## THE LUXURY OF EATING

“Dis-moi ce que tu manges, je te dirai ce que tu es.”[1]. “Der Mensch ist, was er ißt.”[2]. Or modernly translated as: “ You are what you eat.”[3]. These phrases indicate that what you eat could influence your state of mind or physical health. The last decades the choice of food has become more abundant and increasingly important as is depicted in food trends. Not only are we able to choose between a variety of world-cuisines and exotic ingredients, but the media also feeds us with hypes such as organic food, superfoods containing antioxidants, pro-biotics and carbohydrate-free diets. Which makes it even more difficult to decide what to eat.

Sometimes, however, the question is not what we would like to eat, but rather what we can eat. Some people do not have this choice due to economical-, social status; place of birth or literally due to a physical inability to take up and digest certain foods (malabsorption), which is the case in many intestinal diseases (enteropathies).

## INTRODUCTION TO INTESTINAL DISEASES

This inability to take up food, necessary to feed all the cells in the body, can range from total dysfunction in rare intestinal diseases or be confined to only one type of food, such as wheat, barley and rye in celiac disease. Also, the extent to which malabsorption occurs within one disease can differ per patient. For example, some patients have a mutation (defect in the DNA) that leads to complete abrogation of a protein and therefore loss of function, resulting in severe malabsorption. While other patients, who carry a different mutation in the same gene, might maintain a part of the protein with residual function and, thus, are able to partially take up nutrients. Occasionally, it is possible to treat these patients with supporting medication that conserves or improves the protein function, which is sometimes the case in cystic fibrosis. These diseases will be explained shortly in the next paragraphs.

### Microvillus inclusion disease

An extreme example of an intestinal disease is microvillus inclusion disease (MVID), a rare enteropathy that usually presents itself in a newborn baby (congenital) with severe, watery diarrhea [4, 5]. Their intestine is unable to absorb nutrients. The only therapeutic option is feeding, often life-long, through the blood veins (parenteral feeding) with severe complications as a consequence. Common complications that arise from parental nutrition are liver failure, increased risk of infection, blood clots and, ultimately, the inability to find an accessible vein to feed over. If the latter occurs, small bowel transplantation is the only therapeutic option left.

### Cystic fibrosis

Another congenital disease that could be associated with diarrhea due to malabsorption is cystic fibrosis. This congenital disease is

more known for its lung problems, where mucus, a substance that is usually watery and protects organs from bacteria, is thickened and therefore causes difficulty breathing by blocking of airways and increases risk of infections [6]. In other organs, such as the pancreas and intestine, similar pathology can be seen. The pancreas provides the intestine with enzymes that help to break down fat and other food particles. In cystic fibrosis the thick mucus induces pancreas insufficiency. The lack of pancreatic enzymes can result in fat malabsorption and therefore cause diarrhea. Frequently, persistent intestinal malabsorption, despite pancreas enzyme supplementation, exists due to other intestinal problems caused by cystic fibrosis [7, 8].

#### Celiac disease

In celiac disease, the inability to digest is related to intake of specific food proteins. A genetically predisposed group of patients are not capable of eating food containing wheat, barley or rye (or more specifically gluten, one of the components in these grains) without occurrence of intestinal damage, often accompanied with failure to grow, abdominal pain and/or diarrhea [9]. Currently, the only treatment for these patients is a gluten-free diet. This might sound feasible; nonetheless it has a big impact on simple daily life choices as what to eat.

All these intestinal diseases and others emphasize that to be able to eat what you choose is a luxury. This thesis will address these 3 diseases in which nutrient uptake and/or digestion are often impaired and in which a patient-specific model to study these diseases in more depth is desirable. Yet, before we get into the specifics of these diseases we first need to better understand how the healthy intestine works.

## THE INTESTINE

### Anatomy of the intestine

The intestine is one of the largest organs in the human body with a surface area of approximately 32 m<sup>2</sup> caused by protrusions and invaginations, called the villi and crypts, respectively [10]. While the small intestine accommodates both villi and crypts, the large intestine is composed of only crypts. The large surface area is important for optimal uptake and digestion of nutrients and protection against pathogens. The functions of the small intestine are mainly digestion and uptake of food and consist of three segments from proximal to distal: the duodenum, the jejunum and the ileum. Posterior, the large intestine (colon) is responsible for further processing of undigested food and formation of thickened stool. The large intestine comprises the caecum, the colon -ascendens, -transversum, -descendens, the sigmoid and rectum.

To execute these different functions properly, the intestinal tract consists of four layers from the outside to the inside: the adventitia/

serosa, the muscularis externa, the submucosa and the mucosa. The most outer layer of the intestine is named the adventitia or serosa, depending on the location out/inside the peritoneum (lining of abdominal cavity) and protects the intestine from other organs. The muscularis externa comprises two muscle layers that together with the enteric nervous system control peristaltic movement of the gut and thus movement of food particles/stool. The submucosa is a connective tissue layer, which contains blood vessels, lymphatics and nerves, necessary to give oxygen to the cells and connect the intestine to the rest of the body. The mucosa consists of three different layers: a small smooth muscle layer; a lamina propria with connective tissue, blood vessels and immune cells; and the epithelium, a single cell layer on the luminal side of the gut (Figure 1) [11, 12].

The luminal epithelial cell layer performs the major functions of the intestine: food digestion, uptake of nutrients and maintaining a barrier against external pathogens such as bacteria, viruses and fungi. To absorb as many nutrients as possible, the enterocytes on the villi of the intestine have microvilli, small tiny hair-like protrusions on the apical side of the cell, also called the brush-border.

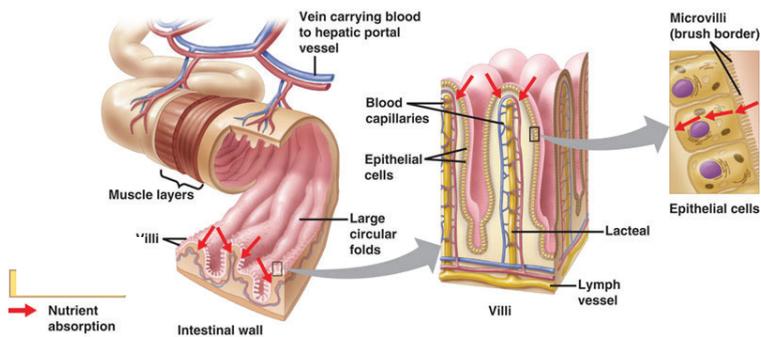

Figure 1. Overview of intestinal layers, structure and microvilli (adapted from kvhs.nbed.nb.ca/gallant/biology/small\_intestine.jpg).

### Intestinal cell types

The major functions of the intestine are mediated by seven differentiated cell types within the epithelial layer: enterocytes, goblet cells, enteroendocrine cells, Paneth cells, microfold (M or membranous) cells at Peyer's patches, tuft cells, and cup cells. The exact role of these last two cell types is still unresolved [13].

Enterocytes are the most common cell type in the villi of the small

intestine, and are capable of digestion and absorption of nutrients. Moreover, they have an important barrier function against pathogens and have the ability to act as antigen presenting cells [14].

The mucus producing goblet cells help to protect the intestine from infections. They are more abundant towards the colon where they also function as lubricant for the stool.

Enteroendocrine cells are scarce and these hormone-secreting cells and have many subtypes, dependent on the hormone they secrete [15]. These cells regulate mainly postprandial (after eating) secretion of gut peptides and motility [16]. M cells are secluded to Peyer's patches (the lymph nodes of the intestine) and are involved in antigen processing and interact directly with lymphocytes [17]. Lastly, Paneth cells have anti-microbial properties and reside in the bottom of small intestinal crypts, alongside intestinal stem cells [18, 19]. Located higher up in the crypt are the transit-amplifying cells that multiply former stem cells and are destined to differentiate into either the secretory or the absorptive lineage (see Figure 2: adapted from [20]).

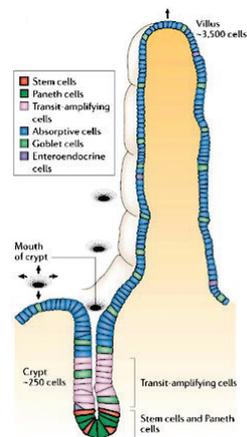

Figure 2. Epithelial cell lineages in the small intestine (adapted from [20]).

### Intestinal stem cell

The properties of a true stem cell is that it can multiply itself for a long period of time and all differentiated lineages arise from these stem cells [12]. An embryonic stem cell is capable to differentiate into any cell type in the body such as a kidney, lung or brain cell. An adult stem cell on the other hand is restricted to one organ only. For example, an adult intestinal stem cell can only become one of the seven differentiated intestinal cell types, and ensures renewal of most intestinal cells every 3 to 5 days. The Clevers group provided functional evidence for an active stem cell, residing in the bottom of

the crypts, by lineage tracing of Lgr5+ columnar base crypt cells (CBC) and in *in vitro* cultures that originated from one single stem cell [21, 22]. Lineage tracing with other CBC markers, such as low-expressing Sox9-EGFP cells, support the role of these active cycling stem cells [23]. A 'sleeping' or quiescent stem cell population at the +4 position from the crypt has been mentioned in the literature as well. Proposed markers for these cells are Bmi1, Lrig1, mTert and Hopx [24-28]. Although, until now, a unique marker for these putative +4 stem cells have not been shown and some of these proposed +4 markers are also seen in the active stem cell population [29, 30]. In addition, there is increasing support that these +4 cells are only active in tissue regeneration and not in intestinal homeostasis [31, 32]. The exact nature of these +4 cells is still unclear, hence the intestinal stem cells that are referred to in this thesis will be the columnar crypt base active cycling stem cells that, among other markers, are identified by expression of Lgr5.

### Crypt-villus regulation

To ensure constant renewal and maintain all the different intestinal functions two processes are tightly regulated in the intestinal epithelium: proliferation and differentiation. Proliferation ensures the growth or production of cells by multiplication of intestinal cells, this occurs mainly in the crypt. While on the other hand, differentiation drives the cells towards a specific cell type with a specialized function. For example, the main function of an absorptive enterocyte is to absorb and digest food. A controlled environment is necessary to direct cell fate into either a proliferation or differentiation state, this is regulated by multiple pathways such as bone morphogenetic protein (BMP), hedgehog and EphrinB (EPHB) pathways [33-37]. Two other important regulating pathways are Wnt and Notch signaling. Wnt signalling is active in the crypt (and absent in villi) and promotes proliferation and maintenance of stem- and Paneth cells [38-40]. Paneth cells and mesenchymal cells are known to produce Wnt. Notch signalling is also involved in stem cell maintenance and in deciding the differentiation fate of transit-amplifying cells towards absorptive lineage (Notch on) or secretory lineage (Notch off) [41, 42]. The absence of Wnt, on the other hand, promotes differentiation of cells (excluding Paneth cells), this mainly occurs in the villi of the intestine. An overview of the interaction between Wnt and Notch pathways in intestinal differentiation is given in Figure 3 (adapted from [41]).

### Cell polarity

Another form of regulation exists within the epithelial cell itself: cell polarity. Polarity means having two opposite poles, in epithelial cells this translates to an apical and basolateral side, on the luminal or mesenchymal side of the cell, respectively. Intestinal cell polarity is an essential property to ensure normal function. For example, nutrient uptake, regulation of water balance and bile acid secretion all are dependent on correct polarization. Transmembrane proteins,

such as the enzyme sucrose-isomaltase, are specifically located on the apical side to digest sucrose proteins. The major components that maintain cell polarity are the extracellular matrix (such as the collagens in the lamina propria), and tight junctions proteins that connect epithelial cells on the basolateral side ([43] and Figure 4, adapted from [44]).

## INTESTINAL FUNCTION IN DISEASE

In a healthy person the intestine is tightly regulated, nonetheless, in several intestinal diseases dysregulation of the epithelium can occur.

### Microvillus inclusion disease

One can imagine that if one of the transporter proteins does not function properly, uptake or digestion of food could be distorted. This is the case for a severe, but rare, congenital enteropathy such as Microvillus inclusion disease (MVID) [4, 45]. As the name implicates, the microvilli are not formed properly and can accumulate in vesicles inside the enterocyte. Hence, the transporter proteins, which are normally expressed on the microvilli of the apical membrane, are dislocated intracellularly and are therefore not able to take up nutrients [46, 47]. The lack of nutrient uptake is visible in patients by watery diarrhea and dependency on intravenous feeding [5]. The disease is caused by microvillus atrophy as well as mislocalisation of the transporter proteins. In a healthy cell, newly synthesized transporter proteins are shipped in vesicles from the Golgi system to the

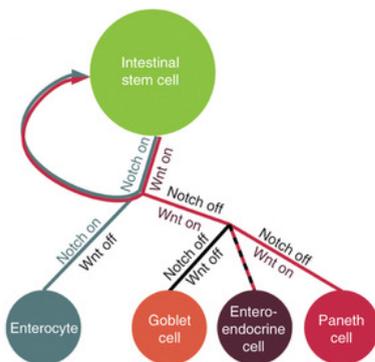

Figure 3. Notch and Wnt regulation in small intestinal cells (adapted from [41]).

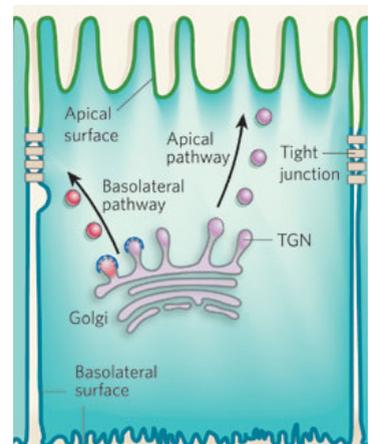

Figure 4. Polarized epithelial cell with an apical and basolateral surface. Figure adapted from [44].

apical membrane by moving over microtubules. Subsequently, vesicles reach the apical membrane, dock and fuse to the membrane and place or secrete the transporter protein onto or out of the membrane [43]. Microvillus inclusion disease is the result of aberrant transport of these apical, and recently discovered, basolateral proteins to the membrane [48, 49]. Microvillus inclusion disease is caused in 90% of the patients by mutations in the *MYO5B* gene, encoding for the myosin 5b protein [50, 51]. MYO5B is an accessory motor protein that connects these vesicles to actin. If MYO5B does not function, newly synthesized proteins are not transported properly to their desired apical location of the cell, which is then unable to absorb nutrients.

We aim to identify other genes that could cause the MVID phenotype. In addition, by understanding these diseases better, we hope to diagnose and treat patients more specifically. Currently, there is no good model that recapitulates this disease and therefore it is difficult to study the pathogenesis in more detail other than by biopsies or, more recently, siRNA CACO2 cell-lines [48, 49]. Although, CACO2 cell lines help to unravel the pathophysiology of MVID, they are not entirely representative for the *in vivo* epithelium.

#### Cystic fibrosis

Another disease that causes congenital diarrhea is cystic fibrosis. Cystic fibrosis is caused by a missing or misfolded transporter protein; the cystic fibrosis transmembrane regulator (CFTR), on the apical membrane of epithelial cells [6, 52]. This transporter is responsible for secreting chloride into the lumen, the negatively charged chloride attracts the positively charged sodium, and therefore water. The main manifestation in patients with cystic fibrosis is a thick mucus layer on the epithelial cells because of diminished water secretion. This thick mucus clogs the cells/ducts and therefore prevents normal functioning of many organs. Different mutations in the *CFTR* gene result in different severity of the disease and response to drugs in patients [53, 54]. However, since even patients with the same mutation respond differently to a certain drug, it is difficult to predict which drug will work for which patient [55]. A tool to advance this knowledge is if CFTR function and patient-specific drug response could be assessed in an *in vitro* model.

#### Celiac disease

Malabsorption may also be confined to one compound. This is the case in celiac disease, where gluten induces a specific T-cell mediated response after being presented by antigen presenting cells. This occurs only in genetically predisposed individuals with HLA-DQ2.2, 2.5 or 8 [56, 57]. Although 30% of the population has one of these HLA types, the prevalence of this disease is estimated to be 1% in Europe [58]. The role of lymphocytes in celiac disease has been extensively studied and is thought to play a big role in developing the disease [59-61]. Yet, there is more necessary to cause the disease. The literature debates the role of the epithelium in celiac

disease. Some claim that gliadin has a direct effect on epithelial cells or cell lines and is differently transported in intestinal biopsies of celiac patients [62-67]. As most studies are either executed on cell lines or whole biopsy material, it is still unclear if the epithelium is involved in celiac disease.

## INTESTINAL STUDY MODEL

Many intestinal diseases have been studied in more detail in animal models, cancerous cell lines or intestinal biopsy material. Although it helped to understand a range of diseases better, the major drawbacks are that animal models and cell lines differ from the patients intestine, while patient biopsy material is often limited and has a short life-span once it is taken from the intestine. Therefore a patient-specific *in vitro* model is desirable for improved understanding, diagnostics and therapy.

### Intestinal organoids

Soon after identification of the Lgr5+ stem cell, an *in vitro* model to culture these stem cells was set up for mouse and human intestinal tissue [22, 68]. To establish human intestinal organoids, crypts (which contain the stem cell) were isolated from intestinal resection material or biopsies. These crypts were embedded in matrigel (which contain collagen and laminin that are also present in the submucosa) and cultured in expansion medium (EM) containing: WNT3A, Rspodin-1 (a WNT-activating protein and ligand for Lgr5), Noggin (a BMP inhibitor), epidermal growth factor (EGF, induces intestinal cell proliferation), A83 (a TGF-beta receptor type 1 inhibitor), n-acetylcysteine, b27, nicotinamide and SB202190 (a selective inhibitor of p38 mitogen-activated protein kinase). As this medium promotes the intestinal crypt or proliferative compartment, WNT3A, nicotinamide and SB202190 were excluded to induce intestinal differentiation [68]. Since organoids represent all cell types of the intestine and are maintained by endogenous stem cell proliferation, they could serve as an appropriate model to study previously mentioned diseases.

