be stabilized on the surface of LaCl₃. These atoms can be characterized as adsorbed surface species, as opposed to lattice Cl anions, because they are held weakly by the surface and are calculated to have a significantly smaller atomic partial charge of -0.09, compared to the calculated charge of about -0.22 for surface lattice Cl anions (Figure 5a). This can be viewed as a build-up of an additional Cl layer for the bulk structure, so that the coordination of surface La atoms increases from 8 to 9, the same as for the bulk La atoms. A gas phase chloromethane, such as CH₂Cl₂, can exchange one of its H atoms for an adsorbed surface Cl atom. The products are gas-phase CHCl₃ and a surface hydride (Figure 5b). Similarly to the surface Cl, surface H is weakly held by the surface, and it has only a small atomic charge of -0.05. The calculated energy change for this reaction is 210 kJ/mol. With gas phase CCl₄ as a reactant (Figure 5c), the reaction regenerates the catalytic surface site and produces gas-phase CHCl₃ as a product, as shown in Figure 5d. This second reaction is predicted to be exothermic at -225 kJ/mol.

Conclusions

It has been shown for the first time that LaCl₃ is able to catalyze the H-Cl exchange reaction of CCl₄ with CH₂Cl₂ as illustrated in Figure 6. To achieve high conversion both on weight and volume basis, the LaCl₃ was supported on CNF, thereby greatly increasing the surface area in comparison to bulk LaCl₃ catalysts. As a support material, carbon has two main advantages for the H-Cl exchange reaction: 1) the support material is able to withstand the harsh pre-treatment with HCl, and 2) it contains no oxygen, which excludes the destructive adsorption of the reactants. DFT calculations have shown that weakly adsorbed H and Cl atoms exist on the catalytic surface as intermediates. The reaction is suited for the efficient conversion of CCl₄, which is a highly stable and toxic compound with low economic value. More importantly, this is the first time that no O atoms are involved in the exchange of H and Cl atoms between gas phase CHCs. This means that no O-containing products are formed during reaction. Moreover, the selectivity of the H-Cl exchange reaction over LaCl₃ is high as opposed to the systems using a source of O atoms.

Exploration of the Catalytic Potential of La-based Materials for the Conversion of Chlorinated Waste Compounds

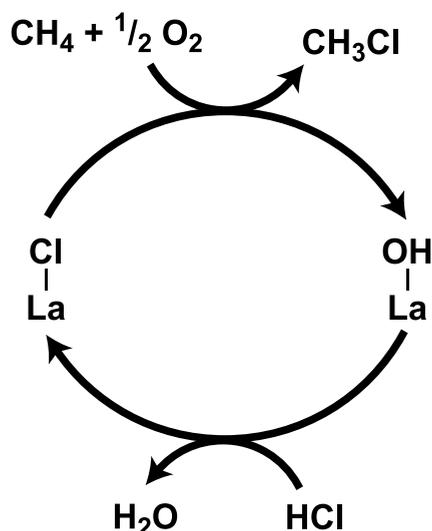

La-based materials have proven to be versatile catalysts in the conversion of chlorinated hydrocarbons (CHCs). The reactions of CHCs over La-based materials may be used for the destruction of these compounds at relatively low temperature or the conversion into more desirable products, such as chemical intermediates or transportation fuels. In this chapter, the potential of these catalyst materials is explored by the following experiments: 1) a mixture of chlorinated C₁ and C₂ (CHC₁₋₂) is converted over La₂O₃-based materials, 2) the destructive adsorption of CCl₄ is combined into a catalytic cycle with the activation of CH₄ over LaCl₃ using O₂, and 3) La₂O₃ is combined with a special silicoaluminophosphate catalyst (SAPO-34) for the one-pot conversion of CH₂Cl₂ into hydrocarbons. The destructive adsorption of chlorinated methanes and the dehydrochlorination of chlorinated ethanes were found to occur simultaneously when a mixture of these compounds is converted over La₂O₃-based catalysts. For the destructive adsorption reaction, the conversion of CHCl₃ and CCl₄ into CO and CO₂ dominate, whereas CH₂Cl₂ is hardly converted. The dehydrochlorination reaction of chlorinated ethanes, however is uninfluenced by the presence of other reactants. For the oxidative chlorination of methane over LaCl₃ in the presence of oxygen, CCl₄ has proven to be a good alternative for HCl. The chlorination of the catalyst via destructive adsorption of CCl₄ enables the regeneration of the chlorine which is lost in the reaction with CH₄, closing the catalytic cycle. Compared to HCl, CCl₄ offers the advantage of having a lower economic value and the fact that no H₂O is formed during reaction, which would make the reaction conditions more corrosive. The experiments on the consecutive conversion of CH₂Cl₂ via CH₃OH into hydrocarbons over La₂O₃ and SAPO-34, respectively, have shown that the combination of these two reactions in one reactor is difficult. The SAPO-34 material possesses very little activity under these conditions and coke formation results in plugging of the reactor. CH₂Cl₂ is converted into CO, CO₂, CH₄ and C₂H₄. After an induction period, an unassigned product is formed, after which the reactor rapidly becomes plugged. SAPO-34 is found to be active for the destructive adsorption of CH₂Cl₂, which could poison the material. Also, the desorption of H₂O from the La₂O₃ material may suppress the conversion of methanol to olefins.

Introduction

La-based materials have proven to possess great potential for the selective conversion of chlorinated hydrocarbons (CHCs) at relatively low temperature. Various reactions, such as destructive adsorption, dehydrochlorination and H/Cl exchange, occur over the catalytic surface of these materials. The versatility of the La-based catalyst opens new opportunities for use in commercially attractive reactions, such as the conversion of the light ends waste mixtures, the activation of methane into CH_3Cl and the one-pot conversion of chlorinated methanes (CHC_1) into hydrocarbons. These options will now be discussed consecutively.

First of all, the light ends waste mixture, which is formed as by-product during the production of vinyl chloride, contains various CHC_{1-2} . La_2O_3 -based materials convert both chlorinated methanes and ethanes. The dehydrochlorination of chlorinated ethanes and the destructive adsorption of CHC_1 proceed over the same active sites on La_2O_3 -based materials. The nature of these reactions, however, is markedly different: destructive adsorption of CHC_1 requires the presence of lattice oxygen, whereas dehydrochlorination of chlorinated ethanes is a catalytic reaction linked to an equilibrium surface composition. When these two reactions occur simultaneously in the same reactor, as would be the case for conversion of the light ends mixture, competitive adsorption between the reactants may result in inhibition of either reaction.

Secondly, LaCl_3 is an active catalyst for the activation of methane into CH_3Cl , which can be used as a reagent in the synthesis of silicone polymers.¹ The presence of oxygen is crucial for activation of methane into CH_3Cl over LaCl_3 using HCl .^{2,3} The catalytic cycle of this reaction is shown in Scheme 1.^{2,3} The key step results is the conversion of a La-Cl bond into a

Scheme 1. Catalytic cycle for the oxidative chlorination of CH_4 over LaCl_3 in the presence of O_2 and HCl .^{2,3}

Exploration of the potential of La-based catalysts

La-OH bond: oxygen and a surface Cl are proposed to form a hypochlorite (OCl^-) site, which converts methane into CH_3Cl consecutively. The role of HCl is limited to the regeneration of the La-Cl bond. Therefore, the destructive adsorption of CHC_1 could be used as an alternative for the regeneration step using HCl, since both reactions result in a net chlorination of the surface. The use of CCl_4 as a source of chlorine instead of HCl would be advantageous because of the lower economic value of CCl_4 .

Finally, the destructive adsorption of chlorinated C_1 over La_2O_3 -base materials results in the formation of oxygenated products, such as CO, CO_2 and CH_3OH . A catalyst which is able to convert these products into re-usable products and is active in the same temperature range would make the one-pot conversion of CHC_1 into chemical intermediates and/or transportation fuels possible. Silicoaluminophosphate materials (SAPO), specifically SAPO-34, are not only known to convert methanol into hydrocarbons^{4, 5}, but have also been used for the conversion of CH_3Cl into olefins.⁶ They are relatively stable under the conditions required for destructive adsorption. CH_2Cl_2 can consecutively be converted into CH_3OH and hydrocarbons over La_2O_3 and SAPO-34, respectively. Therefore, a combination of La_2O_3 -based materials and SAPO-34 could potentially be used for the one-pot conversion of CHC_1 into hydrocarbons.

In this chapter, these three possible applications of the La-based materials are pioneered to evaluate the potential of the catalyst. First, a mixture of several CHCs, namely CCl_4 , CHCl_3 , CH_2Cl_2 , 1,1,2- $\text{C}_2\text{H}_3\text{Cl}_3$ and 1,2- $\text{C}_2\text{H}_2\text{Cl}_2$, is run over La_2O_3 and LaOCl to mimic the conversion of light ends mixtures. Next, CCl_4 and CH_4 are converted together with O_2 over LaCl_3 to explore the potential of CCl_4 as an alternative for HCl as a chlorinating agent. Finally, CH_2Cl_2 is led over a catalyst bed of La_2O_3 and SAPO-34 material. Both materials are present in the same reactor, with La_2O_3 closest to the reactor inlet, to evaluate the one-pot conversion of chlorinated CH_2Cl_2 into hydrocarbons. CH_2Cl_2 is first converted over La_2O_3 into CH_3OH , which is subsequently converted into hydrocarbons over SAPO-34. In all experiments, the reactor effluent was continuously analyzed using gas chromatography (GC).

Experimental

Chlorinated C_1/C_2 Mixtures over La_2O_3 -Based Materials

The activity experiments for the conversion of the mixture of chlorinated C_1 and C_2 were performed in a tubular fixed-bed quartz reactor, which was discussed in detail in Chapter 2. The catalyst bed consisted of 1.0 g LaOCl-P or La_2O_3 (Acros Organics, 99.99 %) pressed in a 200-500 μm sieve fraction, pretreated in 10 mL/min He (Hoekloos, ≥ 99.996 %) at 550 $^\circ\text{C}$. To find the initial reaction temperature, the reaction was carried out from 50 to 400 $^\circ\text{C}$ using a 10 mL/min flow with the total concentration of the reactants at 7-9 vol% reactant in He (Hoekloos, ≥ 99.996 %). The reaction was also performed at 400 $^\circ\text{C}$ over 1.0 g La_2O_3

Chapter 6

(Acros Organics, 99.99 %). A bubbler containing a mixture of liquid chlorinated C₁ and C₂, namely CCl₄ (Acros Organics, 99.8 %), CHCl₃ (Acros Organics, 99.9 %), CH₂Cl₂ (Acros Organics, 99.9 %), 1,2-C₂H₄Cl₂ (Acros Organics, 98+ %) and 1,1,2-C₂H₃Cl₃ (Acros Organics, 98 %), was used to generate the reactant flow. Due to the difference in vapour pressure between the reactants, the relative concentrations steadily changed during the experiments. Especially for the relatively more volatile compounds, such as CHCl₃ and CH₂Cl₂, a strong decrease of the concentration was observed throughout the temperature programmed reactions. In Table 1 an overview is shown for the initial reactant concentrations in each experiment. Because the reaction as a function of time over La₂O₃ was expected to take longer than the temperature-programmed experiments, more CHCl₃ and CH₂Cl₂ was added to the reactant mixture to maintain all reactant concentrations until the end of the experiment.

Table 1. Initial reaction concentrations and experimental conditions for flow-gas experiments using mixtures of chlorinated C₁ and C₂.

Experiment	Material	T (°C)	[Reactant] in He (vol%)				
			CCl ₄	CHCl ₃	CH ₂ Cl ₂	1,2-C ₂ H ₄ Cl ₂	1,1,2-C ₂ H ₃ Cl ₃
1	La ₂ O ₃		2.6	1.5	0.7	1.5	1.6
2	LaOCl		2.5	1.6	1.0	1.4	1.7
3	La ₂ O ₃	400	1.1	4.1	2.1	1.0	1.51

CCl₄/CH₄ and O₂ over LaCl₃

The activity experiments were performed in a tubular fixed-bed quartz reactor. The catalyst bed consisted of 0.5 g LaOCl-P 200-500 μm sieve fraction, pretreated in 10 mL/min He (Hoekloos, ≥99.996 %) at 550 °C. The catalyst was chlorinated for 4 h at 450 °C with 10 ml/min 10 vol% HCl in He (Hoekloos, ≥99.996 %). The setup possessed a by-pass line outside the reactor, which was kept at 150 °C. CCl₄ was added to the reactant flow by injecting liquid CCl₄ into a heated line (170 °C) using a syringe pump (0.1 ml/h). First, the reactor flow was stabilized over the by-pass to 10 vol% CH₄, 8-9 vol% CCl₄ and 12 vol% O₂ in He. All experiments were performed subsequently over the same catalyst bed and after each experiment the reactant flow was switched over the by-pass. First the reaction was run over the catalyst at 450 °C. Next, CCl₄ was removed from the reactant feed. The experiment with CCl₄ present was repeated after re-introduction of CCl₄ to the reactant feed. Finally, O₂ was removed from the feed. An overview of initial concentrations used for each experiment is provided in Figure 1.

Exploration of the potential of La-based catalysts

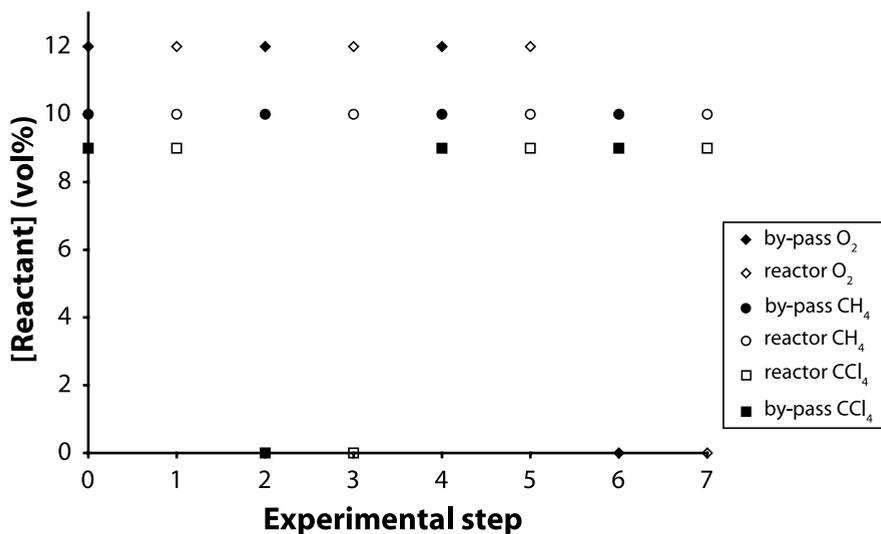

Figure 1. Reaction conditions and initial reactant concentrations throughout experiment with CCl₄/CH₄/O₂ over LaCl₃ (reactor temperature = 450 °C, by-pass temperature = 150 °C).

CH₂Cl₂ over La₂O₃ and SAPO-34

Details on the preparation of the SAPO-34 material used in this work can be found in literature.⁶ In a blank experiment, CH₂Cl₂ (Acros Organics, 99.9 %) was led over 2.0 g of La₂O₃ (Acros Organics, 99.99 %) at 350 °C to test the stability of the conversion into CH₃OH. This temperature was chosen based on the activity results in Chapter 3 and results on the conversion of methanol into hydrocarbons over SAPO-34.^{4, 5} The reactant flow consisted of 10 ml/min 6.1 vol% CH₂Cl₂ (Acros Organics, 99.9 %) in He (Hoekloos, ≥99.996 %). In a second series of experiments, 2.0 g La₂O₃ (Acros Organics, 99.99 %) and 0.5 g SAPO-34 200-500 μm sieve fractions were placed in the reactor in separate catalyst beds with La₂O₃ closest to the reactor inlet. The temperature and flow-rate were varied to find the optimal conditions for the consecutive conversion of CH₂Cl₂ over La₂O₃ and SAPO-34. Finally, the reactor was loaded with 1.0 g La₂O₃ (Acros Organics, 99.99 %) and 1.0 g SAPO-34, both pressed in sieve fractions of 200-500 μm. The reactant flow consisted of 5 ml/min 6.1 vol% (Acros Organics, 99.9 %) CH₂Cl₂ in He (Hoekloos, ≥99.996 %). The experiment was performed as a function of time at 400 °C to test the stability of the catalyst combination.

Results and Discussion

Three commercially attractive reactions for the conversion of CHCs are explored in a series of flow-gas experiments. In this section, the results of each reaction are discussed: 1)

Chapter 6

the conversion of mixtures of CHC_{1-2} over La_2O_3 -based materials, 2) the oxidative chlorination of methane using CCl_4 as a source of chlorine and 3) the one-pot conversion of CH_2Cl_2 into hydrocarbons over a combination of La_2O_3 and SAPO-34 material.

Activity Results CHC_{1-2} Mixtures over La_2O_3 -Based Materials

In Figures 2 and 3, the conversion of the chlorinated C_1 and C_2 hydrocarbons is shown as a function of temperature over La_2O_3 and LaOCl , respectively. In both experiments, the chlorinated methanes are converted into CO and CO_2 and the chlorinated ethanes are converted into chlorinated ethenes. Two types of reaction occur simultaneously: destructive adsorption of CCl_4 , CHCl_3 and CH_2Cl_2 (Reaction Eqs. (1)-(3)), and dehydrochlorination of 1,2- $\text{C}_2\text{H}_4\text{Cl}_2$ and 1,1,2- $\text{C}_2\text{H}_3\text{Cl}_3$ (Reaction Eqs. (4)-(7)). For La_2O_3 and LaOCl , destructive adsorption precedes the dehydrochlorination reaction. The initial temperature of conversion, however, is significantly lower over LaOCl than over La_2O_3 for both destructive adsorption and dehydrochlorination.

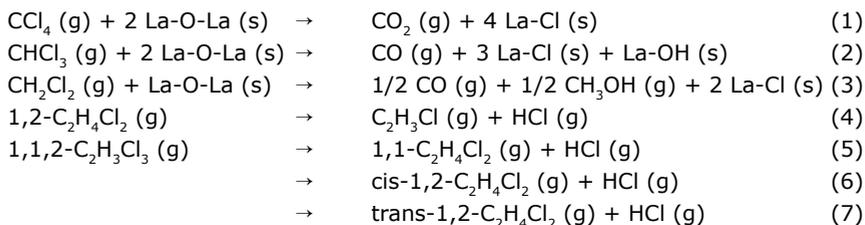

Figure 2 shows that CCl_4 and CHCl_3 are converted via destructive adsorption into CO_2 and CO over La_2O_3 , but the concentrations of these reactants increase towards the end of the experiment as a result of chlorination of the catalyst. The steady decrease of the concentration of CH_2Cl_2 is a result of the difference in vapour pressure between the compounds in the reactant mixture, which was previously discussed in the experimental section. Therefore, the conversion of CH_2Cl_2 is not significant. This is confirmed by the fact that no CH_3OH was observed. The results in Figure 3 show the same trend; CCl_4 and CHCl_3 react into CO_2 and CO , whereas CH_2Cl_2 is not converted.

In Chapter 4, it was found that during an induction period the catalytic surface becomes chlorinated until a specific degree of chlorination is reached. Once this specific surface composition is reached, the product distribution becomes stable. This is best observed in the dehydrochlorination of 1,1,2- $\text{C}_2\text{H}_3\text{Cl}_3$, which was converted over La_2O_3 at 400 °C as a function of time in a previous experiment. During an induction period, 1,1- $\text{C}_2\text{H}_4\text{Cl}_2$, cis-1,2- $\text{C}_2\text{H}_4\text{Cl}_2$, trans-1,2- $\text{C}_2\text{H}_4\text{Cl}_2$ and C_2HCl were formed. In addition, two product were formed which could not be assigned. When a stable product distribution was achieved, 1,1- $\text{C}_2\text{H}_4\text{Cl}_2$, cis-1,2- $\text{C}_2\text{H}_4\text{Cl}_2$ and C_2HCl were formed exclusively. In the experiment with the mixtures

Exploration of the potential of La-based catalysts

of chlorinated C_1 and C_2 , the formation of the two unassigned products is not observed, however, and *trans*-1,2- $C_2H_4Cl_2$ is only formed initially. The formation of C_2HCl could not be verified because this compound co-elutes with C_2H_3Cl , which is also formed from the dehydrochlorination of 1,2- $C_2H_4Cl_2$. It appears that the simultaneous conversion of chlorinated methanes and chlorinated ethanes shortens the induction period. Because lattice oxygen is exchanged for chlorine by the destructive adsorption reaction, the surface composition that is required for a stable product distribution is reached more rapidly. Moreover, the destructive adsorption occurs at lower temperature and therefore the catalytic surface becomes chlorinated before the dehydrochlorination reaction begins. This explains why the two unassigned products are not formed, because they are expected to be formed exclusively on an oxygen-rich surface, such as La_2O_3 .