### Healthy intestine

Nonetheless, it is just as important to truly understand the healthy intestinal epithelium. How could we compare diseased tissue with healthy controls if we do not know what is normal? As the organoid model was quite recently developed at the start of this study, we aimed to understand proliferation and differentiation per specific segment of the intestine. Already from the clinic it is known that bile acids are mainly reabsorbed in the ileum, while iron is especially taken up in the first part of the intestine, the duodenum. Beuling *et al.* showed previously that GATA4 controls the duodenal, and HNF1- $\alpha$  the ileal segment of the intestine [69]. However, it remains elusive if this segmental specificity is maintained in the stem cell or controlled by external factors. To better understand the different segments in

the gut, both mouse and human organoids of the different small intestinal parts were studied for morphology, mRNA and protein levels.

The core of this thesis is to use organoids as a tool to better understand intestinal diseases.

## THESIS OUTLINE

Chapter 2 of this thesis focuses on the healthy intestine, the intestinal stem cell and location-specific properties. In chapter 3, we report our discovery of a new gene mutation for MVID, syntaxin 3. In chapter 4 we elaborate on these STX3 patients and the function/dysfunction of their intestine. In chapter 5, we study cystic fibrosis and use organoids as a model to set up a forskolin-swelling assay that can help to predict patient-specific response on drugs. In chapter 6, we use organoids to discuss the role of the epithelium in celiac disease. At the end of this thesis we will evaluate if organoids, used as intestinal model in all chapters, truly recapitulates the *in vivo* epithelium and discuss possible applications and recommendations for this model.

## ABSTRACT

Differentiation and specialisation of epithelial cells in the small intestine are regulated in two ways. First, there is differentiation along the crypt-villus axis of the intestinal stem cells into absorptive enterocytes, Paneth, goblet, tuft, enteroendocrine, or M-cells, which is mainly regulated by WNT. Second, there is specialization along the cephalocaudal axis with different absorptive and digestive functions in duodenum, jejunum and ileum that is controlled by several transcription factors such as GATA4. However, so far it is unknown whether location-specific functional properties are intrinsically programmed within stem cells or if continuous signalling from mesenchymal cells is necessary to maintain the location-specific identity of the small intestine.

Using the pure epithelial organoid technique, we show that region-specific gene expression profiles are conserved throughout long-term cultures of both mouse and human intestinal stem cells and correlated with differential *Gata4* expression. Furthermore, the human organoid culture system demonstrates that *Gata4*-regulated gene expression is only allowed in absence of WNT signalling.

These data show that location-specific function is intrinsically programmed in the adult stem cells of the small intestine and that their differentiation fate is independent of location-specific extracellular signals. In light of the potential future clinical application of small intestine-derived organoids, our data imply that it is important to generate GATA4-positive and GATA4-negative cultures to regenerate all essential functions of the small intestine.

## INTRODUCTION

The mammalian intestine is responsible for the absorption of dietary nutrients and water, and the excretion of waste materials. The intestine also has an important barrier function in preventing direct contact with bacteria that reside in the lumen. To facilitate these diverse functions, the intestinal surface is covered by specialized epithelial cells that can take up nutrients from the lumen, but also form a continuous lining of cells that are linked close together by tight junctions.

The intestinal epithelium is ordered into crypts of Lieberkühn that harbor the stem and Paneth cells and mainly constitute a proliferative compartment, and the villi that represent the differentiated compartment containing the enterocytes, goblet, tuft, and enteroendocrine cells. It has been shown that four signaling pathways control homeostasis of the intestinal epithelium: WNT, Notch, epidermal growth factor (EGF) and bone morphogenic protein (BMP) (reviewed in [1]). WNT and EGF signaling are active in a gradient from the bottom to the crypt-villus junction, while BMP signalling is active in the villus compartment and Notch signalling determines the differentiation toward the secretory lineage (reviewed in [2]). High expression of WNT induces stem cell survival and proliferation of transit amplifying (TA) cells, while low levels of WNT allow TA cells to fully differentiate into one of the various epithelial cell types [3].

In addition to differentiation along the crypt-villus axis, there are also structural differences along the length of the intestine, such as cell type distribution and expression of proteins with specialized functions [4-6]. These differences correlate with the functionality of the different regions of the intestine and are referred to as regional or spatial differences along the cephalocaudal axis. This structural organization is established during development and is maintained throughout adulthood [7]. The small intestine is roughly divided into three segments along the cephalocaudal axis: duodenum, jejunum and ileum [8]. In mice, the duodenum involves the proximal two centimeters directly after the gastric pylorus [8]. Its

main function is the digestion and absorption of iron, calcium and water-soluble vitamins. The function of the jejunum is the digestion and uptake of nutrients, whereas the ileum absorbs residual nutrients and mediates transport of bile acids and vitamin B12 [8].

To facilitate these highly specialized functions, multiple proteins such as digestive enzymes, nutrient transporters, cytoplasmic carriers and antimicrobial peptides are differentially expressed along the cephalocaudal axis. For example, duodenal cytochrome b reductase 1 (*Cybrd1*), involved in iron metabolism, is expressed only in duodenum [9], lactase-phlorizin hydrolase (Lct) is mainly expressed in jejunum [10] and apical sodium-dependent bile acid transporter (ASBT, *Slc10a2*) in ileum [11]. It has been shown that several transcription factors, for example, GATA4 and CDX2, control the expression of genes along the cephalocaudal axis [12, 13]. As such, GATA4 is expressed in proximal small intestine where it inhibits expression of ileum-specific genes [12], whereas CDX2 is expressed throughout small and large intestine and has an important role in formation of normal intestinal identity [13, 14]. Furthermore, syngeneic and xenogeneic transplantation of intestinal tissue into murine hosts have demonstrated that donor fetal intestine retains its positional information [15-18]. However, it is not known whether the identity of the intestinal epithelium is a hard-wired program within the stem cells or if the microenvironment, such as surrounding mesenchymal cells or luminal content, provides location-specific signals to the stem cells. Recently, we developed a method to grow intestinal epithelial tissue *in vitro* from isolated crypts of both murine [19] and human origin [20]. We characterized the functional properties of organoids that were derived from different segments of the small intestine of mice and human. We found that the functional fate of both murine and human differentiated cell types is intrinsically programmed within location-specific stem cells as specific gene expression programs are maintained in the absence of location-specific external signals from mesenchyme or microbiota.

## MATERIALS AND METHODS

### Mice

C57BL/6 wild type mice (6-12 weeks old) were used for experiments. The mice were specific pathogen free and maintained in an environmentally controlled facility. Experiments were approved by the local Ethical Committee. Murine small intestines were dissected and cut into three equal parts. We isolated small parts of duodenum (proximal 2 cm of the proximal part), jejunum (proximal 2-4 cm of the middle part) and ileum (distal 2-4 cm of the distal part). Each segment was opened longitudinally, washed with cold phosphate buffered saline (PBS), and further processed for crypt isolation. From other mice, similar pieces of intestinal segments were used for *ex vivo* RNA isolation and histology.

### Human material

Approval for this study was obtained by the Ethics Committee of the University Medical Centre Utrecht. Duodenal biopsies were obtained by flexible gastroduodenoscopy and ileal biopsies were obtained from the terminal ileum by colonoscopy. The biopsies were macroscopically and pathologically normal.

### Crypt isolation and organoid culture

Murine organoids were generated from isolated small intestinal crypts and maintained in culture as described previously [19]. Crypt isolation and culture of human intestinal cells from biopsies have been described previously [20, 21]. In short, human organoids were maintained long-term in expansion medium (EM) containing RSPO1, noggin, EGF, A83-01, nicotinamide, SB202190 and WNT3A. For induction of differentiation, cultures were maintained for 5 days in differentiation medium (DM), which is EM without nicotinamide, SB202190 and WNT3A. We used conditioned media for RSPO1 (stably transfected *RSPO1* HEK293T cells were kindly provided by Dr. C. J. Kuo, Department of Medicine, Stanford, CA), noggin and WNT3A. The medium was changed every 2-3 days and organoids were passaged 1:6 every week.

### RNA isolation and qPCR

From dissected tissue or cultured organoids, RNA was isolated with the RNeasy minikit or microkit (Qiagen, Venlo, the Netherlands), respectively, and quantified by optical density. cDNA was synthesized from 1 µg of RNA by performing reverse-transcription (Invitrogen, Carlsbad, CA or iScript, Biorad, Hercules, CA). Messenger RNA (mRNA) abundances were determined by real-time PCR using validated primer pairs (Suppl. Table S1) with the SYBR Green method (Bio-Rad, Hercules, CA). Glyceraldehyde-3-phosphate dehydrogenase (*Gapdh*) or *ACTIN* mRNA abundance was used to normalize mouse or human data, respectively.

### RNA sequencing

Freshly isolated villi, crypts or organoids (cultured for 12 weeks) were used for mRNA sequencing. Total RNA was isolated using Trizol LS reagent (Invitrogen). Total RNA was purified using the Poly(A)Purist MAG Kit (Life Technologies, Ghent, Belgium) and subsequently re-purified using the mRNA-ONLY Eukaryotic mRNA Isolation Kit (Epicentre, Madison, Wisconsin) to obtain full length mRNA. Sequencing libraries were constructed using the SOLiD® Total RNA-Seq Kit (Life technologies, Ghent, Belgium) and sequenced on a SOLiD 4 sequencer to produce 50-bp long reads. Reads per 1,000 base pairs of transcript per million reads sequenced (RPKM) values were calculated for all RefSeq annotated genes and quantile normalized. A location-specific gene was defined as a gene with expression >10 RPKM (crypt) or >5 RPKM (villi) in at least one part of the intestine and with >1.5-fold higher expression in a specific part compared to any other part separately in both replicates (crypt) or in single replicate (villi). The gene ontology analysis was performed using the ToppGene Suite website [22]. The mRNA-seq datasets can be accessed via GEO (<http://www.ncbi.nlm.nih.gov/geo>) accession number GSE53297.

### Immunohistochemistry

Intestinal segments and organoids were fixed in neutral buffered formalin and sectioned. After deparaffination and dehydration, epitope

retrieval was performed by boiling for 15 minutes at 120°C in target retrieval solution pH = 6.0 (DAKO, Glostrup, Denmark). Slides were blocked for endogenous peroxidase with 3% H<sub>2</sub>O<sub>2</sub>/PBS for 20 min and blocked with 1% bovine serum albumin (BSA)/PBS for 30 min at RT. Primary antibodies were diluted in 0.05 % BSA/PBS and incubated for 1 hour at RT or o/n at 4°C. Next, slides were incubated with secondary antibody (Envision anti-Rabbit-HRP or Envision anti-mouse-HRP, DAKO) 30min at RT, with Vector-Nova Red (Vector Labs, Burlingame, CA) to develop staining and counterstained with hematoxylin. Primary antibodies were monoclonal mouse anti-human proliferating cell nuclear antigen (NCL-PCNA, Leica Biosystems, Wetzlar, Germany), polyclonal rabbit anti-human sucrose-isomaltase (SI, HPA011897, Sigma, St. Louis, MO), and polyclonal rabbit anti-human SLC10A2 (ASBT, HPA004795, Sigma). Alcian Blue - periodic acid Schiff (AB-PAS) staining was performed according to standard methods.

### Statistics

Data were expressed as means ± SEM and analyzed using one-way ANOVA and Tukey's Multiple Comparison Post-Test.

## RESULTS

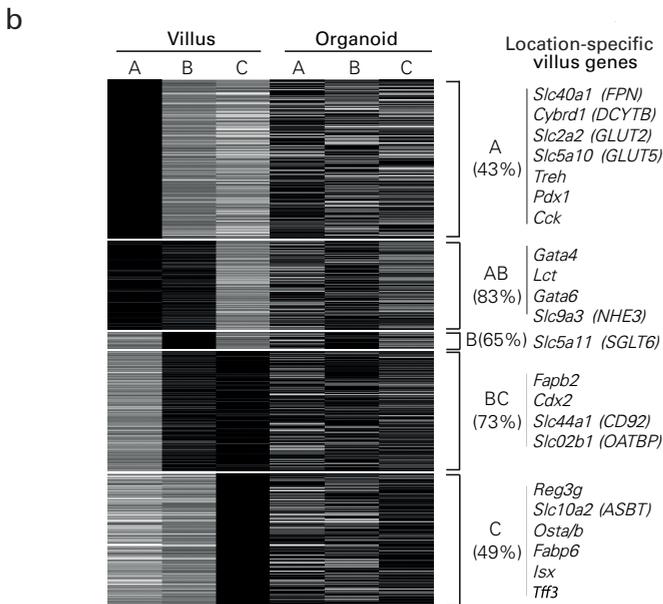

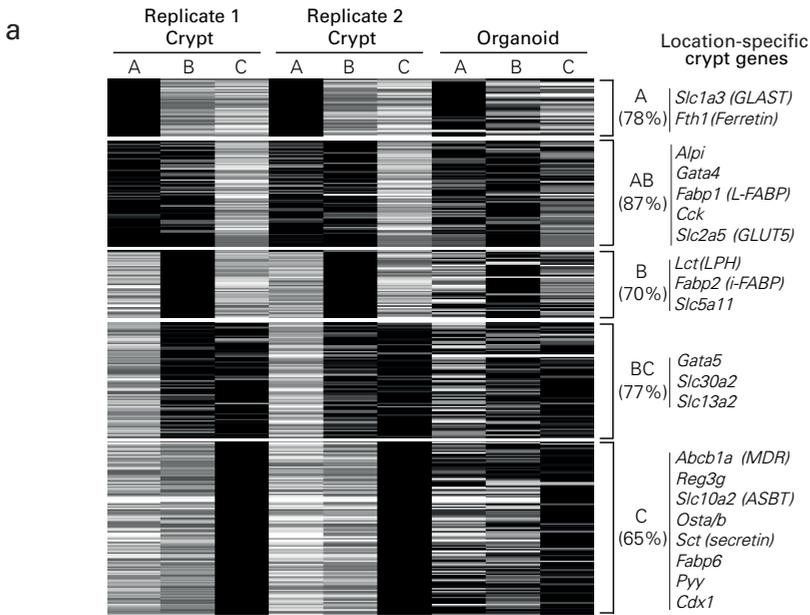

### Location-specific signatures within the murine small intestinal crypts are maintained in long-term epithelial cell cultures

To obtain a systematic overview of location-specific gene expression, we performed mRNA sequencing on crypts and villi isolated from three equal parts of the small intestine. For analysis, we listed genes that were most strongly expressed in duodenum (A), jejunum (B) and ileum (C) or in two adjacent compartments (AB, BC). Next, we generated organoids from similar crypt preparations of the three small intestinal segments and cultured them for 12 weeks. mRNA sequencing profiles of these cultures were compared to their location-specific crypt-derived (Figure 1A) and villus-derived (Figure 1B) *ex vivo* counterparts. For example, we found that from those genes

that were specifically expressed in crypts or villi of duodenum, 78% or 43% of these genes was also specifically expressed in organoids derived from duodenum, respectively (Figure 1 and Table 1). Similarly, 87% versus 83% of duodenal-jejunal, 70% versus 65% of jejunal, 77% versus 73% of jejunal-ileal and 65% versus 49% of ileal crypt- versus villi-specific genes were maintained in organoids derived from their *ex vivo* counterparts, respectively (Figure 1 and Table 1).

GO analysis of the selected genes was performed (Suppl. Tables S2, S3) and showed that the location-specific crypt- or villus-derived genes are mainly involved in digestion, transport, and metabolic processes. The complete list of location-specific crypt- and villi-genes is deposited in the GEO database. In summary, we confirmed differential expression of several genes that are known to be involved in location-specific function of the small intestine, such as genes coding for the proteins ferroportin (FPN) (*Slc40a1*) in duodenum, lactase (*Lct*) in jejunum, GATA4 (*Gata4*) in duodenum-jejunum, and ASBT (*Slc10a2*) in ileum (Figure 1). These data show that crypt-derived genes were highly maintained in organoid cultures, indicating that mouse organoids are mainly crypt-based structures. However, organoids do contain differentiated cells that express villus-derived genes, albeit in low levels. As the organoids were cultured in the same conditions, that is, in Matrigel and in presence of EGF, noggin, and R-spondin-1, these data indicate that epithelial stem cells maintain their identity, without location-specific external signals from mesenchyme or luminal content.

To validate the mRNA sequencing data, we determined expression of several location-specific genes by quantitative reverse transcription PCR (qRT-PCR). We used small pieces (~2cm) of each compartment of the small intestine for direct *ex vivo* RNA isolation or generation of organoid cultures that were maintained short term (3 weeks) or long-term (10-12 weeks). The transcription factor GATA4 has been shown to be a key regulator of location-specific gene expression in the mouse small intestine by repressing ileum-specific genes [12, 23]. In

**Figure 1.** RNA sequencing profiles in *ex vivo* crypts, villi, and in cultured organoids derived from mouse small intestine. Intestines were divided in three equal parts, A (duodenum), B (jejunum), and C (ileum). Crypts (n = 2) and villi (n = 1) were harvested for mRNA sequencing. Part of the crypts were used for generation of long-term (12 weeks) organoid cultures (pool of n = 2). Since the absolute expression values can differ between crypts, villi, and organoids, mRNA RPKM values were normalized separately for (panel A) crypts and organoids and (panel B) villi and organoids with black as maximal expression and white as zero expression. In each compartment, genes are sorted by chromosomal location. Percentages of genes expressed in crypts (panel A) or villi (panel B) that were maintained in location-specific organoids and examples of genes are indicated per location. All mRNA-seq datasets are deposited in the GEO database.

Table 1. Number of location-specific crypt (upper panel) and villus (lower panel) genes whose expression is maintained in organoids of the *ex vivo* counterpart duodenum, jejunum, or ileum.

Ex vivo location	Total number of crypt genes	Organoid duodenum	Organoid jejunum	Organoid ileum
duodenum	40	31 (78%)	5 (13%)	3 (8%)
duodenum-jejunum	75	23 (31%)	42 (56%)	9 (12%)
jejunum	46	6 (13%)	32 (70%)	7 (15%)
jejunum-ileum	81	17 (21%)	24 (30%)	38 (47%)
ileum	121	23 (19%)	19 (65%)	79 (65%)

Ex vivo location	Total number of villus genes	Organoid duodenum	Organoid jejunum	Organoid ileum
duodenum	512	219 (43%)	146 (29%)	131 (26%)
duodenum-jejunum	462	174 (38%)	190 (41%)	83 (18%)
jejunum	51	10 (20%)	33 (65%)	8 (16%)
jejunum-ileum	554	153 (28%)	215 (39%)	172 (31%)
ileum	437	114 (26%)	102 (23%)	202 (46%)

Gene expression was determined by mRNA sequencing as described in Figure 1.

concordance, mRNA sequencing as well as qRT-PCR analysis confirmed that *Gata4* expression is high in duodenum and jejunum but almost absent in ileum. We found that this expression pattern was maintained in organoids that were cultured for 3 and 10-12 weeks (Figure 1 and 2A).