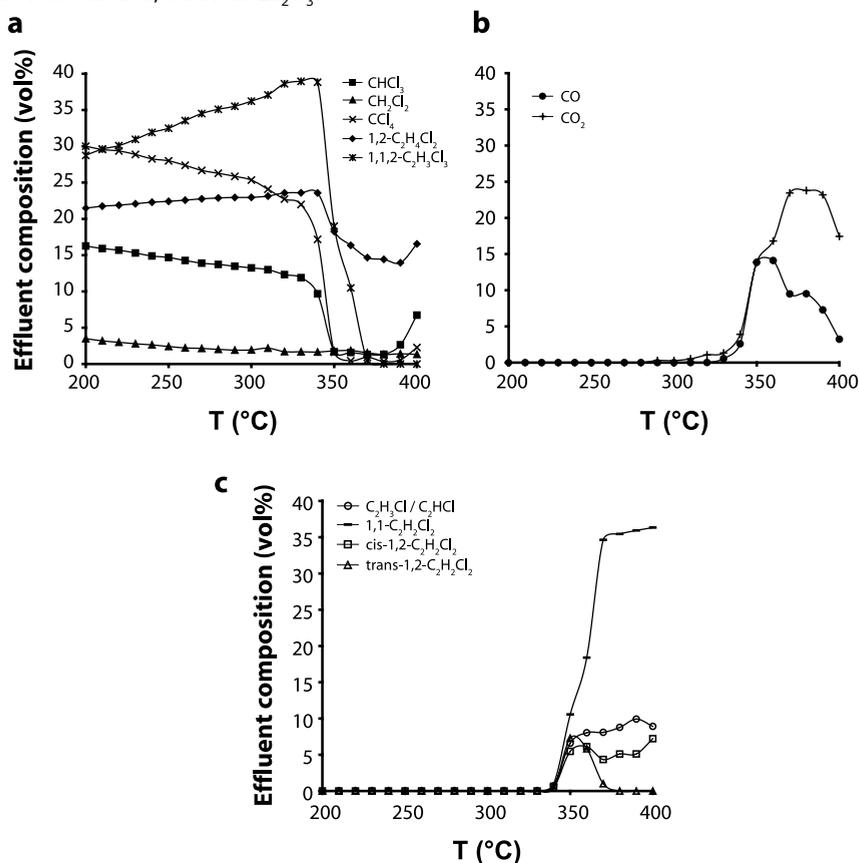

Figure 2. Effluent composition of a mixture of chlorinated methanes and ethanes over La_2O_3 as a function of temperature: a) reactant concentrations, b) concentrations of products formed as a result of destructive adsorption, and c) concentrations of products formed as a result of dehydrochlorination. The concentrations in the graph are calculated based on the reactants and products without He (inlet concentrations are shown in Table 1, GHSV = 800 h^{-1}).

Chapter 6

The conversion of the reactant mixture at 400 °C over La_2O_3 as a function of time is shown in Figure 4. Initially, CCl_4 and CHCl_3 are fully converted, whereas no reaction of CH_2Cl_2 occurs. However, the activity towards CHCl_3 decreases more rapidly than in the case of CCl_4 . The conversion and product distribution of the dehydrochlorination reactions with 1,2- $\text{C}_2\text{H}_4\text{Cl}_2$ and 1,1,2- $\text{C}_2\text{H}_3\text{Cl}_3$ are relatively stable throughout the experiment. The results show that the destructive adsorption and dehydrochlorination reaction can occur simultaneously on the same catalyst material. The conversion of CH_2Cl_2 , however, appears to be hindered by the competitive adsorption of the other reactants. The destructive adsorption reaction is dependent on the presence of a certain amount of lattice oxygen. Once the catalytic surface

The concentrations in the graph are based on the reactants and products without He (inlet concentrations are shown in Table 1, GHSV = 800 h^{-1}).

Chapter 6

becomes chlorinated, the reaction becomes limited by the solid-state diffusion of oxygen from the bulk of the material to the catalytic surface. This ultimately results in deactivation of the material for the destructive adsorption reaction. The dehydrochlorination reaction, on the other hand, is catalytic and shows no signs of deactivation throughout the experiment.

Activity Results CCl₄/CH₄ and O₂ over LaCl₃

The experiment with CCl₄/CH₄ and O₂ over LaCl₃ was performed under various reaction conditions as shown in Figure 5. First, the reactant concentrations were stabilized over the bypass (Figure 5, region 1). Then, the feed was switched to the reactor at 450 °C (Figure 5, region 2). When the feed is switched over the reactor, several products are formed, namely CO, CO₂, CH₂Cl₂ and CH₃Cl. The products are the result of two reactions: the oxidative chlorination of CH_xCl_{4-x} (x > 0) and the destructive adsorption of CH_xCl_{4-x} (x < 4).

The CH₄ molecule is chlorinated by the LaCl₃ material, as shown in Reaction Eq. (8)-(10). The chlorination reaction may be repeated when the formed chlorinated C₁ is re-adsorbed, which is described by Reaction Eqs. (9)-(11). As a result of this reaction, chlorine is removed from the catalyst material and hydroxyl groups are formed.^{2,3} The hydroxyl groups may react into H₂O or HCl according to Reaction Eqs. (12) and (13). Another possibility is that the LaCl₃ phase becomes partially hydrated (LaCl₃•nH₂O).

Without a source of chlorine to regenerate the catalytic surface, the availability of chlorine would decrease and, consequently, the conversion of CH₄. The destructive adsorption reaction counterbalances the oxygenation of the catalytic surface. CCl₄ is abundantly present as a reactant, but re-adsorption of the chlorinated C₁ formed from methane also contributes to the destructive adsorption reaction. For CCl₄, CHCl₃ and CH₂Cl₂, the reaction equations for the destructive adsorption over La₂O₃-based materials are shown in Reaction Eqs. (1)-(3). CH₃Cl may also be converted according to Reaction Eq. (14) at the temperature used in this experiment (450 °C), but the activity is expected to be relatively low compared to the other chlorinated C₁. Based on the results with the mixture of chlorinated C₁ and C₂ (Figure 4), the contribution of the destructive adsorption of CH₂Cl₂ is also considered relatively low with CCl₄ and CHCl₃ present.

Exploration of the potential of La-based catalysts

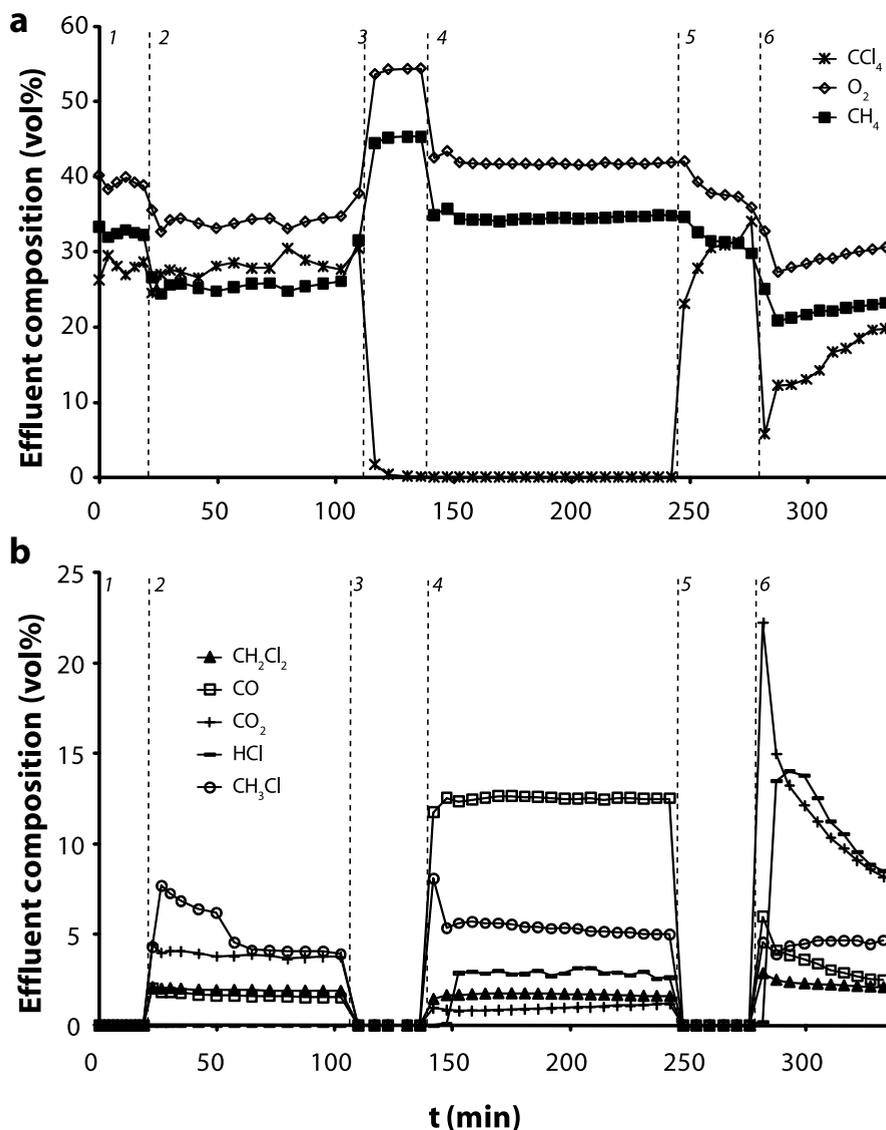

Figure 5. Effluent composition for a) reactants and b) products for the conversion of CH_4 , CCl_4 and O_2 over LaCl_3 at 450 °C: 1) stabilization of CH_4 , CCl_4 and O_2 over by-pass, 2) CH_4 , CCl_4 and O_2 over reactor, 3) stabilization of CH_4 and O_2 over by-pass, 4) CH_4 and O_2 over reactor, 5) stabilization of CH_4 , CCl_4 and O_2 over by-pass, 6) CH_4 , CCl_4 and O_2 over reactor (Reaction conditions are shown in Figure 1, GHSV = 400 h⁻¹).

Chapter 6

After some time the reactant flow was switched back to the by-pass (Figure 5, region 3). To evaluate the influence of CCl_4 on the stability and selectivity of the catalyst, the syringe pump containing CCl_4 was stopped, which resulted in an increase in concentration for CH_4 and O_2 . Once stabilized, the feed was switched back to the reactor (Figure 5, region 4). Without CCl_4 , the selectivity towards CO_2 decreases, whereas the selectivity towards CO increases. Also, without CCl_4 the formation of HCl is observed. The increase in CO indicates that the destructive adsorption of CHCl_3 and CH_2Cl_2 has become more pronounced without the presence of CCl_4 . Consequently, less CO_2 is formed, since this is primarily formed via the destructive adsorption of CCl_4 . The product distribution is relatively stable, even though the availability of chlorine at the catalyst surface is expected to decrease. A likely explanation is that solid-state diffusion of lattice oxygen occurs from the catalytic surface into the bulk phase of the material. The opposite has been observed in the destructive adsorption reaction over La_2O_3 ; the catalytic surface becomes chlorinated as a result of the chlorine/oxygen exchange between the gas phase and the catalyst material, respectively. To compensate for the difference in O/Cl ratio between the bulk phase and the catalytic surface, oxygen atoms diffuse from the bulk to the surface and the chlorine atoms vice versa. In the case of the reaction with CH_4 and O_2 , the principle is the same, but the oxygen atoms diffuse in the opposite direction compared to the destructive adsorption, namely from the catalytic surface into the bulk phase of the material. This results in relatively constant surface composition, which explains the formation of HCl according to Reaction Eq. (13). This solid-state diffusion combined with the destructive adsorption of re-adsorbed chlorinated C_1 may result in a relatively constant conversion, but this effect is expected to be temporary. As the bulk phase also becomes oxygenated, the driving force for the regeneration of surface chlorine decreases and the catalyst becomes deactivated.

The reactant feed was switched to the bypass and CCl_4 was reintroduced (Figure 5, region 5). When the reactant concentrations were stable, the feed was switched back to the reactor (Figure 5, region 6). The strong increase in concentration of CO_2 compared to the CO_2 concentration in Figure 5b shows that the catalyst material has become oxygenated. The CO_2 concentration decreases gradually with time and is expected to stabilize to the level of Figure 5b. It should be noted that the concentrations of CH_3Cl and CH_2Cl_2 remain relatively stable throughout the experiment. Apparently, the oxidative chlorination of CH_4 is not strongly influenced by the absence of a chlorinating agent or the use of a chlorinating agent other than HCl .

Activity Results CH_2Cl_2 over La_2O_3 and SAPO-34

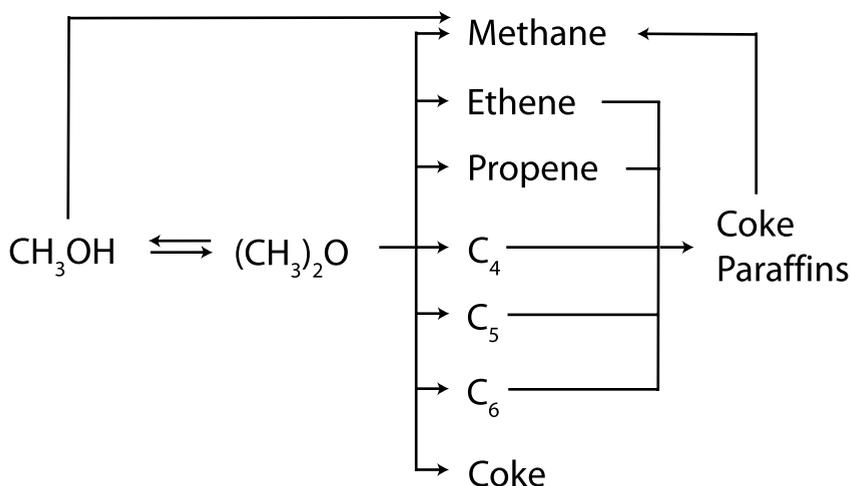

SAPO-34 is an active catalyst for the conversion of methanol into hydrocarbons at 300 °C and higher temperatures.⁴ A reaction network has been proposed for the conversion of methanol over SAPO-34, which is shown in Scheme 2.⁶ CH_3OH is converted into a primary product, $(\text{CH}_3)_2\text{O}$, which is subsequently converted into hydrocarbons. In ad-

Exploration of the potential of La-based catalysts

dition, C_2H_6 and C_3H_8 are formed as tertiary products. Moreover, the formation of coke, which leads to deactivation, increases with increasing reaction temperature.⁵ Therefore, the temperature at which CH_2Cl_2 is significantly converted into CH_3OH over La_2O_3 should match this temperature range, preferably at a relatively low temperature. The destructive adsorption of CH_2Cl_2 over La_2O_3 was tested at 350 °C as a function of time as shown in Figure 6. The experiment shows that CH_2Cl_2 is not fully converted under these conditions, but no deactivation is observed during 4 h. The formation of CH_3OH and CO is relatively stable throughout the experiment. The concentration of CO_2 steadily increases. During reaction carbonates are formed on the catalytic surface of the La_2O_3 , which dissociate into CO_2 as the material becomes more chlorinated.

Next, the La_2O_3 and SAPO-34 were loaded in the same reactor as separate catalyst beds with the La_2O_3 closest to the reactor inlet. The reaction conditions were varied to find the optimal conversion as shown in Figure 7. First, the conversion of CH_2Cl_2 was performed over the La_2O_3 -SAPO-34 combination at 350 °C (Figure 7a). Remarkably, more CH_2Cl_2 is converted over the catalyst combination than in the experiment with La_2O_3 only. Also, the sum of the reactant and products is the same in both experiments (not shown). This implies that the SAPO-34 is also active for the destructive adsorption of CH_2Cl_2 , which might lead to the collapse of the SAPO-34 structure as a result of chlorination. However, SAPO-34 has been found to be relative stability in the presence of chlorine.⁶

Since no hydrocarbons were detected at 350 °C, the temperature was raised to 400 °C (Figure 7b). At this temperature, CH_2Cl_2 is fully converted over the catalyst combination. CH_3OH is no longer detected and low amounts of CH_4 and C_2H_4 are formed, indicating that the SAPO-34 catalyst is active for the methanol to hydrocarbon conversion at this temperature. The CO concentration first strongly increases and then steadily decreases, which is

Scheme 2. Reaction network for methanol to olefin reaction over SAPO-34.

Chapter 6

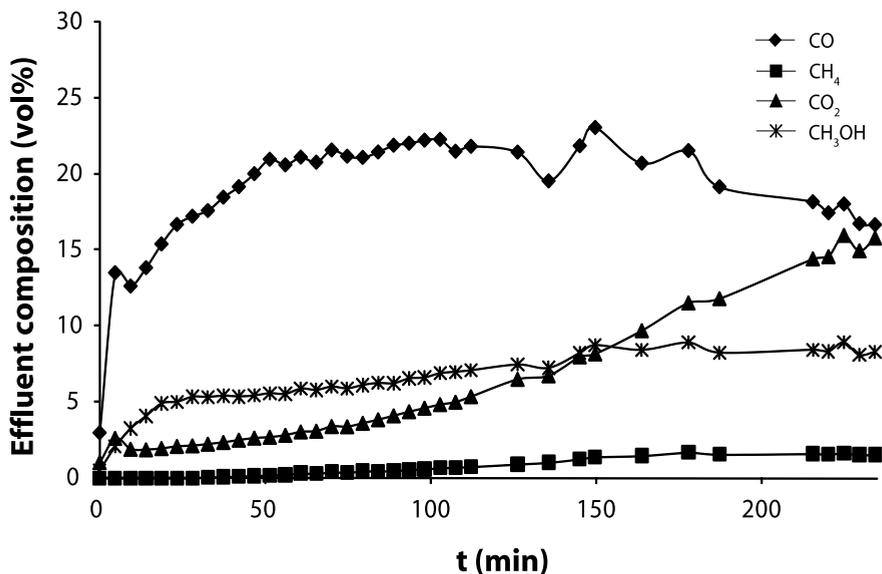

Figure 6. Effluent composition of CH_2Cl_2 at 350 °C over La_2O_3 as a function of time. The concentrations in the graph are based on the reactants and products without He ($[\text{CH}_2\text{Cl}_2] = 6.1 \text{ vol}\%$, GHSV = 800 h^{-1}).

most likely due to the decreasing availability of lattice oxygen at the catalytic surface of the La_2O_3 material. The concentration of CO_2 , on the other hand, is steadily increasing as a result of the dissociation of carbonates on La_2O_3 .

When the temperature is raised to 450 °C, a lower selectivity towards CH_4 is observed. Finally, the flow-rate was lowered to increase the residence time (Figure 7d) of the reactant. After 105 min, the concentration of CO_2 is decreasing which is paralleled by the increase of the CO concentration. Possibly, the majority of the carbonates has dissociated as a result of the chlorination of La_2O_3 . At this point, the product concentrations stabilize and an unassigned product is formed. This product is detected on the column for the chlorinated hydrocarbons (RL2 T5a, Table 1 Chapter 2). The retention time, which is close to that of CH_3OH and CH_3Cl , is low and in the same range as, for example H_2O , CH_3OH , CO , CH_4 and CO_2 . For the conversion of CH_3Cl into hydrocarbons over SAPO-34, the material is activated with propene before reaction to overcome a slow induction period.⁶ This induction period may also have occurred in the experiments here, since the stabilization of the product distribution is accompanied by the formation of a new product. This new product could be assigned to $(\text{CH}_3)_2\text{O}$, since this compound has been proposed to be an intermediate in the formation of hydrocarbons from methanol over SAPO-34 catalysts.⁵ The proposed reaction network of CH_3OH over SAPO-34 is shown in Scheme 2. $(\text{CH}_3)_2\text{O}$ was formed together with CH_3OH during the destructive adsorption of CH_3Cl over LaOCl as shown by the infrared results in Chapter 3. It was, however, not detected in the flow-gas experiments in Chapter 3. If the retention time of $(\text{CH}_3)_2\text{O}$ is close to that of CH_3Cl and CH_3OH , its peak may have overlapped with the strong CH_3Cl peak,

Exploration of the potential of La-based catalysts

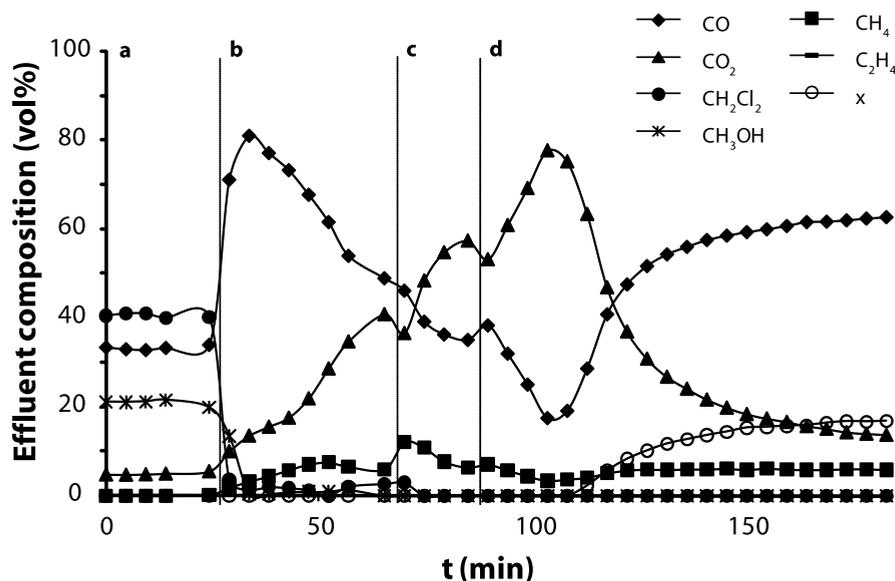

Figure 7. Effluent composition of CH_2Cl_2 over La_2O_3 -SAPO-34 combination: (a) 350 °C, GHSV = 800 h^{-1} , (b) 400 °C, GHSV = 800 h^{-1} , (c) 450 °C, GHSV = 800 h^{-1} and (d) 450 °C, GHSV = 400 h^{-1} . The concentrations in the graph are based on the reactants and products without He (x represents an unassigned product, $[\text{CH}_2\text{Cl}_2] = 6.1 \text{ vol}\%$).

which was used as a reactant in that experiment. This would explain why $(\text{CH}_3)_2\text{O}$ was not observed in the previous experiment. It should be noted that the sum of the reactant and product concentrations strongly decreased when the temperature was raised to 450 °C (not shown), indicating the formation of coke. The reaction eventually was stopped because of the reactor bed became plugged. After reaction, both catalyst beds in the reactor indeed showed significant coke formation, while no coke formation was observed on the reactor walls or quartz wool.