### Duodenum-specific gene expression

The uptake of nutritional iron involves the reduction of Fe<sup>3+</sup> into Fe<sup>2+</sup> by ferric reductases such as CYBRD1 (encoded by *Cybrd1*) in the intestinal brush border and the subsequent transport of Fe<sup>2+</sup> across the apical membrane of enterocytes by the divalent metal transporter 1 [9]. Iron is eventually exported across the basolateral membrane into the bloodstream via the solute carrier and Fe<sup>2+</sup> transporter ferroportin (FPN, encoded by *Slc40a1*) [24]. Transcripts of these genes were only found in our villus-based mRNA sequencing data (Figure 1B) because they are expressed at the tips of the villi *in vivo* [9].

We determined mRNA expression levels of *Cybrd1* and *Slc40a1* by qRT-PCR and found that their expression *ex vivo* is indeed restricted to the duodenum and this cephalocaudal expression pattern remained stable in cultured organoids (Figure 2B).

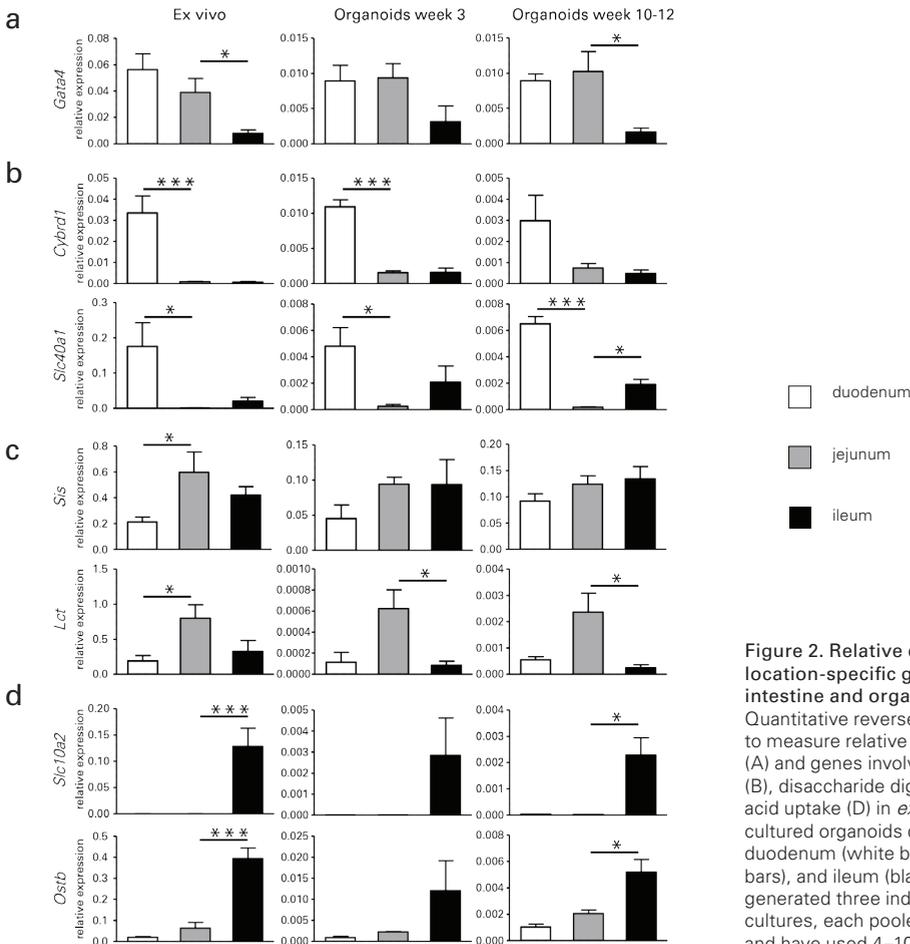

### Jejunum-specific gene expression

It has been shown that disaccharidases, like

lactase (encoded by *Lct*) and sucrase-isomaltase (encoded by *Sis*), show the highest expression and activity in the jejunum [25]. We confirmed these expression patterns in *ex vivo* tissue and for *Lct* we also found highest expression in jejunum-derived organoid cultures, whereas the specific expression pattern of *Sis* was less obvious (Figure 2C).

### Ileum-specific gene expression

The bile acid transporter ASBT (encoded by *Slc10a2*) is expressed apically on enterocytes in the ileum and can take up bile from the intestinal lumen, while organic solute transporter (OST) $\alpha/\beta$  form a pore at the basolateral side of the cell to export bile acids from the enterocytes to the blood [26]. We found by mRNA sequencing and qRT-PCR that the expression of both *Slc10a2* and *Ostb* were highly specific for the ileum, and that expression was maintained throughout organoid culture (Figure 1 and 2D). We observed low *Ostb* expression in *ex vivo* jejunum, which was also reflected in the cultures. Collectively, these data show that the functional fate of mature intestinal epithelial cells is intrinsically programmed within the stem cell niches of each location and that these signatures are maintained even after long-term organoid culture where stem cells are not exposed to exogenous signals from mesenchyme or luminal content.

**Figure 2. Relative expression of location-specific genes in murine intestine and organoid cultures.** Quantitative reverse transcription PCR to measure relative expression of *Gata4* (A) and genes involved in iron uptake (B), disaccharide digestion (C), and bile acid uptake (D) in *ex vivo* tissue and in cultured organoids derived from murine duodenum (white bars), jejunum (gray bars), and ileum (black bars). We have generated three independent organoid cultures, each pooled from two mice and have used 4–10 mice for *ex vivo* RNA isolation. Data were normalized to *Gapdh* housekeeping mRNA levels and are represented as means  $\pm$  SEM; \*,  $p < .01$ ; and \*\*\*,  $p < .005$ .

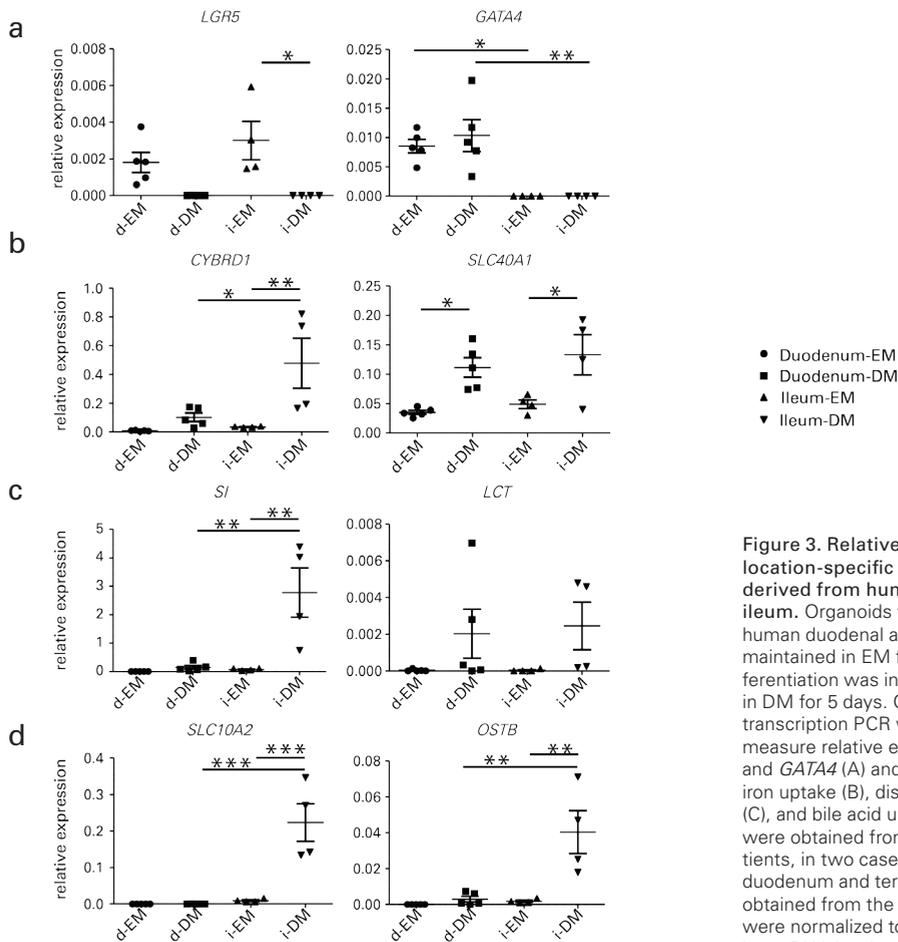

## Mouse organoids do not require exogenous WNT for long-term maintenance

We have shown that mouse stem cells maintain their location-specific origin during organoid culture by analyzing expression patterns of genes that are involved in location-specific functions along the cephalocaudal axis of the small intestine.

However, mouse organoids consist mainly of crypt compartments and contain only limited amounts of fully differentiated enterocytes that fulfill the location-specific function [19]. As such, the percentages of location-specific

genes that were maintained in organoids were higher for crypt-derived genes compared to villus-derived genes (Figure 1 and Table 1). Furthermore, it has been shown that mouse small intestinal organoids have an intrinsic WNT gradient, which allows proliferation but limits differentiation [19], resulting in low levels of gene transcripts for the genes of interest.

By adding WNT3A-conditioned media to the location-specific mouse cultures, we show that WNT inhibits the expression of differentiation markers, such as *Sis* and *Slc10a2*, whereas the expression of *Gata4* remains unchanged

**Figure 3. Relative expression of location-specific genes in organoids derived from human duodenum and ileum.** Organoids were generated from human duodenal and ileal biopsies and maintained in EM for 7 weeks. Differentiation was induced by incubation in DM for 5 days. Quantitative reverse transcription PCR was performed to measure relative expression of *LGR5* and *GATA4* (A) and genes involved in iron uptake (B), disaccharide digestion (C), and bile acid uptake (D). Biopsies were obtained from four to five patients, in two cases biopsies from both duodenum and terminal ileum were obtained from the same patient. Data were normalized to *ACTIN* housekeeping mRNA levels and are represented as means  $\pm$  SEM; \*,  $p < .05$ ; \*\*,  $p < .01$ ; and \*\*\*,  $p < .005$ . Abbreviations: DM, differentiation medium; EM, expansion medium.

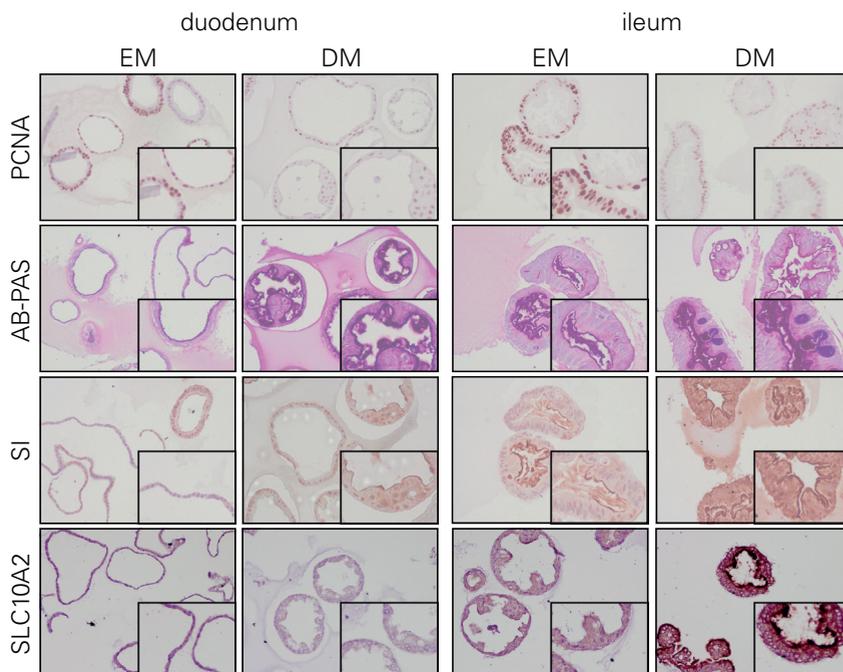

(Suppl. Figure 1A). Morphologically, the addition of WNT results in more spherical organoids compared to the standard culture condition (Suppl. Figure 1B), an indication for induced proliferation.

### Location-specific genes are induced upon differentiation of human organoid cultures

In contrast to mouse small intestinal organoids, human small intestinal organoid cultures produce little endogenous WNT. Therefore, their proliferation is dependent on exogenous WNT and differentiation is only initiated upon withdrawal of WNT [20]. Here, we use the

human organoid system to delineate the effects of WNT on human location-specific small intestinal organoid cultures and show the full differentiation capacity of location-specific stem cells.

Human organoid cultures were established from crypts that were isolated from duodenal and ileal small intestinal biopsies. The organoids were maintained in so-called EM, containing WNT3A conditioned medium, which induces expansion of stem cells and repression of differentiation. We cultured the organoids for 3 (data not shown) or 7 weeks in

**Figure 4. Immunohistochemical characterization of human organoids.** Organoids were generated from human duodenal and ileal biopsies and maintained in EM for 7 weeks. Differentiation was induced by incubation in DM for 5 days. Organoids were embedded in paraffin, sectioned, and stained for PCNA, AB-PAS, SI, and SLC10A2 (ASBT). Original magnification  $\times 20$ , insets  $\times 50$ . Abbreviations: AB-PAS, Alcian Blue periodic acid Schiff; DM, differentiation medium; EM, expansion medium; PCNA, proliferating cell nuclear antigen; SI, sucrase-isomaltase.

EM, after which the medium was replaced by so-called DM for 5 days. DM lacks WNT3A, Nicotinamide and SB202190 in order to inhibit expansion and induce differentiation, demonstrated by the loss of *LGR5* mRNA (Figure 3A left), more dense morphology (Suppl. Figure 2) and loss of PCNA staining on immunohistochemistry (Figure 4). Incubation in DM also induced the differentiation of Goblet cells and production of glycoproteins as shown by AB-PAS staining of both duodenal and ileal organoids (Figure 4).

We confirmed *GATA4* as a specific marker for duodenum and found that the expression levels did not change in the absence of WNT3A

(Figure 3A right). This was in concordance with the previously reported finding that *GATA4* protein in proximal small intestine is expressed in all cells from crypt to tips of the villi [27]. We found that induction of *CYBRD1* and *SLC40A1* was equal or even higher in ileal organoids compared to duodenal organoids (Figure 3B) and that *SI* (coding for SI) expression was only induced in organoids derived from human ileum and not in duodenal organoids (Figure 3C and 4). In contrast, *LCT* was induced in both duodenum and ileum, but expression was rather low. The ileal markers *SLC10A2* and *OSTB* were highly restricted to differentiated organoids derived from ileum (Figure 3D and 4). Notably, not all of the

location-specific gene expression profiles in human intestinal organoids corresponded with the profiles in mice.

Collectively, these data show that WNT signaling inhibits expression of genes involved in the function of differentiated cells (*LCT*, *SLC10A2*) but not those that are involved in spatial patterning (*GATA4*). Furthermore, by using the organoid technique we show that location-specific stem cell fate is programmed within the stem cell niche, as the removal of WNT only induces expression of those genes that are not repressed by *GATA4*.

## DISCUSSION

It has been shown that WNT is expressed by Paneth cells in the crypt compartments of the small intestine to enable proliferation (and inhibit differentiation) in the crypt [28, 29]. WNT signalling activity tapers off toward the crypt-villus junction, thereby reducing proliferation and inducing the differentiation into enterocytes, goblet, tuft, or enteroendocrine cells. Conversely, spatial compartmentalisation of the small intestine along the cephalocaudal axis is regulated by expression gradients of transcription factors, such as *GATA4* and *CDX2* [12, 13]. These transcription factors are expressed in epithelial cells and have been shown to regulate expression of genes that are involved in functional properties of differentiated enterocytes.

As such, WNT expression is regulating differentiation along the crypt–villus axis, whereas *GATA4* is regulating regional specification and the linked differentiation along the cephalocaudal axis. To date, it was not known whether the expression of location-specific genes is programmed in a hard-wired fashion within the stem cells or if continuous signalling from mesenchymal cells is necessary to maintain the location-specific identity.

Using the organoid culturing technique, we now show that pure epithelial cell cultures that originated from location-specific stem cells are intrinsically programmed to differentiate into

enterocytes with defined regional gene expression profiles. The organoid culture technique is based on the fact that *Lgr5*+ murine stem cells can be grown in laminin-rich Matrigel in the presence of the WNT-agonist and *Lgr5*-ligand R-spondin-1, the BMP-antagonist noggin, and EGF [2, 19]. In the presence of these extracellular signals, which are *in vivo* derived from Paneth cells and underlying mesenchyme, isolated crypts from the intestine can generate crypt-villus structures, which can be maintained in long-term culture [19]. Others have shown that mesenchymal cells are required for long-term culture of intestinal stem cells using myofibroblasts as well as stem cell niche signalling molecules to establish long-term cultures of intestine and colon [30].

Recently, it has been shown that *in vivo*, murine mesenchymal cells produce various WNT proteins [28], whereas Paneth cells produce EGF and WNT3A [31]. However, Paneth cells within organoids only produce WNT3A [28]. Endogenous Paneth cell-derived WNT3A is sufficient to maintain mouse small intestinal organoids in the presence of EGF, noggin and R-spondin-1 and allow generation of all differentiated epithelial cell types concomitant with stem cell self-renewal [28]. The addition of WNT3A to these mouse organoid cultures interferes with intestinal differentiation and yields organoids that largely consist of undifferentiated progenitors ([19] and Suppl. Figure 1).