Based on the results in Figure 7, a reaction temperature of 400 °C and GHSV of 400 h^{-1} was chosen as the optimum conditions for the conversion of CH_2Cl_2 over the La_2O_3 -SAPO-34 combination. In addition, the amount of La_2O_3 material was halved while the amount of SAPO-34 was doubled in an attempt to increase the conversion of methanol into hydrocarbons. The results for the conversion of CH_2Cl_2 over the catalyst combination at 400 °C are shown in Figure 8. CH_3OH is initially observed, but its concentration rapidly decreases to zero. Similarly to the experiment shown in Figure 7, low concentrations of CH_4 and C_2H_4 are detected. In this experiment, a steady increase of the CO_2 concentration is also paralleled by a decrease in CO concentration. After approximately 100 min, the CO_2 concentration strongly decreases, while the concentration of CO increases. At the same time, the unknown product is formed. This induction period was also observed in Figure 7. The reaction was stopped when the reactor became plugged. In summary, no significant amounts of C_2 hydrocarbons were detected in the experiments described here. The low selectivity towards olefins may be

Chapter 6

a result of H₂O desorbing from the La₂O₃ material, since H₂O is known to suppress the formation of olefins over SAPO-34.^{7, 8} The desorption of H₂O is expected to be temporary, however, since desorption of HCl is more favourable on a more chlorinated catalyst surface.

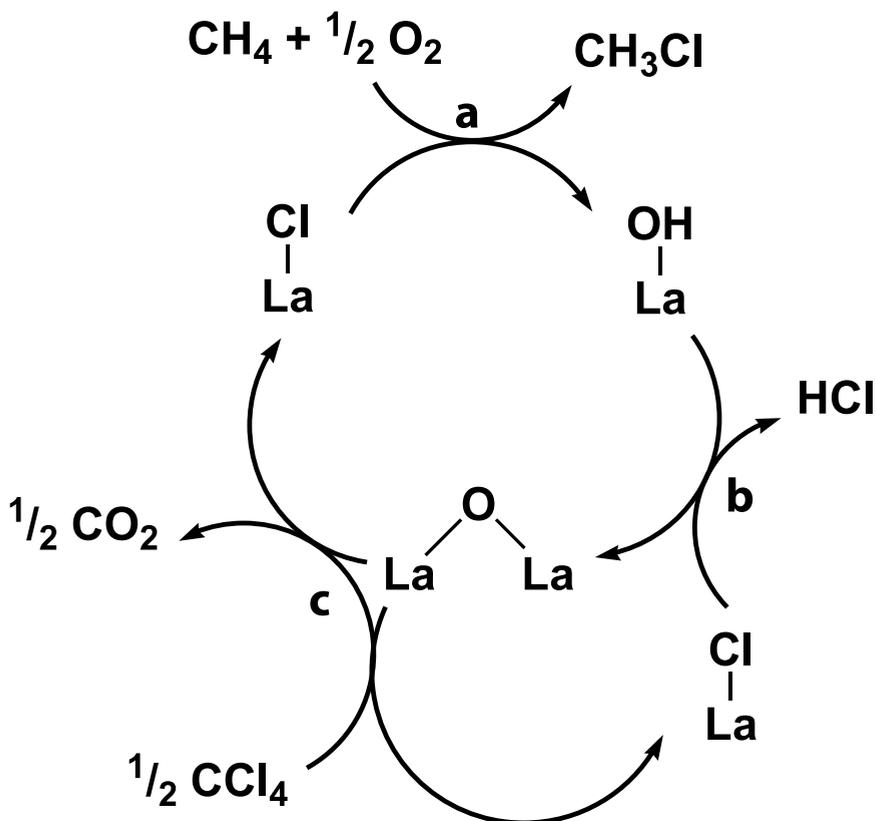

Conclusions

It has been shown that a mixture of chlorinated methanes and ethanes, as in the case of the light ends mixtures, can be converted into oxygenated products and chlorinated ethenes, respectively. The destructive adsorption of chlorinated C₁ compounds results in the formation of CO and CO₂. The destructive adsorption of CH₂Cl₂ is, however, less favourable when CCl₄ and CHCl₃ are present. The destructive adsorption reaction is dependent on the presence of lattice oxygen and, as a result, the conversion decreases as the catalyst material becomes more chlorinated. The dehydrochlorination of the chlorinated ethenes is uninfluenced by the destructive adsorption reaction. In fact, a more chlorinated catalyst surface translates into higher selectivity towards chlorinated ethenes. Therefore, the chlorination of the catalyst as a result of the destructive adsorption of chlorinated C₁ benefits the selectivity of the dehydrochlorination reaction. With the right method to regenerate the lattice oxygen of the catalyst material, the La₂O₃-based material could be used to selectively convert a mixture of chlorinated methanes, ethanes and ethenes into CO, CO₂ and chlorinated ethenes. This enables conversion of chlorinated C₁ compounds into combustion products at a significantly lower temperature than conventional incineration, and the recycling of chlorinated ethenes, such as C₂H₃Cl and 1,1-C₂H₂Cl₂, for the production of polyvinyl chloride (PVC) and poly vinylidene chloride (PVDC), respectively.

CCl₄ has proven to be an excellent substitute for HCl in the activation of methane over LaCl₃ in the presence of O₂. The hydroxyl groups, which are formed on the catalytic surface as a result of the chlorination of methane, react with HCl under formation of H₂O (Scheme 1). When CCl₄ is used as a chlorinating agent, the catalytic cycle is closed via an additional step: CCl₄ is converted into CO₂ resulting in chlorination of the catalytic surface after which the hydroxyl groups dissociate into HCl (Scheme 3). The advantage of using CCl₄ would be that this compound has a lower economic value compared to HCl and the fact that the highly corrosive mixture of HCl and H₂O is avoided when CCl₄ is used.

The one-pot conversion of CH₂Cl₂ into hydrocarbons was tested over a combination of a La₂O₃ and a SAPO-34 catalyst bed in the same reactor. First, CH₂Cl₂ is converted into CH₃OH over La₂O₃ and is then consecutively converted into hydrocarbons over the SAPO-34 catalyst. The results show that only a small amount of CH₂Cl₂ is converted into CH₄ and C₂H₄. It appears that the SAPO-34 material is also active for the destructive adsorption of CH₂Cl₂, which may lead to poisoning of the catalyst. In addition, the desorption of H₂O may temporarily suppress the formation of olefins over SAPO-34. The latter problem could be circumvented by using a more chlorinated material, such as LaOCl, which is less likely to release H₂O. The one-pot conversion of CH₂Cl₂ over a combination of a La₂O₃-based catalyst

Exploration of the potential of La-based catalysts

Scheme 3. Catalytic cycle for the oxidative chlorination of CH_4 over LaCl_3 in the presence of O_2 and CCl_4 .

and SAPO-34 is possible in principle. However, a great challenge lies in the control of the reaction conditions and the properties of the La-based catalyst material that is used.

Acknowledgements

Elvira Peringer (Technical University of Munich, Germany) is thanked for performing the reactions of CH_4 , CCl_4 and O_2 over LaCl_3 and for her help with the discussion of the results. Unni Olsbye (University of Oslo, Norway) is thanked for providing the SAPO-34 material for the experiments on the conversion of CH_2Cl_2 . The exchange with the Technical University of Munich, where the results on the activation of methane were measured, was supported by the Integrated Design of Catalytic Nanomaterials for a Sustainable Production (IDECAT) network. This work was supported by the National Research School Combination Catalysis (NRSCC) and the Dutch Science Foundation (VICI/NWO-CW grant).

Summary and concluding remarks

Chapter 7

More than one third of all chlorine consumption is used for the production of polyvinyl chloride (PVC). The monomer that is produced as precursor is C_2H_3Cl . This product is synthesized industrially by the chlorination of C_2H_4 into $1,2-C_2H_4Cl_2$. The latter is subsequently cracked into C_2H_3Cl and HCl. Even though the production process of C_2H_3Cl is rather selective, several by-products are formed. Due to the scale of the process, the amount of by-products is relatively large, however. These by-products are mainly chlorinated C_1 , e.g. CCl_4 , $CHCl_3$ and CH_2Cl_2 , and C_2 , e.g. $1,1,2-C_2H_3Cl_3$ and C_2H_5Cl , and are collected as a mixture known as the light ends. Regulation of the removal and production of chlorinated C_1 and C_2 demands for efficient disposal of the chlorinated by-products of the PVC industry. Currently, the preferred route of destruction is incineration. Though efficient, this is a costly process due to the high temperature that is required for the incineration of chlorinated hydrocarbons (CHCs). Furthermore, incineration results in the loss of feedstock.

La-based materials are active materials for the conversion of CHCs: they enable the destruction of CHCs at relatively low temperature, but also offer the possibility for recycling of some of the by-products. In this PhD thesis, the conversion of different chlorinated C_1 and C_2 compounds over La-based materials was studied to evaluate the potential of these catalyst materials and to gain more insight into the reactions that occur over the catalytic surface. Special attention has been devoted to the influence of the chlorination degree of the catalyst material, which is able to tune the catalyst selectivity and activity.