Previously, it has been shown that intestine-specific deletion of *Gata4* results in expression of *Slc10a2* in the proximal intestine. As such, *GATA4* is normally restricting the expression of *Slc10a2* to the distal small intestine by repressing its expression in the proximal part [12].

Furthermore, reduction of *GATA4* activity in the small intestine results in an induction of bile acid absorption in the proximal small intestine that is sufficient to correct bile acid malabsorption associated with ileocecal resected mice [32]. In contrast, *CDX2* has been shown to be a master regulator in the posterior endoderm by

repressing the foregut differentiation program in the posterior gut [13, 33].

In the human organoid system, we demonstrate that GATA4 is expressed both under expansion and differentiation conditions, while the expression of differentiation genes, such as SLC10A2, is only induced in DM. We can explain this by the fact that EM contains WNT3-conditioned medium, which is inhibiting differentiation.

Recently, these data were supported by the finding that genetic regulatory networks and compartment-specific stem cell differences direct regional diversity in the *Drosophila* midgut [34, 35]. Furthermore, the GATAe transcription factor, a master regulator of midgut development, was shown to control compartment-specific gene expression along the length of the adult intestine, whereas gradients of WNT activity were shown to refine the location of boundaries [34].

As our key observation, we found differences in location-specific gene expression patterns, even though all cells were exposed to the same extracellular factors. This suggests that the cephalocaudal programming in the small intestine is not dependent on mesenchymal or niche factors, but rather on the location-specific expression of patterning genes such as *Gata4*.

## CONCLUSION

Here, we show that adult stem cells of the small intestine are regionally specified in a cell-autonomous fashion and retain their location-specific gene expression profiles even after long-term culture. Furthermore, our data are also of importance with respect to the differentiation of intestinal tissue from induced pluripotent stem cells [36, 37]. To date, there is a generally accepted tendency to define small intestinal tissue as CDX2+, but we here show that especially the expression of GATA4 will determine the functional fate of the established cultures. Moreover, in light of the potential future clinical application of organoids, either derived from iPS cells or intestinal

adult stem cells [38, 39], our data imply that it is important to generate GATA4-positive and GATA4-negative cultures to regenerate all essential functions of the small intestine.

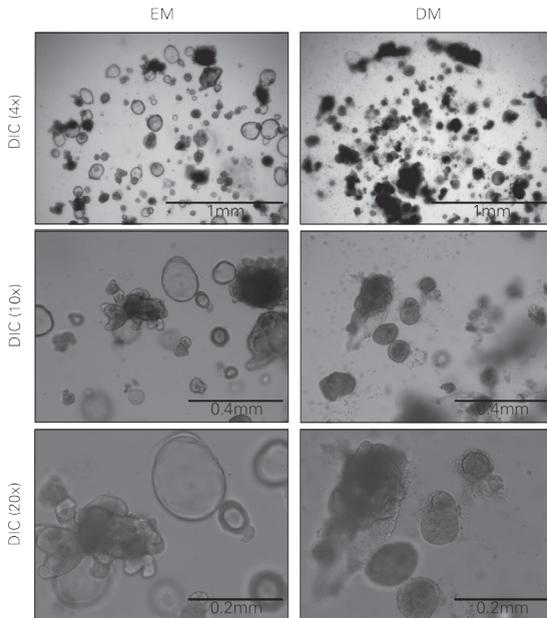

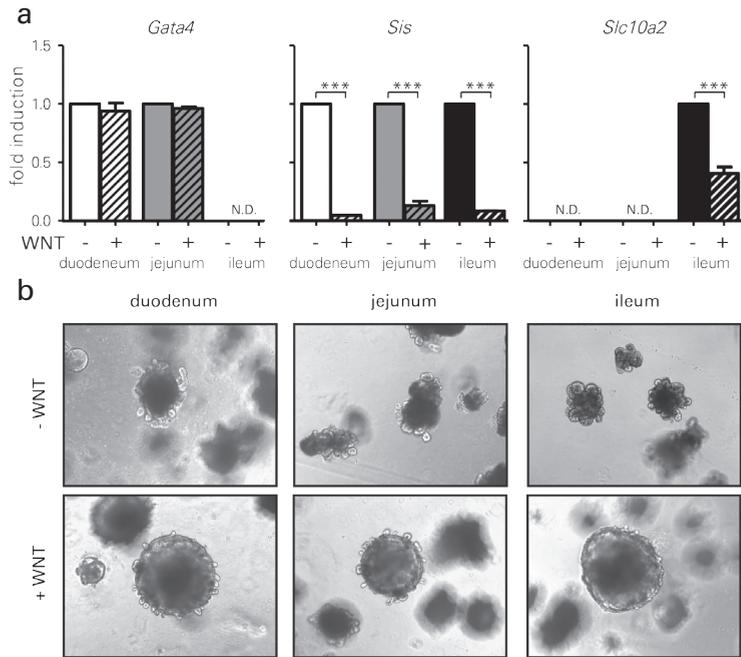

## ACKNOWLEDGMENTS

We thank Stieneke van den Brink, Hans Teunissen and Joyce Blokker for practical guidance and providing noggin- and WNT3A-conditioned media; Akifumi Ootani for providing the R-spondin-1-producing cell line; the gastroenterologists of the Wilhelmina Children's Hospital and the department of gastroenterology of the University Medical Center Utrecht for obtaining biopsies; Sylvia Brugman and Sabrina Roth for critically reading the manuscript.

**Supplementary Figure 1.**  
**Addition of WNT3A to murine organoid cultures induces proliferation and inhibits differentiation.** Murine organoids derived from duodenum, jejunum and ileum were grown for 2 weeks and then incubated with or without WNT3A for 7 days. (A) qRT-PCR for *Gata4*, *Sis* (sucrase isomaltase) and *Slc10a2* (ASBT). Data from two independent experiments were normalized to *Gapdh* house-keeping mRNA levels and are represented as fold induction relative to cultures without WNT  $\pm$  SEM; \*\*\* $p < 0.005$ . (B) Differential interference contrast (DIC) pictures of the organoid cultures in presence or absence of WNT for 7 days after splitting. Original magnification 10x.

**Supplementary Figure 2.** Differential interference contrast (DIC) pictures from human duodenal organoid cultures. Organoids were generated from human duodenal biopsies and maintained in expansion medium (EM) for 7 weeks. Differentiation was induced by incubation in differentiation medium (DM) for 5 days.

## ABSTRACT

Microvillus inclusion disease (MVID) is a disorder of intestinal epithelial differentiation characterized by life-threatening intractable diarrhea. MVID can be diagnosed based on loss of microvilli, microvillus inclusions, and accumulation of subapical vesicles. Most patients with MVID have mutations in myosin Vb that cause defects in recycling of apical vesicles. Whole-exome sequencing of DNA from patients with variant MVID showed homozygous truncating mutations in syntaxin 3 (*STX3*). *STX3* is an apical receptor involved in membrane fusion of apical vesicles in enterocytes. Patient-derived organoid cultures and overexpression of truncated *STX3* in Caco-2 cells recapitulated most characteristics of variant MVID. We conclude that loss of *STX3* function causes variant MVID.

## BRIEF REPORT

Microvillus inclusion disease (MVID) represents a form of congenital diarrhea. Patients typically present with persistent diarrhea within a few days, weeks, or months after birth, resulting in severe dehydration and metabolic acidosis. Current treatment comprises life-long total parenteral nutrition (TPN) and eventual small-bowel and/or liver transplantation [1]. The pathologic hallmarks of MVID are variable loss of brush-border microvilli, microvillus inclusions, and numerous subapical vesicles (secretory granules) in villus enterocytes [2]. In parallel, variant cases of MVID are described with milder clinical phenotypes permitting partial or complete weaning from TPN [3, 4].

Mutations in myosin Vb (*MYO5B*) have been found to cause classic MVID and our mutation detection rate exceeded 90% in more than 60 MVID patients [5, 6] (and unpublished data). *MYO5B* is a motor protein that facilitates protein trafficking and recycling in polarized cells by Rab11-dependent mechanisms. *MYO5B* mutations result in mislocalization of apical proteins and disrupted enterocyte polarization, leading to MVID [5, 7]. Interestingly, *MYO5B* mutations were absent in 2 referrals classified as variant MVID on the basis of clinical presentation.

Patient 1 was a 1-year-old Dutch girl born as the third child of a niece–uncle marriage, who developed watery diarrhea and severe metabolic acidosis from the second day of life. Currently, she receives daily intravenous sodium bicarbonate supplementation and is TPN-dependent but tolerates minimal enteral feeding for varying periods.

Patient 2 was an 18-month-old boy from Pakistan, the first child of a first-cousin marriage, who presented with frequent watery stools in the second week of life and several episodes of severe acidosis. The frequency of loose stools decreased after the early introduction of hydrolysate formula. Pulmonary infections occur frequently and he persistently suffers from mild acidosis, renal tubulopathy, and episodic vomiting. Despite increasing

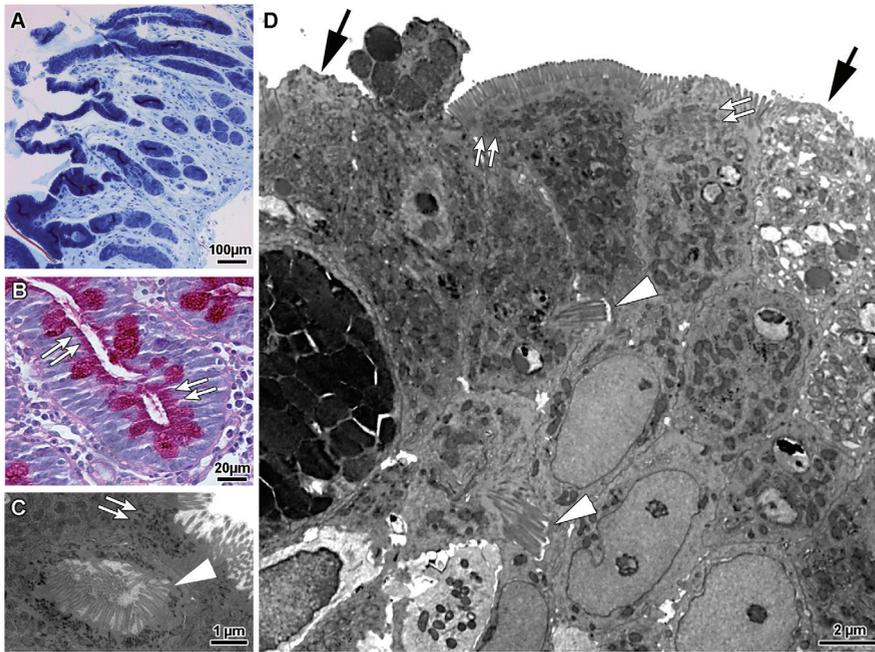

tolerance of enteral nutrition, he still requires partial parenteral nutrition and daily sodium bicarbonate supplementation for adequate growth.

Light and electron microscopy on duodenal and rectal biopsy specimens from both patients showed the histologic characteristics of MVID (Figure 1A–D and Supplementary Figure 1): accumulation of periodic acid–Schiff–positive subapical vesicles, intracellular microvillus inclusions, and variable loss of brush border. In contrast to classic MVID, we observed multiple microvilli at the basolateral membranes.

After the exclusion of *MYO5B* mutations by Sanger sequencing, we performed whole-exome sequencing—independently for patients 1 and 2—for identifying the causal gene. One single gene, *syntaxin 3* (*STX3*), harbored supposedly disease-causing mutations in both patients. We identified a homozygous nonsense mutation (c.739C>T, p.Arg247\*, Ensembl COSM193004) in exon 9 and a homozygous frame-shifting 2-bp insertion (c.372\_373dup, p.Arg125Leufs\*7) in exon 6 of *STX3* in patients 1 and 2, respectively (Supplementary Figure 2A and B). Both mutations were confirmed by Sanger sequencing, co-segregated with the disease in the families, and were predicted to cause cellular *STX3* protein depletion and truncation (Figure 1E), which was supported by Western blotting (Supplementary Figure 2C). Sanger sequencing of 5 additional *MYO5B*-negative MVID samples did not show *STX3* mutations.

Stable expression of truncated versions of *STX3*, corresponding to the patients' mutations, recapitulated all histologic hallmarks of MVID in Caco-2 cell cultures (Figure 2 and Supplementary Figure 3A–E), including a statistically significant increase of both microvillus inclusions and basolateral microvilli (Supplementary Table 1).

Disruption of cell polarity was reflected further by the formation of intercellular lumina within the cell multilayer (Figure 2 and Supplementary Figure 3C and D). Confocal laser-scanning microscopy showed mislocalization of *STX3* (Supplementary Figure 3F), and Western

STX3

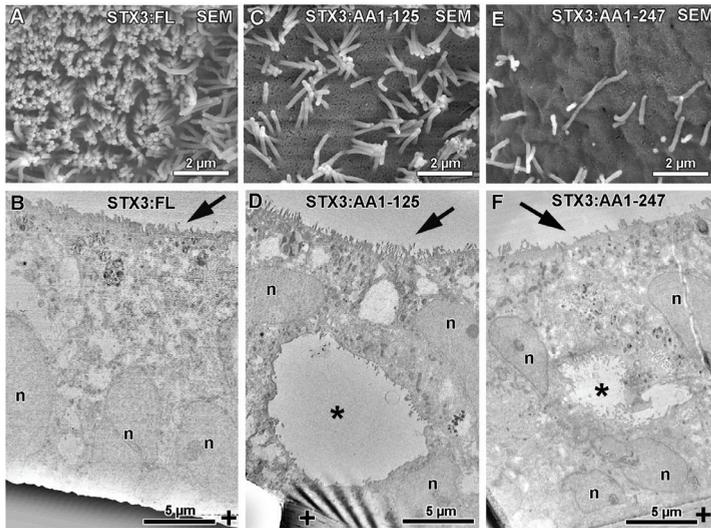

Patient 1

Patient 2

Figure 1. Histology of duodenal biopsy specimens from patients with variant MVID. (A) Toluidine blue staining shows mild focal villus atrophy. (B) Subapical accumulation of periodic acid-Schiff-positive vesicles in crypt epithelium (double arrows). (C) Secretory granules (double arrows) and microvilli inclusions (arrowhead). (D) Transmission electron microscopy shows basolateral microvilli (arrowheads), subapical vesicles (double arrows), atrophic brush border (arrows), and local cell shedding. (E) STX3 protein is predicted to be truncated in patient 1 (premature stop at Arg247) and patient 2 (2-bp insertion at Arg125 and premature stop after Arg130). TMD, transmembrane domain.

**Figure 2.** Scanning electron microscopy (SEM) and transmission electron microscopy of Caco-2 cells overexpressing full-length or truncated STX3 (STX3:FL, and STX3:AA1-125 or STX3:AA1-247). (A and B) Polarized monolayer with intact brush border (arrow). (C and D) Impaired brush border. Note wide intercellular lumen (asterisk) with scarce microvilli within the cell multilayer. (E and F) Cell multilayer with highly eroded brush border and intercellular lumen. n, nuclei; +, cell culture filter membrane.

blotting confirmed a reduction of endogenous STX3 levels by overexpression of truncated—but not full-length—STX3 protein (Supplementary Figure 4). Together, these data suggest a dominant-negative effect of truncated STX3, disturbing epithelial polarity.

In addition, we used a recently established 3-dimensional culture of intestinal stem cells (organoids) [8]. Differentiated organoids from duodenal biopsy specimens of MVID patient 1 were devoid of syntaxin 3 staining and recapitulated most morphologic characteristics of the disease (Supplementary Figure 5).

The maintenance of epithelial cell function requires the establishment and continuous renewal of differentiated apical and basolateral plasma membrane domains with distinct lipid and protein compositions. STX3, an apically targeted N-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) establishes and maintains polarity, which is

necessary for protein trafficking, vesicle fusion, and exocytosis in intestinal, liver, kidney, and gastric parietal cells [9-11]. Target-SNAREs assemble into complexes with vesicle SNAREs, attached to recycling or biosynthetic vesicles [12]. In enterocytes, the apical SNARE complex including STX3 facilitates fusion of the target membrane and vesicles that have been trafficked into close apposition by the Rab11-regulated effector protein MYO5B [11].

Here, we have identified *STX3* mutations in 2 patients with variant MVID, in whom *MYO5B* mutations had been excluded. We were able to mimic the human MVID phenotype by overexpression of truncated STX3 *in vitro*, indicating loss of STX3 causes variant MVID. Consistent with our findings, it was reported that disruption of STX3 function or ablation of its apical targeting signal impairs delivery of apical markers *in vitro*, emphasizing syntaxin 3 is likely to act as a key regulatory SNARE in intestinal epithelium [10, 13].

Disturbed delivery of apical constituents is a common defect in both classic and variant MVID. In classic MVID, MYO5B deficiency disrupts trafficking between apical recycling endosomes and the apical membrane [14]. In variant MVID, a traffic arrest of apically destined vesicles results from STX3 loss-of-function owing to defective apical docking and exocytosis. Both classic and variant MVID enterocytes display characteristic microvillus inclusions, which might arise from the fusion of apical transport or recycling vesicles under conditions of reduced delivery to the apical plasma membrane. The appearance of microvilli at the basolateral membrane in variant MVID might result from the binding of vesicles to the basolateral syntaxin 4 protein, which is highly homologous to STX3 [13].

Interestingly, patients with mutations in the STX3 binding protein *STXBP2/Munc18-2*, causing familial hemophagocytic lymphohistiocytosis type 5, who have persistent chronic diarrhea after hematopoietic stem cell transplantation, also showed microvillus atrophy and histologic findings reminiscent of MVID [15].

In conclusion, these data provide a conceptual advance in MVID research because the newly identified causal gene *STX3* will improve the diagnosis, prognosis, genetic counseling, and prenatal screening for MVID.

## ACKNOWLEDGMENTS

The authors thank members of the Clevers lab (Hubrecht Institute); The Cell Microscopy Center (University Medical Center Utrecht); B. Witting, K. Gutleben, C. Herrmann (Innsbruck), and Y. Meng Heng (Toronto) for technical assistance; and K. Biermann (Pathology, Erasmus MC) for biopsy specimens of patient 1.