In **Chapter 2**, the destructive adsorption of CCl_4 over La_2O_3 -based materials was studied to establish a link between activity and acid-base properties of the catalyst material. It was found that the synthesis method of LaOCl materials has a dramatic influence on the bulk as well as on the surface properties. In flow-gas experiments, the following activity trend was observed: $LaCl_3 \ll La_2O_3 < LaOCl-S < LaOCl-P$. CH_3OH probing shows that LaOCl-P contains a larger number of strong adsorption sites than LaOCl-S, more specifically sites that are likely used for the destructive adsorption of CCl_4 . The larger amount of chlorine at the surface appears to increase the number of active Lewis acid sites at the surface of LaOCl-P. However, these differences in strength cannot be revealed by CO IR adsorption measurements. Nevertheless, we believe that the strength of the Lewis acid sites remains a key factor for activity and that stronger Lewis acid sites result in a higher intrinsic activity for CCl_4 destruction. Basic oxygen sites remain necessary to enable the conversion of CCl_4 to CO_2 . In other words, the appropriate acid-base pair should be available at the catalyst surface to have an active material.

Chapter 3 dealt with the destructive adsorption of the H-containing chlorinated C_1 compounds, namely $CHCl_3$, CH_2Cl_2 and CH_3Cl , over La_2O_3 -based catalysts. Two reaction pathways are established that lead to the formation of phosgene-like gas phase intermediates ($CH_xCl_{2-x}O$). It was found that a basic O site is able to abstract a H atom from the gas phase reactant, which is a new aspect for the destructive adsorption in comparison to the experiments with CCl_4 . The $CH_xCl_{2-x}O$ intermediate can rapidly re-adsorb on the catalyst surface and form surface species, such as carbonates, formates and methoxy groups. The surface species can then interconvert and/or dissociate into gas phase products. The dissociation

Summary and concluding remarks

of the surface species is dependent on the reaction temperature and the degree of surface chlorination. The flow-gas experiments showed that as the number of hydrogen atoms in the molecule increases, the initial temperature of reaction increases. This trend is believed to be a result of the decreasing polarization of the bonds in the C_1 molecule as a consequence of more hydrogen atoms. A second factor which influences conversion is the chlorination degree of the LaOCl surface. An optimum degree of surface chlorination exists, which translates to an optimal combination of Lewis acidic and basic surface sites. The surface chlorination is, in view of the proposed reaction scheme, of direct influence on the selectivity. A catalyst with ample O promotes the reaction pathway involving H/Cl removal. The removal of H results in less hydrogenated, and hence less desirable, surface intermediates and gas phase products. The surface chlorination also inhibits the formation of carbonates, which reduces the formation of CO_2 . Therefore, a chlorinated catalyst is more selective than, for example, pure La_2O_3 .

In **Chapter 4**, the focus is on the dehydrochlorination of chlorinated C_2 compounds, in particular C_2H_5Cl , $1,2-C_2H_4Cl_2$ and $1,1,2-C_2H_3Cl_3$, over La_2O_3 -based materials. A hydrogen and chlorine atom is abstracted from the chlorinated ethane by the catalytic surface, resulting in the formation of a hydroxyl group and a lattice chloride. In the case of an O-rich surface, such as La_2O_3 , the hydroxyl groups will react with other hydroxyl groups under formation of H_2O . However, when a specific degree of chlorination of the catalytic surface is reached, the elimination of H_2O becomes less pronounced and HCl is formed. After the induction period characterized by the formation of H_2O , the product distribution and conversion become stable and the chlorination degree of the catalyst surface also remains constant. In situ IR experiments have shown that at relatively high temperature, secondary reactions may occur, such as a second dehydrochlorination step resulting in the formation of an ethyne, or destructive adsorption leading to the formation of CO and CO_2 . This indicates that the reaction temperature and chlorination degree are key factors to achieve optimal selectivity towards the formation of ethenes.

In **Chapter 5**, it has been shown that $LaCl_3$ is able to catalyze the H-Cl exchange reaction of CCl_4 with CH_2Cl_2 without the presence of oxygen atoms. To achieve high conversion both on weight and volume basis, $LaCl_3$ was supported on carbon nanofibers (CNF), thereby greatly increasing the surface area in comparison to bulk $LaCl_3$. As a support material, CNF have two main advantages for the H-Cl exchange reaction: 1) the support material is able to withstand the harsh pre-treatment with HCl, and 2) it contains no oxygen, which excludes the destructive adsorption of the reactants. DFT calculations have shown that weakly adsorbed H and Cl atoms exist on the catalytic surface as intermediates. The reaction is suited for the efficient conversion of CCl_4 , which is a highly stable and toxic compound with low economic value. More importantly, this is the first time that no O atoms are involved in the exchange of H and Cl atoms between gas phase CHCs.

From the findings mentioned above it is clear that La-based catalysts are versatile catalysts, which are able to convert chlorinated C_1 and C_2 compounds via different reactions, such as destructive adsorption, dehydrochlorination and H-Cl exchange. Therefore, the use

Chapter 7

of La-based materials in several relevant test cases has been explored in **Chapter 6**.

First of all, it has been shown that a mixture of chlorinated methanes and ethanes, i.e. CCl_4 , CHCl_3 , CH_2Cl_2 , $1,1,2\text{-C}_2\text{H}_3\text{Cl}_3$ and $1,2\text{-C}_2\text{H}_4\text{Cl}_2$, as in the case of the light ends mixtures, can be converted into oxygenated products and chlorinated ethenes, respectively. The destructive adsorption of chlorinated C_1 compounds results in the formation of CO and CO_2 . The destructive adsorption of CH_2Cl_2 is, however, less favourable when CCl_4 and CHCl_3 are present. The dehydrochlorination of the chlorinated ethanes is not inhibited by the destructive adsorption reaction. In fact, a more chlorinated catalyst surface translates into higher selectivity towards chlorinated ethenes. Therefore, the chlorination of the catalyst as a result of the destructive adsorption of chlorinated C_1 benefits the selectivity of the dehydrochlorination reaction.

In a second part, CCl_4 has proven to be a good substitute for HCl in the activation of methane over LaCl_3 in the presence of O_2 . The hydroxyl groups, which are formed on the catalytic surface as a result of the chlorination of methane, conventionally react with HCl under formation of H_2O . When CCl_4 is used as a chlorinating agent, the catalytic cycle is closed via an additional step: CCl_4 is converted into CO_2 resulting in chlorination of the catalytic surface after which the hydroxyl groups dissociate into HCl.

Finally, the one-pot conversion of CH_2Cl_2 into hydrocarbons was tested over a combination of a La_2O_3 and a SAPO-34 catalyst bed in the same reactor. The results show that only a small amount of CH_2Cl_2 is converted into CH_4 and C_2H_4 . It appears that the SAPO-34 material is also active for the destructive adsorption of CH_2Cl_2 , which may lead to catalyst poisoning. The one-pot conversion of CH_2Cl_2 over a combination of a La_2O_3 -based catalyst and SAPO-34 is in principle possible. However, a great challenge lies in the control of the reaction conditions and the La-based catalyst material that is used.

This PhD thesis has shown that the chlorination degree of La-based catalyst materials is of direct influence on their activity and selectivity for the conversion of CHCs. However, the degree of chlorination also changes as a result of the reactions with CHCs. Therefore, the next challenge lies in the control of the chlorination degree during reaction. Steam has been used to make the destructive adsorption of CCl_4 catalytic over La_2O_3 -based materials, but the influence of steam on the destructive adsorption of H-containing chlorinated C_1 compounds and the dehydrochlorination of chlorinated ethanes has not been studied so far. Further investigation on the regeneration of oxygen, and hence the dechlorination of the catalyst material, is needed to enable control of the catalyst composition and the reactions of CHCs over the catalyst. Furthermore, research on new combinations of catalytic materials and reactions, as illustrated in Chapter 6, can be used to make the conversion of chlorinated waste streams more efficient and less costly. Even though more complex technological systems are needed to facilitate catalytic conversion of chlorinated waste compounds, the La-based material could be highly advantageous for applications using microreactor technology. This technology offers the advantage of detailed optimization for the conversion of CHCs with minimal risks of exposure.

Samenvatting en conclusies

De productie van polyvinylchloride (PVC) is verantwoordelijk voor meer dan een derde van alle chloorconsumptie. C_2H_3Cl is de monomeer die gebruikt wordt als precursor hiervoor. Dit product wordt industrieel gesynthetiseerd via de chlorering van C_2H_4 tot $1,2-C_2H_4Cl_2$. Het laatstgenoemde product wordt vervolgens gekraakt tot C_2H_3Cl en HCl. Ook al is het productieproces van C_2H_3Cl selectief, toch worden een aantal bijproducten gevormd. Gezien de grote schaal waarop het proces plaatsvindt, is de hoeveelheid bijproducten echter relatief hoog. Deze bijproducten zijn voornamelijk gechloreerde C_1 , bv. CCl_4 , $CHCl_3$ and CH_2Cl_2 , en C_2 , bv. $1,1,2-C_2H_3Cl_3$ and C_2H_5Cl , en worden verzameld als een mengsel dat bekend staat als de light ends. De regulering voor de verwijdering en productie van gechloreerde C_1 en C_2 eist een efficiënte afbraak van de gechloreerde bijproducten uit de PVC-industrie. Momenteel heeft verbranding de voorkeur als afbraaktechniek. Hoewel dit een efficiënte techniek is, zijn de kosten voor dit proces hoog vanwege de hoge temperaturen die nodig zijn voor de verbranding van gechloreerde koolwaterstoffen (CKWs). Bovendien heeft verbranding het verlies van grondstoffen tot gevolg.

La-gebaseerde materialen zijn actief voor de omzetting van CKWs: ze zijn in staat deze op lagere temperaturen af te breken, maar bieden ook de mogelijkheid tot hergebruik van sommige bijproducten. In dit proefschrift wordt de omzetting van verschillende gechloreerde C_1 en C_2 op La-gebaseerde materialen bestudeerd om het vermogen van deze katalysator-materialen te evalueren en om meer inzicht te verkrijgen in de reacties die plaatsvinden over het katalytisch oppervlak. De aandacht wordt met name gericht op de invloed het chloorgehalte van het katalysatormateriaal, welke in staat is om de activiteit en selectiviteit van de katalysator te bepalen.

In **Hoofdstuk 2** is de destructieve adsorptie van CCl_4 op La_2O_3 -gebaseerde materialen bestudeerd om een verband te vinden tussen de activiteit en de zuur-base eigenschappen van het katalysatormateriaal. De synthesemethode voor de LaOCl-materialen bleek van grote invloed te zijn op zowel de bulk- als oppervlakte-eigenschappen. In de experimenten met gasstromen werd de volgende trend in activiteit waargenomen: $LaCl_3 \ll La_2O_3 < LaOCl-S < LaOCl-P$. Het gebruik van CH_3OH als probe-gas liet zien dat LaOCl-P een hoger aantal sterke Lewis-zure plaatsen bevat dan LaOCl-S, in het bijzonder plaatsen die waarschijnlijk gebruikt worden voor de destructieve adsorptie van CCl_4 . De hogere hoeveelheid chloor aan het oppervlak lijkt het aantal actieve Lewis-zure plaatsen aan het katalytisch oppervlak van LaOCl-P te verhogen. Dit verschil in sterkte van Lewis-zure plaatsen komt echter niet tot uiting in de CO adsorptie metingen met infrarood (IR) spectroscopie. Desalniettemin, geloven we dat de sterkte van de Lewis-zure plaats een belang-rijke factor is voor activiteit en dat sterkere Lewis-zure plaatsen resulteren in hogere intrinsieke activiteit voor de destructie van CCl_4 . Basische zuurstof-plaatsen blijven nodig om de omzetting van CCl_4 tot CO_2 mogelijk te maken. Met andere woorden, een actief materiaal vereist een geschikt zuur-base paar op het katalytisch oppervlak.