## SUPPLEMENTARY MATERIALS AND METHODS

### Human Material

All participants provided written informed consent to participate in this study according to a protocol reviewed and approved by our institutional review boards. Duodenal organoids from 3 healthy controls and patient 1 were generated from duodenal biopsy specimens obtained during duodenoscopy for diagnostic purposes. Whole blood was collected for genetic analysis. The healthy control group included patients susceptible for celiac disease or inflammatory bowel disease with normal pathology.

### Whole-Exome Sequencing

Genomic DNA was isolated from whole-blood samples using standard manual or robotic procedures. Exome sequencing on patient 1 and her parents was performed as reported previously,<sup>1</sup> with the exception that the Agilent (Santa Clara, CA) SureSelect Human All Exon 50Mb Kit V4 was used for enrichment, and sequencing was performed according to the manufacturer's protocol on the Solid5500 (Life technologies, Carlsbad, CA) sequencing platform. We obtained an average coverage of 59-, 63-, and 59-fold for the mother, father, and patient, respectively. Alignment and variant annotation was performed as reported previously.<sup>1</sup> Filtering of rare variants (allele frequency, <0.1; seen <10 times in our in-house database consisting of exome data from 150 individuals and never seen in the homozygous state in our in-house database) with a predicted effect at the protein level for a recessive inheritance model left us with 2 variants, of which the nonsense variant in STX3 was the strongest candidate based on the literature.

The exome of patient 2 was enriched from genomic DNA using Roche-Nimblegen's SeqCap EZ Exome v2 (35-Mb capture region) Exome Enrichment Kit and sequenced using the Illumina HiSeq2000 to a median coverage of 74× according to the manufacturer's protocol, producing approximately 10 gigabases of paired-end 101-bp sequence reads by

analysis with CASAVA v1.8 (Illumina, Inc). Sequencing reads were aligned to the human genome (hg19) with Burrows–Wheeler transformation. Polymerase chain reaction duplicates were removed with PICARD (available: <http://picard.sourceforge.net>) and single-nucleotide substitutions (SNPs), and small indels were identified with the samtools mpileup software and quality-filtered with the Genome Analysis Toolkit (Dice Holdings, New York, NY). All variants were submitted to SeattleSeq (available: <http://snp.gs.washington.edu/SeattleSeqAnnotation/>) for annotation, categorization into synonymous and nonsynonymous SNPs or indels, and for filtering using the data from the Single Nucleotide Polymorphism database (dbSNP137), the 1000 Genomes Project, the National Heart, Lung, and Blood Institute Exome Sequencing Project Exome Variant Server. The identified mutation was absent from an in-house database of 70 sequenced individuals. Where applicable, variants were classified by predicted protein effects with Polymorphism Phenotyping v2 (PolyPhen 2) and Scale-invariant feature transform (SIFT).

A spreadsheet-based comparison of all nonconservative and rare homozygous exomic variants of patients 1 and 2 showed a single gene, STX3, which harbored supposedly deleterious mutations in both patients.

### Sanger Sequencing

The STX3 mutations from patients 1 and 2 and their parents were verified using Sanger sequencing. Exons 9 and 6 of STX3 were polymerase chain reaction–amplified in total genomic DNA isolated from peripheral blood lymphocytes of patients 1 and 2 and their parents, respectively, using intronic primers (all sequences available on request). Purified with the Exonuclease I–shrimp alkaline phosphatase enzymes (USB, Cleveland, OH), polymerase chain reaction products were sequenced bidirectionally using the BigDye Terminator v3.1 Cycle Sequencing Kit (Applied Biosystems, Foster City, CA). Fragments were separated electrophoretically on an ABI3730xl DNA Analyzer (Applied Biosystems) and analyzed with JSI SeqPilot software

(Kippenheim, Germany). Codon numbering was based on the published online amino acid and messenger RNA sequences of STX3 (available: <http://www.ncbi.nlm.nih.gov.proxy.library.uu.nl/>) using the first methionine as an initiation codon.

### **Organoid Culture**

Crypts were isolated from duodenal biopsy specimens of patient 1 and 3 healthy controls and cultured as described previously.<sup>2</sup> The organoids were maintained in expansion medium (containing epidermal growth factor, noggin, R-spondin1, WNT3A, nicotinamide, SB202190, and A83-01) and passaged weekly for 5–10 weeks. To induce differentiation, organoids were cultured in differentiation medium (which is expansion medium without SB202190, nicotinamide, and WNT3A) for 5 days.

### **Plasmids**

Human full-length and truncated STX3 complementary DNA was polymerase chain reaction–amplified from Caco-2 complementary DNA and ligated into a pENTR4-mCitrine vector using EcoRI and XbaI restriction sites, c-terminally, and in frame with the mCitrine fluorescent protein. The fusion constructs were cloned into the lentiviral expression vector pCCL-EF1a-BlastiR-DEST using the Gateway multicloning technology (Life technologies).

### **Cell Culture**

Caco-2 cells (American Type Culture Collection, Manassas, VA) were grown under standard conditions in Dulbecco's modified Eagle medium containing high glucose, 10% heat-inactivated fetal bovine serum, 100 U/mL penicillin, 100 µg/mL streptomycin, and 1mM sodium pyruvate. For lentiviral transduction of Caco-2 cells, Hek293LTV cells were transfected using Lipofectamine LTX (Invitrogen) with the lentiviral expression plasmids together with the vesicular stomatitis virus–G plasmid and the lentiviral gag-pol packaging vector PAX2. Forty-eight and 72 hours after transfection, the viral particle containing supernatant was harvested and directly used for Caco-2 cell infection. Six days after infection, Caco-2 cells were selected with 10 µg/mL BlastidinS (Invitrogen). For biochemical and microscopical

analyses, untreated and genetically modified Caco-2 cells were grown for 14 days on 24-mm Costar Transwell polycarbonate filters (Corning, NY). Three biological replicates from 2 independent experiments were analyzed.

### **Western Blotting**

Western blotting after 10% sodium dodecyl sulfate–polyacrylamide gel electrophoresis and transfer onto polyvinylidene difluoride membranes (GE Healthcare, Little Chalfont, United Kingdom) of Caco-2 lysates was performed as previously described.<sup>3</sup> Incubation with primary antibodies was performed overnight at 4°C. Blots were developed using a chemiluminescence detection system (Santa Cruz). Mouse monoclonal antitubulin (1:5000; Sigma Aldrich, Cambridge, United Kingdom), mouse monoclonal anti-enhanced green fluorescent protein (1:1000; Roche, Penzberg, Germany), and rabbit monoclonal anti–syntaxin 3 (1:1000; Abcam ab133750) were used. Secondary horseradish-peroxidase–conjugated anti-rabbit and anti-mouse antibodies (Sigma Aldrich) were used at a dilution of 1:5000.

Organoids were lysed in Laemmli buffer (0.12 mol/L Tris-HCl, pH 6.8, 4% sodium dodecyl sulfate, 20% glycerol, 0.05 µg/µL bromophenol blue, and 35 mmol/L β-mercaptoethanol) and incubated at 100°C for 5 minutes. Detection of syntaxin 3 and tubulin was performed using the Odyssey system (LI-COR, Lincoln, NE) by incubating the blots with donkey anti-rabbit IgG IRDye 680RD (926-68073; LI-COR) and donkey anti-mouse IgG IRDye 680 (926-32222; LI-COR).

### **Histology**

Paraffin slides were generated from biopsy material and organoids. Tissues were fixed in 4% formalin overnight and 4% neutral buffered formalin for 45 minutes at room temperature, respectively. Sections (3-µm thick) were subjected to periodic acid–Schiff staining according to standard techniques. Semithin resin sections (see later) were stained with 1% toluidine blue to illustrate gross morphology of the intestinal mucosa.

## Immunofluorescence and Immunohistochemistry

Duodenal biopsy specimens were embedded in Tissue-Tek optimum cutting temperature Compound and frozen at  $-80^{\circ}\text{C}$ . Sections were fixed for 20 minutes in 4% PFA in phosphate-buffered saline without calcium and magnesium, and permeabilized for 5 minutes with 0.3% Triton X-100 (Sigma Aldrich). After washing with phosphate-buffered saline, slides were blocked for 1 hour at room temperature with 5% bovine serum albumin and 15% goat serum in phosphate-buffered saline. Incubation with primary antibodies was performed overnight at  $4^{\circ}\text{C}$  with rabbit monoclonal anti-syntaxin 3 (Abcam) or mouse monoclonal anti-CD10 (ImmunoTools, Germany). Alexa568 goat anti-rabbit, Alexa568 goat anti-mouse and Alexa488 phalloidin (Life technologies) were used for fluorescence and actin cytoskeleton labeling, respectively.

Caco-2 cells grown for 14 days on filters were fixed with 4% buffered paraformaldehyde solution and processed essentially as previously described.<sup>4</sup> Briefly, fixed Caco-2 cells were permeabilized with 0.3% Triton X-100 (Sigma-Aldrich) for 30 minutes and subsequently blocked with phosphate-buffered saline containing 15% goat serum for 1 hour at room temperature. Mouse monoclonal anti-CD26/dipeptidylpeptidase IV (HBB3/775/42, obtained from the Developmental Studies Hybridoma Bank, created by the National Institute of Child Health and Human Development of the National Institutes of Health, and maintained at the Department of Biology, University of Iowa, Iowa City, IA) and rabbit monoclonal anti-syntaxin 3 (Abcam) primary antibody was incubated overnight at  $4^{\circ}\text{C}$  and labeled with secondary antibody Alexa568 goat anti-mouse and anti-rabbit (Invitrogen), respectively. Actin filaments were stained with phalloidin-Alexa568 (1:500; Invitrogen) in blocking solution for 1 hour at room temperature. Both biopsy material and Caco-2 cells were incubated with Hoechst 33342 (1:10,000; Thermo Scientific, Waltham, MA) to stain nuclei and mounted in Mowiol (Sigma-Aldrich). Epifluorescence images were recorded with an

Axio Imager M1 (Carl Zeiss; Oberkochen, Germany) fluorescent microscope equipped with a charge-coupled device camera (SPOT Xplorer; Visitron Systems, Puchheim, Germany) and analyzed with ImageJ, version 1.49a software (National Institutes of Health, Bethesda, MD). Confocal image stacks were recorded with a Leica SP5 confocal fluorescence microscope (Leica Microsystems), deconvolved using Huygens Professional Deconvolution and Analysis Software (Scientific Volume Imaging, Hilversum, The Netherlands), exported using Imaris 3D rendering (Bitplane AG, Zürich, Switzerland), and afterward adjusted for brightness, contrast, and pixel size in GNU Image Manipulation Program version 2.8.10 (GIMP) open source software.

Organoids were cultured for 5 days in expansion medium and fixed in 4% buffered paraformaldehyde solution for 30 minutes at room temperature. Immunofluorescent labeling was performed as described.<sup>5</sup> Primary monoclonal antibodies used were rabbit anti-human syntaxin 3 (clone EPR8543, 1:100; Abcam) and rat anti-human  $\alpha 6$ -integrin (clone GoH3, 1:200; BD Pharmingen). Secondary antibodies used were Alexa488-conjugated goat anti-rabbit (Life Technologies) and Dylight649-conjugated goat anti-rat (Biolegend). F-actin was stained with phalloidin-Tetramethylrhodamine (TRITC) (Sigma-Aldrich). Confocal image stacks were recorded with a LSM 710 confocal fluorescent microscope (Carl Zeiss) and analyzed with Volocity software version 6.3 (Perkin Elmer).

## Transmission Electron Microscopy

Intestinal biopsy specimens, organoids, and Caco-2 cell cultures were processed according to standard procedures.<sup>4</sup> Briefly, biopsy specimens and Caco-2 cells were fixed with 4% buffered paraformaldehyde solution overnight at room temperature and organoids in 0.1 mol/L PHEM buffer (60 mmol/L 1,4-piperazinediethanesulfonic acid, 25 mmol/L HEPES, 2 mmol/L  $\text{MgCl}_2$ , 10 mmol/L ethylene glycol-bis( $\beta$ -aminoethyl ether)-N,N,N',N'-tetraacetic acid, pH 6.9) for 3.5 hours at room temperature and then stored in 1% paraformaldehyde in 0.1 mol/L PHEM buffer at  $4^{\circ}\text{C}$ . Before embedding, the specimens were

postfixed with 1% OsO<sub>4</sub> (optionally followed by 1.5% K<sub>3</sub>Fe[CN]<sub>6</sub>, and subsequently 0.5% uranyl acetate). Samples then were dehydrated and embedded into Epon epoxy resin (Polysciences GmbH, Eppelheim, Germany). Ultrathin sections of 60 nm were contrasted with uranyl acetate and lead citrate.

comprised intracellular microvillus inclusions, as well as sites of basolateral microvilli. Transmission electron microscopy was used to further distinguish intracellular microvillus inclusions from sites of basolateral microvilli ( Supplementary Table 1).

### Scanning Electron Microscopy

Caco-2 cell cultures were processed according to standard procedures.<sup>6</sup>

### Morphometry and Statistics

The frequency of microvillus inclusions and sites of basolateral microvilli in Caco-2 cells, stably expressing mCitrine-STX3:FL, mCitrine-STX3:AA1-125, and mCitrine-STX3:AA1-247, was estimated by quantitative epifluorescence microscopy and transmission electron microscopy of thin sections cut perpendicularly to the cell culture surface (3 samples from 2 independent experiments, 460–650 cells per condition). The significance of differences between mCitrine-STX3:FL controls and the truncating mutations was tested using 2-sided (2-tailed) P values using the Fisher exact test. Epifluorescence microscopy was used to count the number of ring- and dot-like structures, positive either for actin or the apical marker CD26/dipeptidylpeptidase IV as compared with the cell number; thus, these structures

## ABSTRACT

Microvillus inclusion disease (MVID) is a congenital enteropathy characterized by severe diarrhea and dependence on total parental nutrition (TPN). The disease is often caused by a loss-of-function mutation in myosin Vb (*MYO5B*), which results in defective intracellular trafficking in enterocytes and loss of cell polarity. Some patients with a milder clinical phenotype and variable periods of weaning of TPN carry mutations in syntaxin 3 (*STX3*). *STX3* is a t-SNARE protein involved in fusion and exocytosis of vesicles to the apical membrane of enterocytes. However, the precise role of *STX3* in the pathogenesis of MVID is unknown. Here we show that duodenum of *STX3*-mutant patients exhibit a disturbed cell organization with multi-layered enterocytes and presence of inclusion bodies in the cytoplasm or basolateral membrane of enterocytes. We found that apical membrane proteins, such as sucrase-isomaltase (SI), were mislocalized in biopsies and patient-derived organoids, while the basolateral proteins Na/K-ATPase and E-cadherin were localized correctly. Notably, the distribution of the intracellular trafficking protein RAB11A and lysosomes was disturbed in these patients. Our results show that *STX3* is involved in apical membrane protein trafficking in human intestinal epithelial cells.

## INTRODUCTION

Microvillus inclusion disease (MVID) is a severe congenital enteropathy. Patients present with failure to thrive and persistent diarrhea that results in metabolic acidosis and dehydration [1]. For survival, MVID patients need parental nutrition, which is often accompanied with severe complications, such as venal obstruction, sepsis and liver failure. Ultimately, these complications could lead to the necessity of intestinal bowel transplantation [2]. MVID is histologically characterized by villus atrophy and subapical accumulation of Periodic Acid Schiff (PAS) positive secretory-like granules. On electron microscopy, loss of microvilli and inclusion bodies lined with microvilli are identified in villus enterocytes [1, 3-8]. Immunohistochemistry on biopsies of these patients show mislocalization of apical brush border proteins such as CD10, villin-1 and sucrase isomaltase (SI) [9-12].

MVID can be classified into two types based on their clinical presentation: classic MVID, which requires total parental nutrition and a variant form, which allows variable periods of partial weaning of parental nutrition [13-16]. Classic MVID has predominantly been associated with loss-of-function mutations in myosin Vb (*MYO5B*), an accessory motor protein that facilitates vesicle trafficking on F-actin strands [17, 18]. *MYO5B* can bind to the small GTPase molecules *RAB8A* and *RAB11A*, which are associated with intracellular vesicle trafficking [19-21]. Previously, it has been shown that villus enterocytes of MVID patients have a disturbed cell polarity due to mislocalization of apical and basolateral proteins and intracellular trafficking proteins, such as *RAB8A*, *RAB11A*, early endosomes (*EEA1*) and late endosomes (*LAMP2*) [9-11]. In addition, it has been described that loss of *MYO5B* results in less stable tight junctions [9, 10].

Recently, we identified that a loss-of-function mutation in syntaxin 3 (*STX3*) was responsible for variant MVID in two patients [15]. *STX3* is a target- soluble N-ethylmaleimide-sensitive factor attachment protein receptor (t-SNARE) that is involved in docking and fusion of

vesicles to the apical plasma membrane [22-25]. These patients feature similar histological hallmarks as classic MVID, such as variable loss of microvilli, subapical accumulation of PAS-positive vesicles and microvillus inclusions, although we have shown that microvilli were also located on the basolateral site of enterocytes [15]. Apical brush border proteins were mislocalized intracellularly and F-actin positive inclusions were detected in MVID patient biopsies [15]. However, cell polarity and distribution of intracellular trafficking components were not yet studied in these patients. To better understand the role of *STX3* in the pathogenesis of MVID, we analysed patient biopsies and generated *in vitro* patient-derived intestinal organoids from the two previously described patients with *STX3* mutations. In addition, we have grown organoids in monolayers [26] and induced differentiation to perform two functional assays: assessment of tight junction assembly by measuring trans epithelial electrical resistance (TEER) and assessment of enzymatic activity of SI at the apical membrane.

## METHODS

### Study approval

This study was approved by the local medical ethics committee. Written informed consent from participating families was received prior to inclusion. Additional duodenal biopsies for this study were obtained during a diagnostic endoscopy. Healthy control biopsies (n=2) were collected from patients that had an endoscopy for a suspected intestinal disease such as celiac disease, however, showed normal pathology.

### Patient description and material

MVID patients included in this study have been extensively described in our previous study [15]. In short, patient 1 is a microvillus inclusion disease patient with a homozygous nonsense mutation in (c.739C>T, p.Arg247\*, Ensembl COSM193004) in exon 9 of *STX3*. Patient 2 has a homozygous frame-shifting 2-bp insertion (c.372\_373dup, p.Arg125Leufs\*7) in exon 6 of *STX3*. Both patients presented with congenital

diarrhoea within the first two weeks after birth and have variable dependency on parental nutrition.

### Cell culture

Intestinal organoids were established from isolated crypts derived from patient biopsies, as described previously [27]. In brief, biopsies were washed, incubated in EDTA for crypt detachment and isolated crypts were seeded in matrigel with expansion medium (EM) containing WNT3A, epidermal growth factor (EGF), noggin, R-spondin, A83, SB202190, nicotinamide, N-acetylcysteine and B27.

Organoids were passaged weekly in a 1 to 4 ratio. For histological and functional analysis organoids were trypsinized and  $2 \times 10^5$  cells were seeded in polycarbonate 0.4  $\mu\text{m}$  pore-sized 24-well transwell inserts (Corning), according to an adapted protocol [26].

Organoids seeded for 2D monolayers were cultured in EM with 10  $\mu\text{M}$  Rho-associated protein kinase inhibitor Y-27632 (Sigma-Aldrich) for the first day. Hereafter, organoids were cultured in normal EM medium for 7 days and then harvested or induced for differentiation with differentiation medium (DM: which is EM medium without Wnt, SB202190 and nicotinamide) for 7 days .

### Immunofluorescence

Patient-derived paraffin embedded biopsies were provided by the pathology department. The organoids that were cultured in transwell inserts, were fixed in 4% PFA for 30 minutes at room temperature, dehydrated and embedded vertically into paraffin. Five  $\mu\text{m}$  thick sections were generated for stainings. For immunofluorescent stainings, slides were deparaffanized to distilled water, subjected to the appropriate heat-mediated antigen retrieval method, Tris/EDTA pH 9.0 or citrate pH 6.0 (DAKO) depending on the antibody used, and blocked in 15% normal goat and/or 15% horse serum in 5% BSA at 4 °C overnight.

Hereafter, slides were incubated with the primary antibody for 2 hours at room temperature, washed and incubated with the fluorescent conjugated secondary antibody for one hour at room temperature, washed in PBS,

incubated with DAPI (Sigma) and mounted with Fluorsave mounting medium (Millipore). Some antibodies were labelled with the Zenon Rabbit IgG labelling kit (Life technologies) according to manufacturers protocol in order to co-stain with multiple rabbit antibodies. Stained slides were analysed on a LSM 710 confocal fluorescent microscope (Carl Zeiss) and analyzed with Volocity software version 6.3 (Perkin Elmer). Primary antibodies and dilutions used in this study are listed in Suppl. Table 2.

### Cellular junction measurements and calcium-switch assay

In organoid 2D monolayers, trans-epithelial electric resistance (TEER) was measured with an epithelial volt/ohm meter (EVOM, World Precision Instruments, Inc) to measure cellular junction assembly. Ohm measurements were recalculated for cell surface per  $\text{cm}^2$ . Cellular junctions were disassembled by adding 4 mM of the calcium-chelator EGTA to the cultures for 30 minutes at 37 °C. Re-assembly of junctions was induced by adding normal calcium-containing expansion medium. TEER-values were measured every 10 minutes.

### Sucrose uptake assay

Sucrose uptake assay was measured adapted from previous literature [28, 29]. Concisely, transwells were preincubated in PBS at 37 °C to ensure no glucose was left in cell cultures. Hereafter, sucrose was added to the apical compartment of a transwell containing an organoid monolayer. Sucrase enzyme activity was assessed by collecting the supernatant of the apical chamber at selected time points. Sucrose is converted to glucose by the sucrase enzyme. The amount of glucose in the supernatant is measured by incubation with a glucose oxidase reagent for 1 hour at 37 °C. Oxidized glucose was measured with a Fluoroskan Ascent 2.5 with excitation and emission spectra of 544 nm and 590 nm, respectively.

## RESULTS

### Disturbed enterocyte architecture and pERM/Ezrin-positive inclusion bodies in

### STX3-deficient patients

First, we studied the general cell architecture and cell polarity of STX3-deficient biopsies and organoids. Since we have shown previously that STX3-mutant patients show aberrancies in enterocytes located in both villi and crypts, we determined expression patterns of several proteins in both entities. Furthermore, organoid cultures were established from duodenal biopsies from STX3-mutant MVID patient 1 and 2 and maintained in expansion medium (EM) as described previously [15, 27]. For experiments, the organoids were seeded in a transwell to form a monolayer and grown in EM for a week before organoids were induced to differentiate by incubation in differentiation medium (DM) for another 7 days. TEER measurements show that monolayers that were maintained in EM for 7 days had TEERs of 90-150  $\Omega$ /cm<sup>2</sup>, which was increased to 700-1200  $\Omega$ /cm<sup>2</sup> upon differentiation (Suppl. Fig. 1). Until day 11, TEER measurements were similar in organoid monolayers derived from patients and controls. After 11 days of culture, an increase in TEER was detected in STX3-mutant MVID patients compared to healthy controls. Collectively, the TEER measurements confirm that organoids differentiate properly when seeded in a monolayer, and can thus be used for assessment of cellular polarity.

First, we looked at the localization of two apical proteins, Ezrin and phosphorylated Ezrin/Radixin/Moesin-complex (pERM), because of their role in polarity and brush border formation. Ezrin is an apical terminal web protein that provides a platform for microvilli, is linked to the actin-cytoskeleton and is involved in localization of several apical proteins [30]. Phosphorylated Ezrin binds F-actin and is essential for well-formed brush borders of intestinal cells [31-33]. Additionally, the basolateral adherens junction E-cadherin was investigated due to its involvement in maintaining cell polarity [34].

We found that pERM and Ezrin were co-localized at the apical membrane in healthy control and MVID patient 1 and 2, suggesting that the majority of crypt and villus enterocytes maintain correct apical polarity (Figure 1AB).

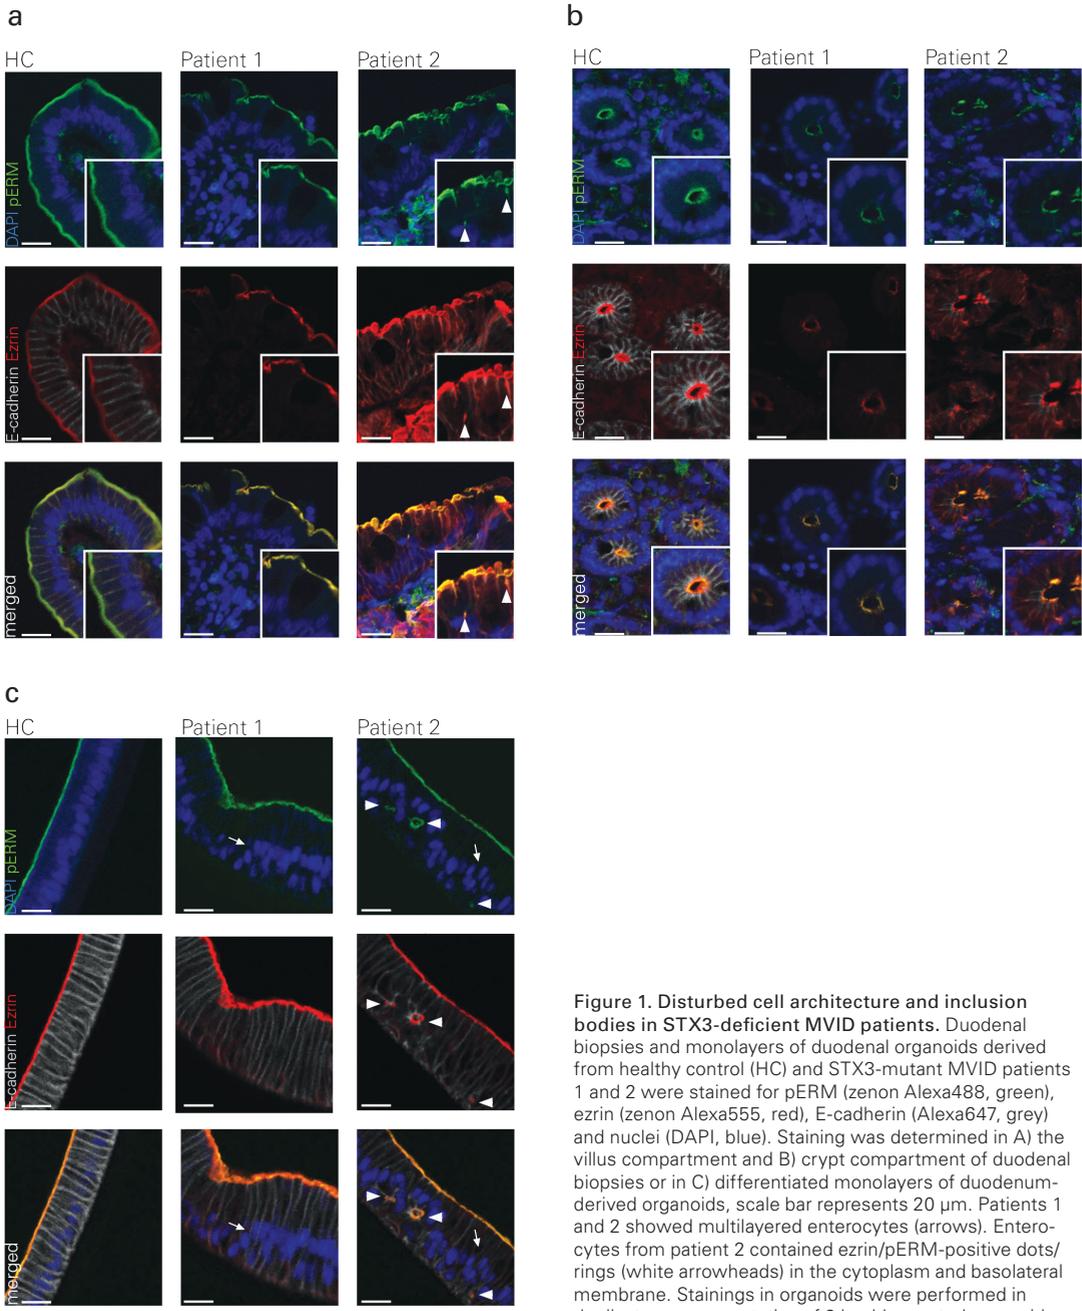

Nonetheless, Ezrin/pERM-positive ring structures that were not located at the apical membrane and as such presumably represent inclusion bodies or basolateral localized microvilli, were observed in villus enterocytes of MVID patient 2 (Figure 1A). In concordance, differentiated organoids of patient 2 contained pERM/Ezrin-positive rings/dots in ~5,7% of the enterocytes, whereas these were observed in only ~0,3% of enterocytes in healthy controls and patient 1 (Figure 1C and Suppl. Table 1).

Next, we determined the localisation of the adherens junction protein E-cadherin, which is confined to the basolateral membrane. Yet, in the biopsy of patient 1, the intensity of E-cadherin staining was immensely diminished compared to patient 2 and healthy controls (Figure 1AB). However, in organoids derived from patient 1, E-cadherin intensity was comparable to controls (Figure 1C), indicating that localisation of E-cadherin is not disturbed by loss of STX3.

In addition to those occasional aberrancies in apical polarity, we observed multi-layering of enterocytes in biopsies and monolayers of STX3-mutant MVID patients. We quantified multi-layering in 2D organoid cultures and found that this phenomenon was predominantly present in patient 2 (88% of cells) and less obvious in patient 1 (23% of cells), while only 12% of the cells in healthy control 2D organoids showed multi-layering (Suppl. Table 1).

### Assembly and maintenance of cellular junctions is not defective in STX3-mutant patients.

Next, we assessed maintenance of cell polarity by analysing the disassembly and re-assembly of cellular junctions by means of a calcium-switch assay in organoids [23, 35-38]. Cellular junctions are necessary to provide contact between neighbouring cells and also build up the paracellular barrier of epithelia and control the paracellular transport in epithelia. They are located at the junction between the apical and basolateral membranes and are involved in maintaining epithelial cell polarity. In a calcium-switch assay, cellular junctions were

**Figure 1. Disturbed cell architecture and inclusion bodies in STX3-deficient MVID patients.** Duodenal biopsies and monolayers of duodenal organoids derived from healthy control (HC) and STX3-mutant MVID patients 1 and 2 were stained for pERM (zenon Alexa488, green), ezrin (zenon Alexa555, red), E-cadherin (Alexa647, grey) and nuclei (DAPI, blue). Staining was determined in A) the villus compartment and B) crypt compartment of duodenal biopsies or in C) differentiated monolayers of duodenum-derived organoids, scale bar represents 20  $\mu$ m. Patients 1 and 2 showed multilayered enterocytes (arrows). Enterocytes from patient 2 contained ezrin/pERM-positive dots/rings (white arrowheads) in the cytoplasm and basolateral membrane. Stainings in organoids were performed in duplicate, a representative of 2 healthy control organoids is shown. D) Response to calcium-switch assay was equal in all organoids derived from healthy controls compared to STX3-mutant patients. The TEER measured during calcium-switch is represented as mean  $\pm$  SD of 4 independent wells derived from healthy controls (n=2) or patient 1 or 2.

disassembled by calcium-depletion through ethylene glycol tetra-acetic acid (EGTA) and re-established after adding normal calcium-containing medium. Disassembly and re-assembly of cellular junctions were monitored by TEER measurements. We did not observe any difference in disassembly or re-assembly of cellular junctions in patient-derived organoids compared to controls (Figure 1D), indicating that disturbed cell polarity in STX3-mutant MVID patients was not associated with defects in cellular junctions.

### Altered expression of Na/K-ATPase and SI in STX3-mutant MVID patients

Previously, it has been shown that enterocytes of classical MYO5B-mutant MVID patients have various mislocalized proteins, such as lysosome-associated membrane protein 1 (LAMP1), sucrase isomaltase (SI), RAB8A, RAB11A and Na/K-ATPase [9-11]. Therefore, we have assessed the localisation of these proteins in STX3-mutant MVID patients.

Analysis of the apical protein SI showed that SI was expressed in the subapical compartments of duodenal biopsies and patient-derived organoids and only partially co-localized with the apical protein Ezrin (Figure 2A-C). In contrast, healthy control organoids showed strict localization to the apical plasma membrane and full co-localization with Ezrin (Figure 2C). Of note, in this image we have enhanced the Ezrin signal twice as bright in patient 1 compared to patient 2 and healthy control to visualize a signal.

The basolateral marker Na/K-ATPase was shown to be both normally and abnormally distributed in different MYO5B-mutant MVID patients [9-11].

We observed normal distribution of Na/K-ATPase in the two STX3-mutant patients, although expression levels were markedly diminished in biopsies of patient 1 and 2, when compared to healthy control (Figure 2AB). In contrast, Na/K-ATPase was expressed in normal levels in patient-derived organoids and was similar to controls (Figure 2C).

### STX3-deficient MVID patients show altered distribution of LAMP1

LAMP1, which marks lysosomes and normally

accumulates in the subapical region, was distributed more diffusely in the cytoplasm and closer to the supranuclear region in biopsy of patient 2 (Figure 3AB), and in organoids of patient 1 and 2 (Figure 3C).

Although both, SI and LAMP1 showed altered expression in MVID patients, SI did not co-localize with the lysosomal marker LAMP1 (Figure 3A-C), indicating that SI was accumulated intracellularly but not in the lysosomal compartments.