Hoofdstuk 3 behandelt de destructieve adsorptie van H-bevattende gechloreerde C_1 , namelijk $CHCl_3$, CH_2Cl_2 and CH_3Cl , over op La_2O_3 -gebaseerde materialen. Twee reactiepaden zijn aangetoond, die resulteren in de vorming van fosgeen-achtige tussenproducten in de

Samenvatting en conclusies

gasfase ($\text{CH}_x\text{Cl}_{2-x}\text{O}$). De basische zuurstof-plaats is in staat een H te onttrekken aan de reactant in de gasfase. Dit is een nieuw aspect voor de destructieve adsorptie in vergelijking met de experimenten met CCl_4 . Het $\text{CH}_x\text{Cl}_{2-x}\text{O}$ tussenproduct kan heradsorberen op het katalytisch oppervlak en door middel van chemisorptie worden verschillende oppervlaktestructuren gevormd, zoals carbonaten, formaten en methoxygroepen. De oppervlaktestructuren kunnen in elkaar omgezet worden en/of dissociëren tot gasvormige producten. De dissociatie van de oppervlaktestructuren is afhankelijk van de reactietemperatuur en het chloorgehalte van het katalytisch oppervlak. De gasstroomexperimenten toonden dat de initiële reactietemperatuur toeneemt met een afnemend aantal chlooratomen in het molecuul van de reactant. Deze trend is mogelijk het gevolg van de afnemende polarisatie in de bindingen van het C_1 molecuul als gevolg van het toenemende aantal H atomen. Een tweede factor van invloed is de mate van chlorering van katalytische oppervlak van LaOCl . Er bestaat een optimaal niveau van chlorering van het katalytisch oppervlak, wat zich vertaalt naar een optimale combinatie van Lewis-zure en basische oppervlakte-plaatsen. De chlorering van het oppervlak is, met betrekking tot het voorgestelde reactieschema, van directe invloed op de selectiviteit. Een materiaal met voldoende O bevordert het reactiepad waarbij H/Cl verwijderd wordt van het reactantmolecuul. Als H van het molecuul verwijderd wordt, dan worden minder gehydrogeneerde, en dus minder aantrekkelijke, tussenproducten en eindproducten gevormd. De chlorering van het katalytisch oppervlak gaat ook de vorming van carbonaten en CO_2 tegen. Daarom is een gechloreerde katalysator selectiever dan bijvoorbeeld zuiver La_2O_3 .

In **Hoofdstuk 4** wordt de aandacht verlegd naar de dehydrochlorering van gechloreerde C_2 , in het bijzonder $\text{C}_2\text{H}_5\text{Cl}$, $1,2\text{-C}_2\text{H}_4\text{Cl}_2$ and $1,1,2\text{-C}_2\text{H}_3\text{Cl}_3$, op La_2O_3 -gebaseerde materialen. Een H en Cl atoom worden door het katalytisch oppervlak afgesplitst van het gechloreerde ethaanmolecuul, wat resulteert in de vorming van een hydroxylgroep en een roosterchlorion. Wanneer het oppervlak O-rijk is, zoals bij La_2O_3 , zullen de hydroxylgroepen met elkaar reageren tot H_2O . Wanneer echter een specifiek chloreringsniveau van het katalytisch oppervlak is bereikt, dan neemt eliminatie van H_2O af en wordt HCl gevormd. Na een inductieperiode die gekenmerkt wordt door de vorming van H_2O , worden de conversie en product-verdeling constant. Ook de chloreringsgraad van het katalytisch oppervlak blijft dan constant. In situ IR experimenten hebben aangetoond dat op een relatief hoge temperatuur secundaire reacties kunnen plaatsvinden, zoals een tweede dehydrochloreringstap leidend tot de vorming van een ethyn, of destructieve adsorptie wat resulteert in de vorming van CO en CO_2 . Dit geeft aan dat de reactietemperatuur en chloreringsgraad belangrijke factoren zijn om een optimale selectiviteit te verkrijgen voor de vorming van ethenen.

In **Hoofdstuk 5** is aangetoond dat LaCl_3 in staat is de H-Cl uitwisselingsreactie tussen CCl_4 en CH_2Cl_2 te katalyseren zonder de aanwezigheid van O-atomen. Om een hoge conversie op zowel volume- als op gewichtsbasis te bewerkstelligen, werden kooldraden als dragermateriaal voor LaCl_3 gebruikt. Het doel hiervan was om het katalytisch oppervlak sterk te vergroten in vergelijking met bulk LaCl_3 -katalysatoren. Kooldraden hebben twee grote voordelen als dragermateriaal voor de H-Cl uitwisselingsreactie: 1) het is in staat de

agressieve voorbehandeling met HCl te weerstaan, en 2) het bevat geen O-atomen, wat destructieve adsorptie van de reactanten voorkomt. Density functional theory (DFT) berekeningen geven aan dat zwakgeadsorbeerde H- en Cl-atomen op het katalytisch oppervlak voorkomen als overgangstoestand. De reactie is geschikt voor de efficiënte omzetting van CCl_4 , wat een stabiele en giftige stof is met een lage economische waarde. Nog belangrijker is het feit dat dit de eerste reactie is waarbij geen O-atomen betrokken zijn bij de uitwisseling van H- en Cl-atomen tussen CKWs in de gasfase.

Uit de bovengenoemde bevindingen blijkt dat op La-gebaseerde materialen veelzijdige katalysatoren zijn, die in staat zijn gechloreerde C_1 en C_2 via verschillende reacties om te zetten, zoals destructieve adsorptie, dehydrochlorering en H-Cl uitwisseling. Daarom is in **Hoofdstuk 6** het gebruik van op La-gebaseerde materialen in een aantal relevante toetsprocessen verkend.

Allereerst is aangetoond dat een mengsel van gechloreerde methanen en ethanen, nl. CCl_4 , CHCl_3 , CH_2Cl_2 , $1,1,2\text{-C}_2\text{H}_3\text{Cl}_3$ en $1,2\text{-C}_2\text{H}_4\text{Cl}_2$, kan worden omgezet tot O-bevattende producten en gechloreerde ethenen, respectievelijk. De destructieve adsorptie van CH_2Cl_2 is minder gunstig indien CCl_4 en CHCl_3 ook aanwezig zijn. De dehydrochloreringsreactie wordt niet gehinderd door de destructieve adsorptie reactie. Sterker nog, een in meerdere mate gechloreerde katalysator vertaalt zich naar hogere selectiviteit voor gechloreerde ethenen.

Het tweede gedeelte bewijst dat CCl_4 een goede vervanger is voor HCl in de activering van methaan over LaCl_3 in aanwezigheid van zuurstof. De hydroxylgroepen die gevormd worden op het katalytisch oppervlak als gevolg van de chlorering van methaan, reageren in de conventionele reactie met HCl tot H_2O . Wanneer CCl_4 gebruikt wordt als chloreringsmiddel dan wordt de katalytische cyclus gesloten door een extra reactiestap: CCl_4 wordt omgezet tot CO_2 wat resulteert in chlorering van het katalytisch oppervlak, waarna de hydroxyl groep dissocieert naar HCl.

Als laatste werd in een enkele reactor de conversie van CH_2Cl_2 naar koolwaterstoffen getest over een La_2O_3 en een SAPO-34 katalysatorbed. De resultaten tonen dat slechts een kleine hoeveelheid CH_2Cl_2 wordt omgezet tot CH_4 and C_2H_4 . Het lijkt erop dat SAPO-34 ook actief is voor de destructieve adsorptie van CH_2Cl_2 , wat zou kunnen leiden tot een irreversibele deactivering van de katalysator. De conversie van CH_2Cl_2 naar koolwaterstoffen over een combinatie van een op La_2O_3 -gebaseerd materiaal en SAPO-34 is in principe mogelijk. Er ligt echter een grote uitdaging in het controleren van o.a. de reactieomstandigheden.

Dit proefschrift heeft laten zien dat de chloreringsgraad van La-gebaseerde materialen van directe invloed is op de activiteit en selectiviteit bij de conversie van CKWs. De chloreringsgraad verandert echter als gevolg van de reacties met de CKWs. Daarom ligt de volgende uitdaging in het controleren van de chloreringsgraad tijdens reactie. Stoom is al gebruikt om de destructieve adsorptie van gechloreerde CCl_4 op La_2O_3 -gebaseerde materialen katalytisch te maken, maar de invloed van stoom op de destructieve adsorptie van H-bevattende gechloreerde C_1 en de dehydrochlorering van gechloreerde ethanen is nog niet bestudeerd. Verder onderzoek naar de terugwinning van rooster-O, en dus de dechlorering van het katalysator-materiaal, is nodig voor controle van de samenstelling van de katalysator en reac-

Samenvatting en conclusies

ties die plaatsvinden op de katalysator. Verder kan onderzoek naar nieuwe combinaties van katalysatormaterialen en reacties, zoals toegelicht in Hoofdstuk 6, worden gebruikt om de omzetting van gechloreerde afvalstromen efficiënter en goedkoper te maken. Er zijn wellicht complexe technologische systemen nodig om de katalytische omzetting van CKWs te faciliteren, maar de op La-gebaseerde materialen kunnen voordelig zijn in toepassingen waarbij microreactortechnologie gebruikt wordt. Deze technologie heeft als voordeel dat de omzetting van de CKWs tot in detail geoptimaliseerd kan worden waarbij de risico's van blootstelling minimaal zijn.

Dankwoord

Dit is het laatste stuk tekst uit dit proefschrift wat ik schrijf. Bij iedere letter die ik tik begin ik meer te beseffen dat het bijna voorbij is. Het zijn 4 jaar van ontdekken, leren en zwoegen geweest die ik niet zou willen of kunnen missen. Hoewel het een korte periode lijkt te zijn geweest, kijk ik met trots en plezier terug op de vele ontdekkingen die we gedaan hebben. Natuurlijk heb ik op allerlei manieren hulp gehad van de mensen om mij heen. Ik wil iedereen hartelijk bedanken voor hun bijdrage en hier bij een aantal mensen in het bijzonder stilstaan om hen toe te spreken.