d

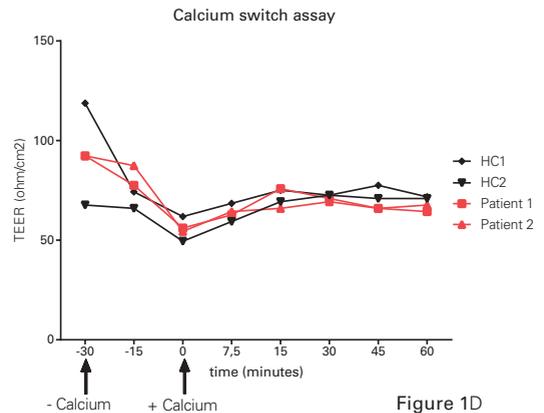

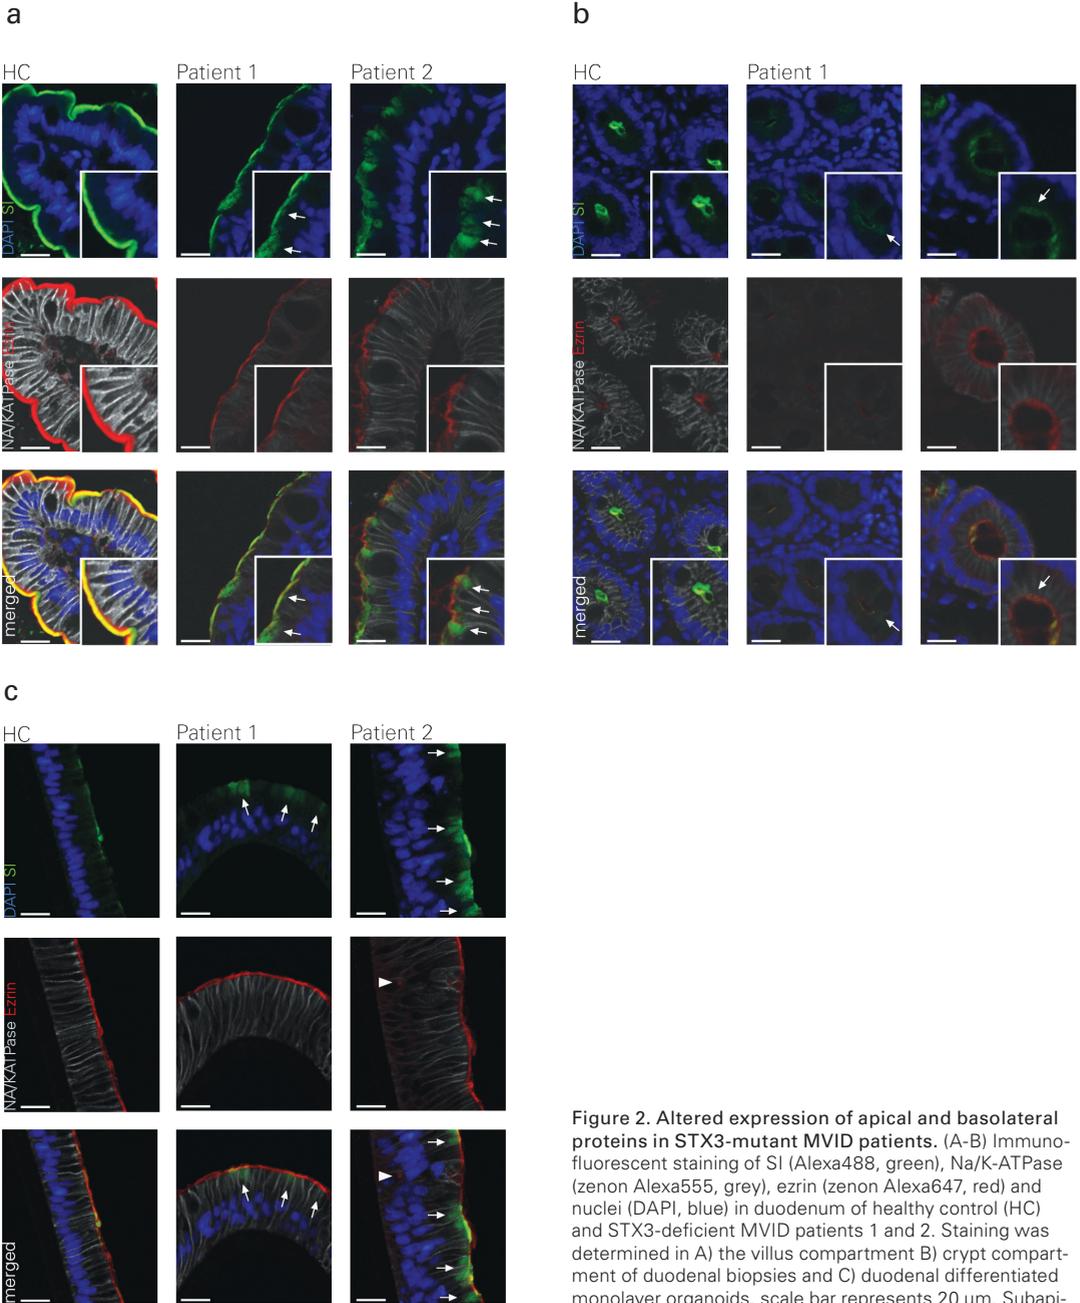

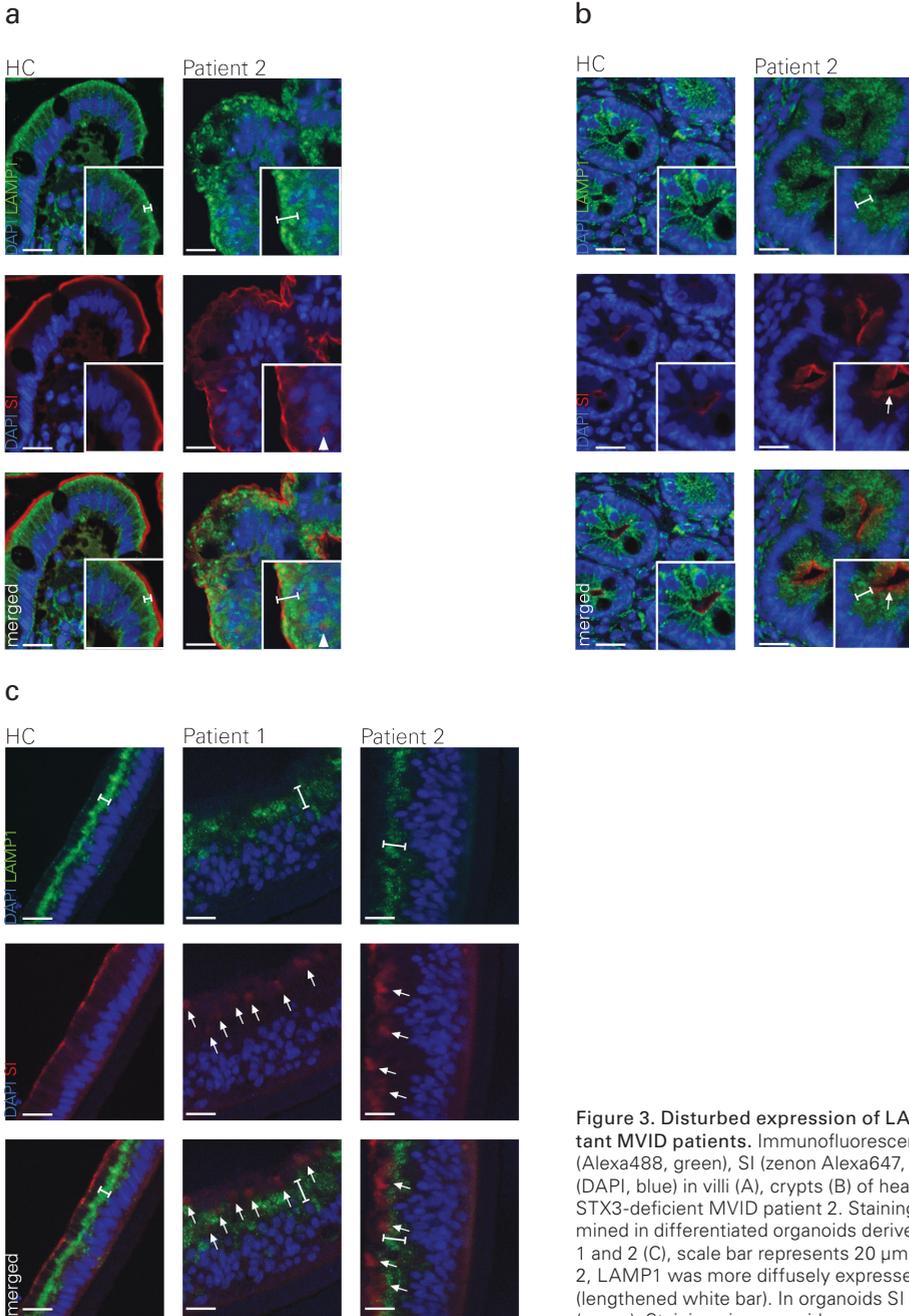

Figure 1D

### Intracellular SI partially co-localizes with RAB11A but not RAB8A in STX3-deficient MVID patients

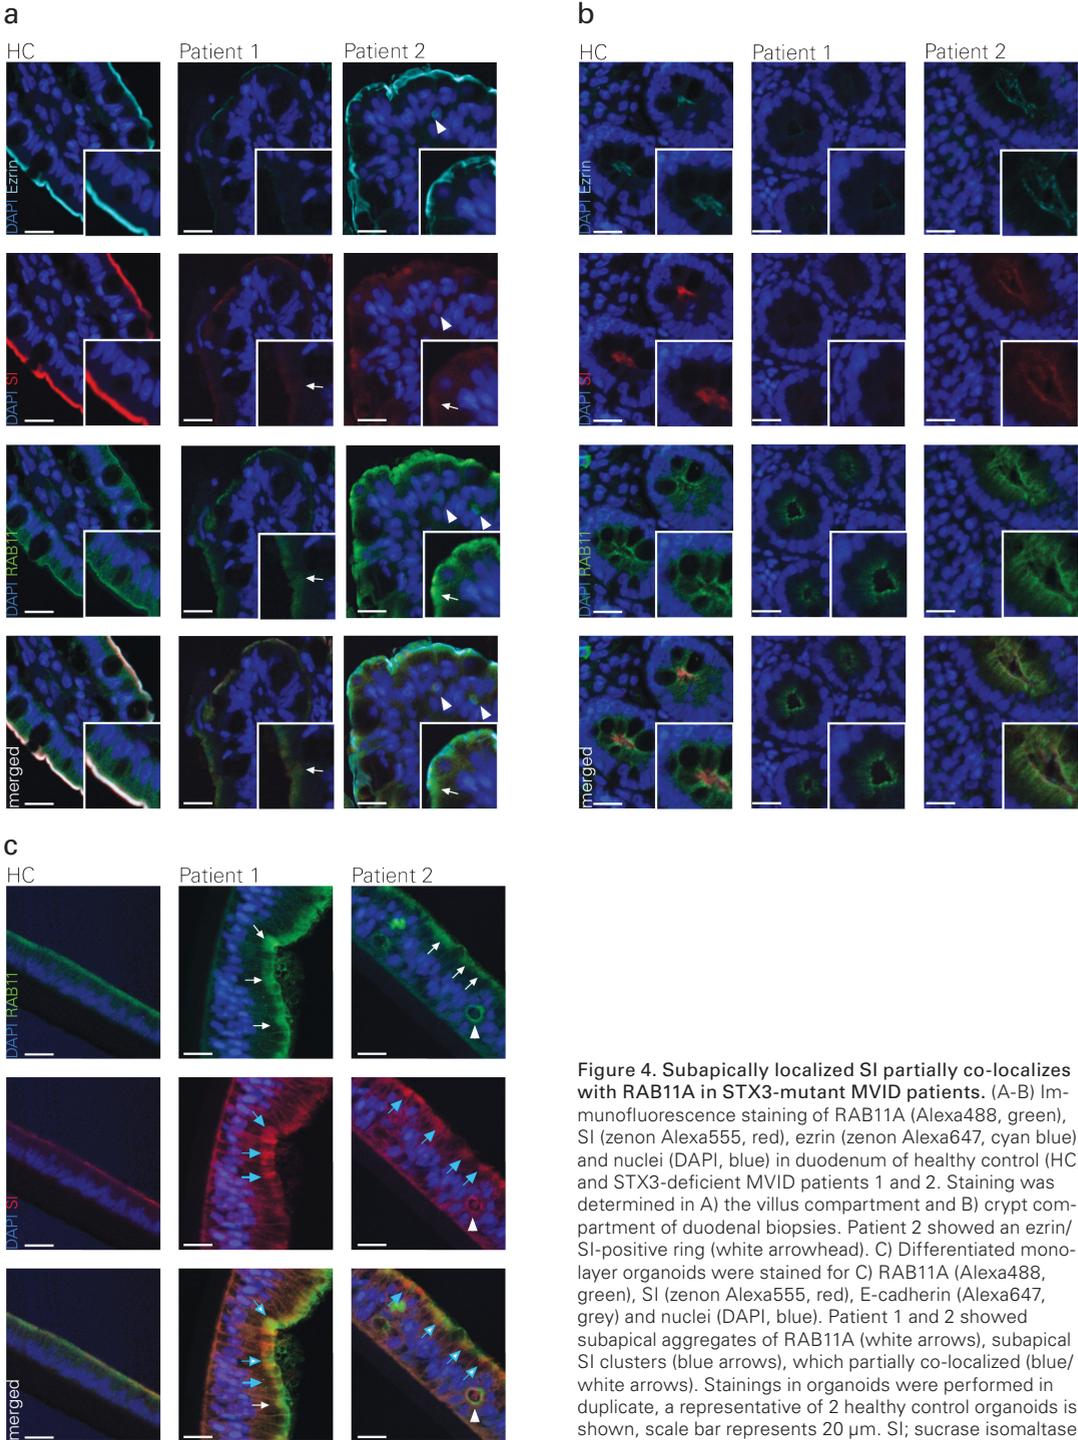

Although SI aggregates did not co-localize with LAMP1, we hypothesised that SI would co-localize with the small GTP-binding protein RAB8A or RAB11A, which regulate apical transport in intestinal cells. Subapical accumulation of apical proteins such as SI had been demonstrated previously in RAB8-deficient mice [39]. In the healthy control biopsy the apical trafficking protein RAB8 was evenly distributed in the cytoplasm of enterocytes in crypt and villi with increased expression at the apical membrane in villus enterocytes. In healthy control and in patients, RAB8A partially co-localized with the apical proteins SI and Ezrin, which was also observed in organoids (data not shown).

**Figure 2. Altered expression of apical and basolateral proteins in STX3-mutant MVID patients.** (A-B) Immunofluorescent staining of SI (Alexa488, green), Na/K-ATPase (zenon Alexa555, grey), ezrin (zenon Alexa647, red) and nuclei (DAPI, blue) in duodenum of healthy control (HC) and STX3-deficient MVID patients 1 and 2. Staining was determined in A) the villus compartment B) crypt compartment of duodenal biopsies and C) duodenal differentiated monolayer organoids, scale bar represents 20  $\mu$ m. Subapical staining of SI was noted in biopsies and organoids of patient 1 and 2 (arrows). Patient 2 showed an ezrin-positive ring (white arrowhead). Note: Ezrin settings for patient 1 were adjusted to twice as bright as the healthy control and patient 2 to maintain a visible signal. Stainings in organoids were performed in duplicate, a representative of 2 healthy control organoids is shown. SI, sucrase isomaltase.

**Figure 3.** Disturbed expression of LAMP1 in STX3-mutant MVID patients. Immunofluorescent staining of LAMP1 (Alexa488, green), SI (zenon Alexa647, red) and nuclei (DAPI, blue) in villi (A), crypts (B) of healthy control (HC) and STX3-deficient MVID patient 2. Stainings were also determined in differentiated organoids derived from HC, patient 1 and 2 (C), scale bar represents 20  $\mu\text{m}$ . In patient 1 and 2, LAMP1 was more diffusely expressed in the cytoplasm (lengthened white bar). In organoids SI is located subapically (arrow). Stainings in organoids were performed in duplicate, a representative of 2 healthy control organoids is shown. SI, sucrase isomaltase.

**Figure 4. Subapically localized SI partially co-localizes with RAB11A in STX3-mutant MVID patients.** (A-B) Immunofluorescence staining of RAB11A (Alexa488, green), SI (zenon Alexa555, red), ezrin (zenon Alexa647, cyan blue) and nuclei (DAPI, blue) in duodenum of healthy control (HC) and STX3-deficient MVID patients 1 and 2. Staining was determined in A) the villus compartment and B) crypt compartment of duodenal biopsies. Patient 2 showed an ezrin/SI-positive ring (white arrowhead). C) Differentiated mono-layer organoids were stained for C) RAB11A (Alexa488, green), SI (zenon Alexa555, red), E-cadherin (Alexa647, grey) and nuclei (DAPI, blue). Patient 1 and 2 showed subapical aggregates of RAB11A (white arrows), subapical SI clusters (blue arrows), which partially co-localized (blue/white arrows). Stainings in organoids were performed in duplicate, a representative of 2 healthy control organoids is shown, scale bar represents 20  $\mu\text{m}$ . SI; sucrose isomaltase.

Another small GTP-binding protein that is well known for its role in apical membrane trafficking is RAB11A. It has been shown to be involved in maintenance of apical microvilli and apical localization of STX3 [40]. SI transport to the apical membrane has been demonstrated to involve RAB11A [41]. In healthy controls, RAB11A was distributed evenly in the cytoplasm, with intensified expression at the apical border of the intestine in both crypt and villus (Figure 4AB). However, in biopsies of patient 1 and 2 RAB11A-positive clusters were noticed subapically of the plasma membrane (Figure 4AB). This phenomenon was also detected in patient-derived organoids, where RAB11A partially co-localized with subapical SI clusters (Figure 4C).

Our data suggest that STX3 is involved in localization of RAB11A and that SI is partially transported by RAB11A trafficking proteins.

### **Sucrase function is not affected in organoids derived from STX3-mutant MVID patients**

In Figure 2A, we noticed subapically and occasionally apically located clusters of SI in STX3-mutant MVID patient-derived organoids. Additionally, STX3-mutant MVID patients partially tolerate minimal enteral feeding next to parental nutrition [15]. To determine the potentially residual enzymatic activity of SI, we investigated the function of the apical brush-border enzyme SI in organoid monolayers after adding sucrose to the apical compartment [28, 29]. To assess enzyme activity of the brush border protein SI in STX3 patients we adapted the described assay for differentiated organoids. We found no differences in SI metabolism at the apical surface of enterocytes, indicating that the low amount of SI that is expressed on the apical membrane is sufficient to digest sucrose (Suppl. Figure 2). We also depicted SI activity for undifferentiated organoids as a negative control.

## **DISCUSSION**

MVID is clinically characterized by severe congenital diarrhea with dehydration and the inability to take up nutrients from an enteral

diet. The current therapy comprises rehydration therapy and parenteral feeding [1]. Although most MVID patients carry a mutation in the *MYO5B* gene, the type of mutations associated with this gene are very heterogeneous [18, 42]. In addition, our previous data show that a variant form of MVID is caused by a mutation in *STX3* [15]. Both *MYO5B* and *STX3* are involved in trafficking of apical proteins. Several studies have examined different *MYO5B*-deficient patients and indeed identified an altered distribution of apical proteins such as SI, DPPIV, RAB8 and RAB11A in intestinal biopsies [9-11]. More recently, mislocalization of basolateral proteins such as Na/K-ATPase, E-cadherin and transferrin has been demonstrated in *MYO5B*-mutant MVID patients [9, 10].

In this study, we assessed if similar aberrations could be identified in the MVID patients with mutations in *STX3*. We demonstrated that overall cell polarity is maintained in *STX3*-deficient patients, shown by apical localization of Ezrin (both native and phosphorylated form) and basolateral localization of E-cadherin and Na/K-ATPase. In addition, a calcium switch assay, which represents cellular junction assembly, did not show any differences in organoids derived from healthy controls or *STX3*-mutant patients. Nonetheless, we did observe an increase in intracellular pERM/Ezrin-positive rings, most evident in patient 2, which are suggestive for microvillus inclusion bodies.

Our data indicate that *STX3* is involved in apical protein trafficking in human intestinal cells, which is in concordance with previous studies in Caco2 cell lines [22, 43] and Madin-Darby Canine Kidney cell lines [25]. Moreover, we observed altered distribution of the lysosomal compartment, which was also noted in *MYO5B*-deficient patients [9]. We found that *STX3* is involved in enterocyte polarity by means of preventing multi-layering of enterocytes and localisation of some apical proteins, such as SI. Loss of function of *STX3* results in formation of pERM/Ezrin-containing inclusions either in the cytoplasm or on the basolateral membranes. However, *STX3* is not involved in

proper assembly of cellular junctions or localisation of the basolateral proteins E-cadherin and Na/K-ATPase.