Bert, ik wil jou ten eerste bedanken voor de mogelijkheid die je me hebt gegeven om dit onderzoek te doen. Jouw positieve en enthousiaste manier van begeleiden heeft mij veel zelfvertrouwen gegeven en me in staat gesteld veel te leren. Ik heb je openhartigheid in persoonlijke gesprekken over wetenschappelijke en niet-wetenschappelijke zaken altijd erg gewaardeerd en heb ook altijd het gevoel gehad dat ik volledig open tegen jou kon zijn. Vooral de momenten dat ik nieuwe resultaten had, die we na vijven met de voeten op het bureau bespraken, waren inspirerend en motiverend. Jouw snelle nakijkwerk en steun voor mijn ontdekkingstocht in de wetenschapscommunicatie hebben ook van de afronding van dit proefschrift een prettige periode gemaakt. Bedankt voor alles wat ik geleerd heb in de afgelopen jaren.

It has been my pleasure to have worked with so many talented people in these past years. I would like to thank all the members of "Team Lanthanum". Olga, thank you for helping me get started with the research and making my first months a lot easier. Virginie, your endless energy and ability to party with anyone made you a great contribution to the research and the working atmosphere. Thank you for everything. Guineviève, you were only with us for a while, but I enjoyed your open way of speaking and will remember the interesting discussions we had. Leti, I can only admire the continuous growth you have shown since I first met you. You were excellent as an Erasmus student and have continued to be so as a PhD student and colleague. I wish you all the best with your own PhD research. I also want to thank Maria for all her hard work on her master's research. Even though I knew it was difficult for you sometimes, you kept working hard with a nice publication as a result. Good luck with your work in the "corporate jungle". René, je enthousiasme en leergierigheid tijdens zowel het tweedejaarsproject en je bacheloronderzoek waren erg plezierig. Veel succes met afronden van je studie en je toekomstige plannen. Ik wil Bart bedanken voor zijn literatuurscriptie die mede de basis heeft gelegd voor de experimenten van Hoofdstuk 6. Ik wens jou ook alle succes met je promotieonderzoek. Ik wil verder nog alle studenten die in het kader van het tweedejaars-project hebben meegewerkt aan dit onderzoek: David, Esther, Johnny, Rob, Hans, Suzanne, Arjan, René, Peter, Anke en Anoeska.

Tijdens metingen in het buitenland heb ik de hulp gehad van diverse experts. Ik wil Joeri Rogiers van Tessenderlo Chemie danken voor de ervaring met de chloorexperimenten en het gebruik van hun faciliteiten toen mijn eigen opstelling nog in opbouw was. I thank Marco Da-

Conversion of Chlorinated Waste Streams from the Production of Polyvinyl Chloride
over La-Based Catalysts*

turi of the University of Caen for helping me get settled in Caen and for his contributions to the measurements and the discussion of the results. I also thank Phillipe Bazin for his practical help with using the IR vacuum cell. Simon Podkolzin of the Dow Chemical Company is thanked for all the valuable discussions and the time he invested in the DFT calculations. You were always kind and patient with me, especially when I was just getting familiar with this topic. Elvira, I want to thank you in particular for the period of the IDECAT exchange. The results that we obtained in Munich were very nice and I thank you for the wonderful time with you and your colleagues in- and outside the lab. I still think you should become an ambassador for Bavaria (the region, not the beer).

Natuurlijk dankwoord niet zonder het noemen van alle mensen die werkzaam zijn bij en rondom onze groep in Utrecht. Ik wil Ad^M bedanken voor alle problemen die hij opgelost heeft en die hij mij heeft leren oplossen. Je zat een kamer verder van mijn opstelling en ik kon altijd binnenlopen als ik advies of gereedschap nodig had. Ik waardeer het enorm dat je ondanks je drukke bezigheden altijd tijd voor me wist vrij te maken. Natuurlijk ook bedankt voor het uitvoeren van de N₂-fysisorptie en XPS-metingen. Tom, de discussies met jou betreffende mijn IR resultaten maakten me altijd weer wijzer, ondanks dat we niet altijd tot een definitieve conclusie konden komen. Ook Fouad wil ik bedanken voor alle keren dat hij me heeft geholpen met spectroscopieperikelen. Jullie ontspannen houding en de subtiële pracht van spectroscopie maakten voor mij de derde verdieping in het Went een heerlijke plek om te werken. Harry, ik wil jou bedanken voor de gemoedelijke werksfeer waarin we samengewerkt hebben op het gebied van de kooldraden en de LaCl₃ katalysator. Fred, ik denk dat van alle keren dat ik de groeten van je kreeg via Kees, de eerste toch altijd het mooist zal blijven. Bedankt voor al je hulp en goede zorg. Dymph en Monique, jullie flexibiliteit en zorgen om alles zo goed mogelijk voor ons te regelen kunnen niet genoeg benadrukt worden. Heel erg bedankt. Verder wil ik Ad^E (XRF), Marjan (SEM/XRD), Vincent (TPD/ICT), Cor van der Spek (TEM), de glasblazerij en de instrumentmakerij bedanken voor hun assistentie.

Natuurlijk wil ik al mijn collega's bedanken voor alle leuke tijden die we meegemaakt hebben tijdens en naast het werk. De BBQs, borrels, sporttoernooien, etentjes en barhangavonden waren een welkome afwisseling van de wetenschap. Ik wil met name de mensen die mij op de kamer hebben moeten doorstaan bedanken voor hun geduld. Kees en Jelle, het is ongelooflijk hoe drie mensen die zoveel gezamenlijke interesses hebben zomaar bij elkaar kunnen komen te zitten in een werkkast in het Went. Ik denk dat we geen betere combinatie van persoonlijkheden hadden kunnen hebben en wil jullie bedanken voor alle humor, discussies en gezelligheid van de laatste jaren. Hoewel de (mid)dagen soms te snel voorbijvlogen op onze kamer, was de sfeer altijd fantastisch. Ik hoop gauw weer naar een SUWU3 optreden te komen Kees! En Jelle, kun jij misschien voor mij ook zo'n ereburgerschap regelen van Bergeijk? Maakt vast indruk bij de familie... Cynthia, thank you for the short time we were "workroomies" and your love for small talk (like me). Best of luck with your postdoc!

Tenslotte wil ik de mensen bedanken die achter de schermen geholpen hebben om dit promotie-onderzoek tot een goed einde te brengen. Ik wil mijn vrienden en familie bedan-

ken voor hun steun en geduld in de laatste maanden toen ik wat minder in de gelegenheid was om af te spreken. In het algemeen wil ik alle mensen van de Zeister tafeltennisvereniging bedanken voor alle gezelligheid en sportiviteit. Mijn buurman Davorin, bedankt voor de gezellige gesprekken als ik pauze nodig had van het schrijven. Sander, een ferme ruzie toen we elkaar voor het eerst ontmoetten en sindsdien zijn we in verschillende fases van ons leven be-vriend gebleven. Bedankt voor al je hulp en vriendschap. Ruud en Laurens, ik noem jullie samen omdat we sinds ons 14^e jaar altijd contact met elkaar hebben gehouden. We hebben alle drie het pad van de promotie gevolgd en ik hoop dat ons contact er altijd zal blijven. Lai Mei, je bent een (studie)vriend door dik en dun en ik ben dan ook erg blij met jou als paranimf. Het feit dat je bereid bent van de andere kant van de wereld ervoor terug te komen vereert me. Natuurlijk is mijn naaste familie ook een vaste steun voor me geweest. Ik wil mijn beiden oma's bedanken, mijn ooms en tantes, neven en nichten. De familiegelegenheden zorgen altijd voor warmte, zelfs als we elkaar lang niet hebben gezien. Mijn opa's kunnen hier helaas niet meer bij zijn, maar de invloed van hun sterke en vriendelijke karakter heeft mij mede gevormd en mag hier niet vergeten worden. Ik wil mijn broer, Ron, bedanken dat hij paranimf wil zijn en dat hij bereid is een pak aan te trekken hiervoor (knipoog). Ik wil ook mijn ouders bedanken voor het feit dat ze van jongs af aan mijn nieuwsgierigheid hebben gestimuleerd en mij geleerd hebben vol te houden en door te zetten. Hierdoor heb ik mezelf kunnen ontplooien en mijn eigen keuzes leren maken.

Mijn laatste regels zijn voor de liefde van mijn leven: Lai Ting. Jij hebt de volledige promotie periode meegemaakt en de laatste twee jaar zelfs van zeer dichtbij. Ik kan je niet genoeg bedanken voor al het goede dat je me hebt gebracht. Je bracht rust, liefde en steun in mijn leven, iets wat onmisbaar was en is. Om nog maar te zwijgen over alle hulp met het grafische werk die je gegeven hebt aan deze soms gefrustreerde wetenschapper. We gaan nu allebei een nieuwe toekomst tegemoet. Ondanks dat we niet precies weten hoe die eruit gaat zien, heb ik er het volste vertrouwen in omdat het samen met jou zal zijn.

Alwies

Conversion of Chlorinated Waste Streams from the Production of Polyvinyl Chloride
over La-Based Catalysts

Curriculum Vitae

Alwies van der Heijden werd geboren op 14 juni 1980 te Bergeijk. In 1998 behaalde hij het VWO-diploma aan Scholengemeenschap Were Di Locatie Merendreef te Valkenswaard. Ditzelfde jaar ging hij ook Scheikunde studeren aan de Universiteit Utrecht. In maart 2004 studeerde hij met genoegen af bij de sectie Anorganische Chemie en Katalyse onder begeleiding van Dr. D.E. Keller en Prof. Dr. Ir. B.M. Weckhuysen. Vanaf februari 2004 werkte hij als assistent in opleiding (AiO) in de groep Anorganische Chemie en Katalyse van de Universiteit Utrecht. De promotie werd gedaan onder supervisie van Prof. Dr. Ir. B.M. Weckhuysen. De bevindingen van het onderzoek zijn beschreven in dit proefschrift.

Alwies van der Heijden was born on the 14th of June 1980 in Bergeijk. In 1998 he obtained his diploma of secondary school at Scholengemeenschap Were Di Locatie Merendreef in Valkenswaard. In the same year he started with a study of Chemistry at Utrecht University. In March 2004 he received his master's degree with credit in the section Inorganic Chemistry and Catalysis under supervision of Dr. D.E. Keller and Prof. Dr. Ir. B.M. Weckhuysen. In February 2004, he started working as a PhD student in the group Inorganic Chemistry and Catalysis at Utrecht University. The research was performed under supervision of Prof. Dr. Ir. B.M. Weckhuysen. The findings of the research are described in this PhD thesis.