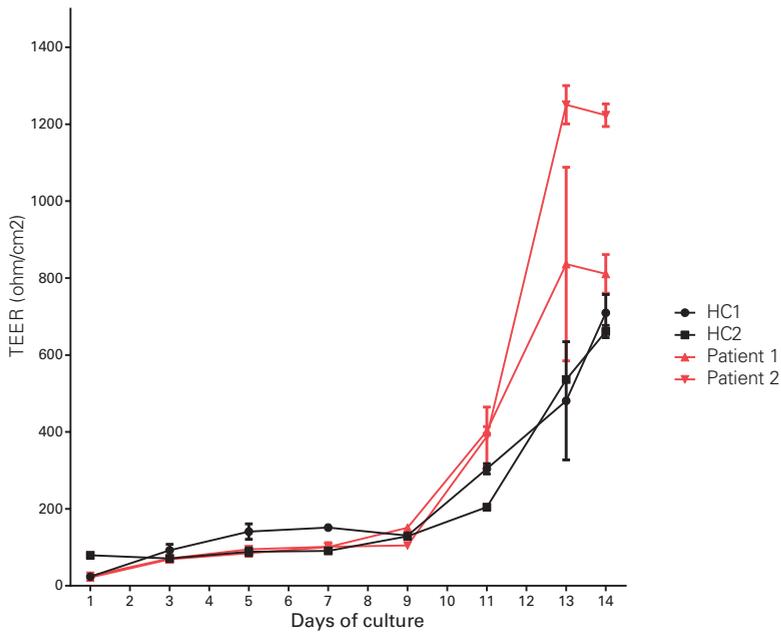

## ACKNOWLEDGMENTS

We thank the pediatric gastroenterologist of the UMC Utrecht, Erasmus MC Rotterdam and University Medical Center Mannheim for performing endoscopies and obtaining duodenal biopsies and Ans Geboers for assistance with the disaccharidase assay.

## ABSTRACT

We recently established conditions allowing for long-term expansion of epithelial organoids from intestine, recapitulating essential features of the *in vivo* tissue architecture. Here we apply this technology to study primary intestinal organoids of people suffering from cystic fibrosis, a disease caused by mutations in *CFTR*, encoding cystic fibrosis transmembrane conductance regulator. Forskolin induces rapid swelling of organoids derived from healthy controls or wild-type mice, but this effect is strongly reduced in organoids of subjects with cystic fibrosis or in mice carrying the *Cftr* F508del mutation and is absent in *Cftr*-deficient organoids. This pattern is phenocopied by CFTR-specific inhibitors. Forskolin-induced swelling of *in vitro*-expanded human control and cystic fibrosis organoids corresponds quantitatively with forskolin-induced anion currents in freshly excised *ex vivo* rectal biopsies. Function of the CFTR F508del mutant protein is restored by incubation at low temperature, as well as by CFTR-restoring compounds. This relatively simple and robust assay will facilitate diagnosis, functional studies, drug development and personalized medicine approaches in cystic fibrosis.

## INTRODUCTION

CFTR functions as an anion channel and is essential for fluid and electrolyte homeostasis at the epithelial surfaces of many organs, including the lung and intestine. Cystic fibrosis is caused by mutations in the *CFTR* gene [1-3], and disease expression is highly variable between individuals (<http://www.cftr2.org/>). People with cystic fibrosis have a median life expectancy of approximately 40 years and accumulate viscous mucus in the pulmonary and gastrointestinal tract, which is associated with bacterial infections, aberrant inflammation and malnutrition [4]. Over 1,900 *CFTR* mutations have been identified, but the most dominant mutation (accounting for ~67% of the total mutant alleles worldwide) is a deletion of phenylalanine at position 508 (CFTR F508del) (<http://www.genet.sickkids.on.ca/>). This causes misfolding, endoplasmic reticulum retention and early degradation of the CFTR protein that prevents its function at the plasma membrane [5]. Other *CFTR* mutations also impair protein folding or production, gating, conductance, splicing or interactions with other proteins [6].

Current therapies for cystic fibrosis are mainly symptomatic and focus on reducing bacterial pressure and inflammation and normalizing nutrient uptake and physical growth. Multiple compounds have been identified recently that target mutation-specific defects of the CFTR protein itself [6,7]. Current clinical trials that target the basic defect aim to (i) induce premature stop codon readthrough, (ii) correct plasma membrane trafficking of CFTR (correctors) and (iii) enhance CFTR gating (potentiators). A phase 3 clinical trial has been successfully completed using the potentiator VX-770 (ivacaftor, Kalydeco) in subjects with the CFTR G551D mutation, demonstrating that mutation-specific drug targeting is feasible [8]. Combination therapy using a corrector (VX-809) and a potentiator (VX-770) is currently being assessed in a phase 2 clinical trial for subjects harboring the CFTR F508del mutation.

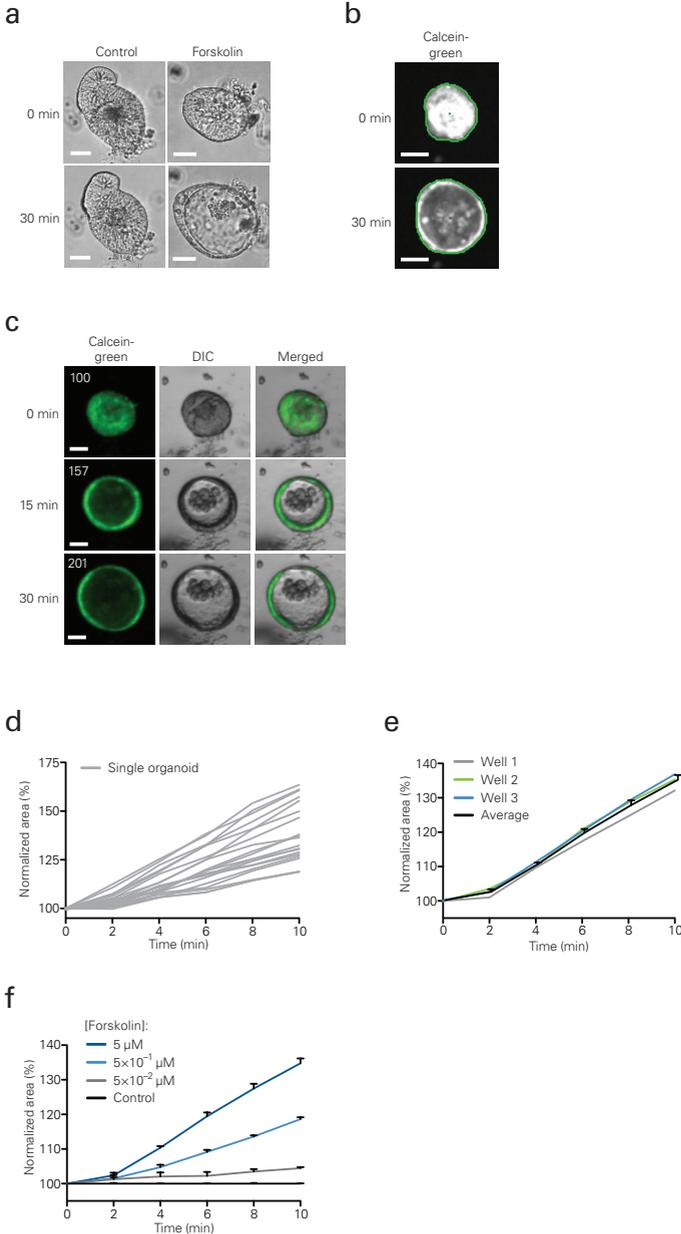

Although CFTR-specific drug targeting is

promising, the amount of functional CFTR restoration is still limited [9-11]. In addition, subjects show variable responses to these therapies due to undefined mechanisms [8,12-14], suggesting that the ability to predict individual drug responses would facilitate clinical efficacy and drug registration. Together this indicates that development of new compounds and screening of drug efficacy at the level of the individual are urgently needed. Thus far, limited primary cell models are available to screen for compounds that restore the function of mutant CFTR proteins. When such an *in vitro* model can be further expanded to analyze the drug responses of individual subjects, it may improve drug efficacy by selecting drug-responsive subgroups.

Here we demonstrate a rapid and quantitative assay for CFTR function in a mouse and human primary intestinal culture method that was recently developed [15-17]. The culture enables intestinal stem cells to expand into closed organoids containing crypt-like structures and an internal lumen lined by differentiated cells, recapitulating the *in vivo* tissue architecture. Intestinal CFTR is predominantly expressed at the apical membrane of the crypt cells, where its activation drives the secretion of electrolytes and fluids [18-20]. We found that forskolin [21] induces a rapid swelling of both human healthy control and mouse wild-type organoids that depends completely on CFTR, as demonstrated by analysis of intestinal organoids from *Cftr*<sup>tm1Cam</sup> knockout (*Cftr*<sup>-/-</sup>) mice or individuals with cystic fibrosis. Forskolin-induced swelling by *in vitro*-expanded rectal organoids is comparable to the forskolin-induced anion currents measured in *ex vivo* human rectal biopsies. Restoration of the function of CFTR F580del mutant protein using low temperature or chemicals was easily detected by organoid-based fluid transport measurements, and responses to CFTR-restoring drugs were variable between organoids derived from different subjects homozygous for F508del. This robust assay is the first functional readout developed in human organoids, to our knowledge, and will facilitate diagnosis, functional studies, drug development and personalized medicine in cystic fibrosis.

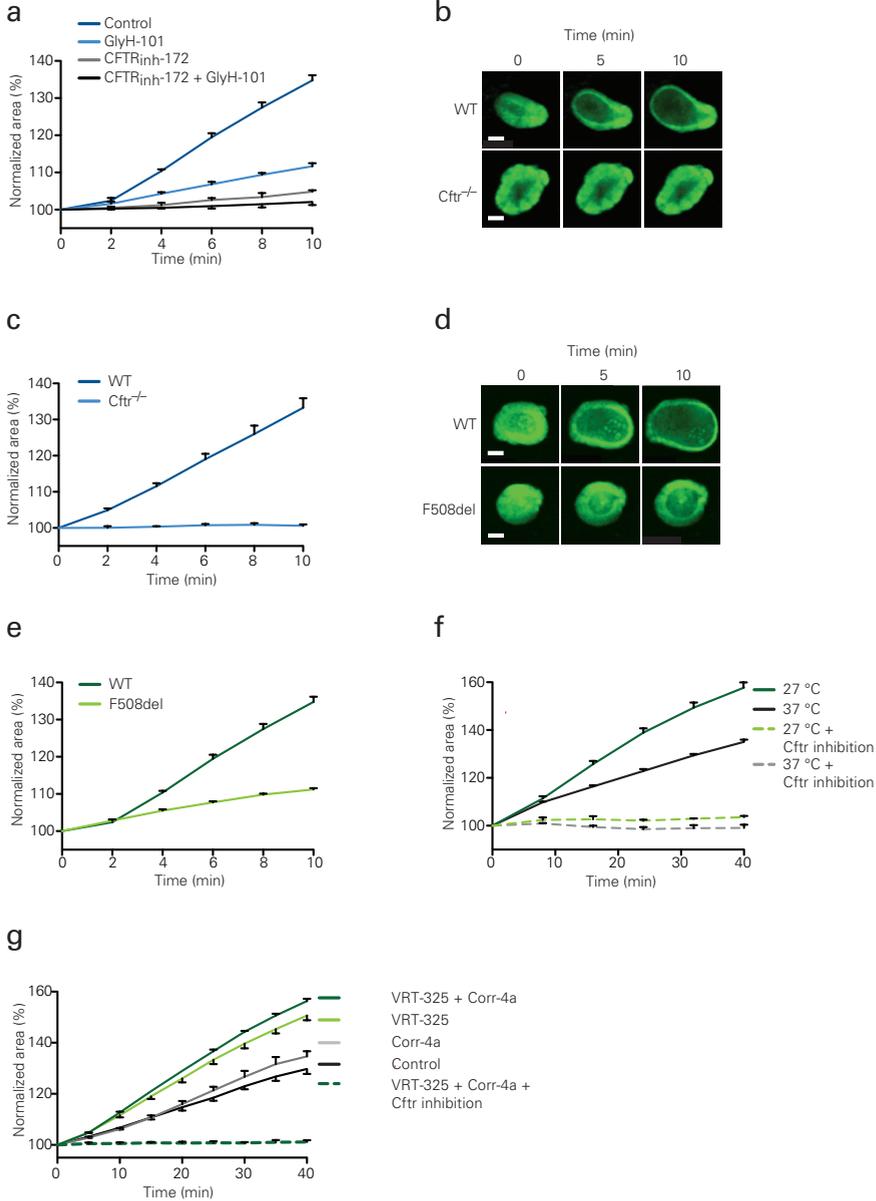

**Figure 1. Quantification of forskolin-induced mouse organoid swelling.**

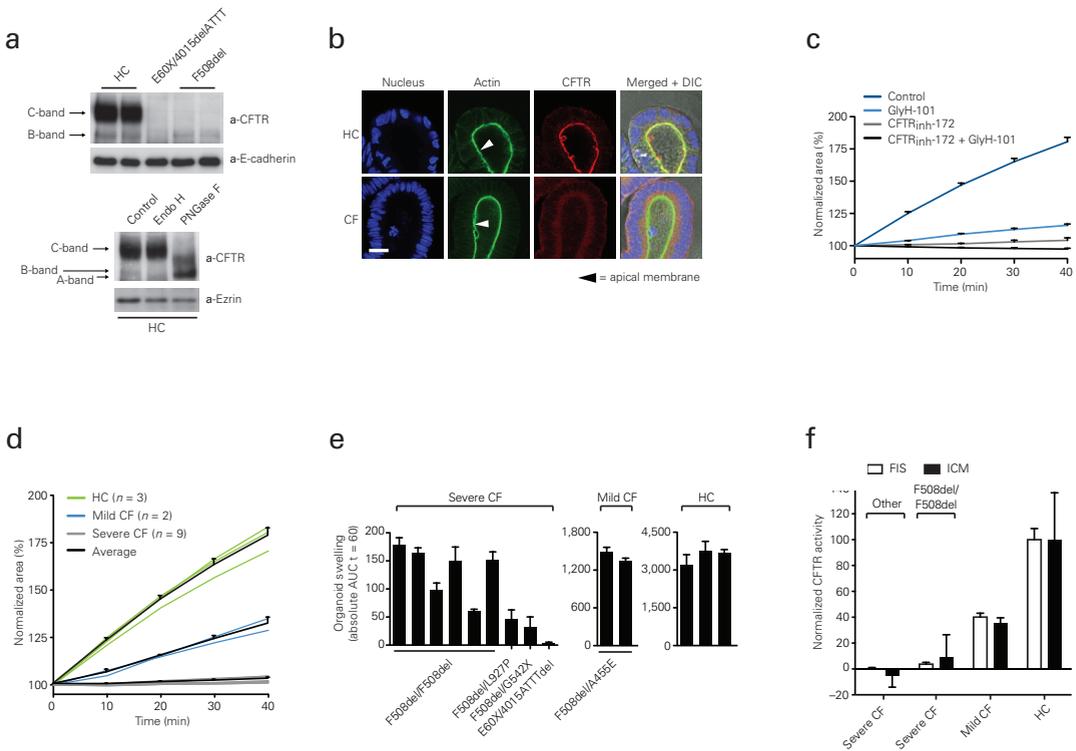

(a) Light microscopy analysis of organoids stimulated with forskolin or DMSO. Representative examples at the indicated time points after the start of stimulation are shown. (b) Fluorescence confocal image of a calcein green-labeled organoid with object recognition (green line) by image analysis software. (c) Representative example of a forskolin-stimulated calcein green-labeled organoid. Differential interference contrast (DIC) and fluorescence were imaged using live-cell confocal microscopy. Surface areas, expressed as percentages relative to that at  $t = 0$  (100%), are indicated in the top-left corners. (d) The surface area relative to that at  $t = 0$  (normalized area) of all responding individual organoids from a single well. (e) The total organoid surface area normalized to that at  $t = 0$  from three independent wells. The average response of the individual wells is indicated in black (mean  $\pm$  s.e.m.). (f) Dose-dependent increase of surface area by forskolin. Each line represents the average response from three individual wells as shown in e (mean  $\pm$  s.e.m.). Scale bars (a–c), 30  $\mu\text{m}$ . All results are representative of at least three independent experiments.

**Figure 2. Forskolin-induced swelling of mouse organoids is Cfr dependent.**

(a) Normalized swelling curves of forskolin-stimulated calcein green-labeled organoids preincubated with DMSO, CFTRinh-172, GlyH-101 or both CFTRinh-172 and GlyH-101 (mean  $\pm$  s.e.m.). (b,c) Representative confocal microscopy images (b) and quantification of swelling (mean  $\pm$  s.e.m.) (c) of calcein green-labeled *Cftr*<sup>-/-</sup> organoids and corresponding wild-type organoids in response to forskolin. Scale bars, 50  $\mu$ m. (d,e) Similar to b and c but for F508del *Cftr* organoids (mean  $\pm$  s.e.m.). Scale bars, 50  $\mu$ m. (f) Forskolin-induced swelling of calcein green-labeled F508del *Cftr* organoids cultured for 24 h at 37 °C or 27 °C with or without CFTR inhibition (mean  $\pm$  s.e.m.). (g) Normalized forskolin-induced swelling of F508del *Cftr* organoids pretreated for 24 h with DMSO, VRT-325, Corr-4a or both correctors with or without CFTR inhibition (mean  $\pm$  s.e.m.). Note that the timescale in f and g is larger than elsewhere in the figure. All results are representative of at least three independent experiments.

**Figure 3. Forskolin-induced swelling in human organoids is CFTR dependent.**

(a) Western blot analysis of CFTR and E-cadherin (loading control) expression in human rectal healthy control (HC; n = 2), E60X 4015del/ATTT (n = 1) and homozygous F508del CFTR (n = 2) organoids (top) and CFTR and ezrin (loading control) expression in whole-cell lysates of human rectal organoids that were either not treated (control) or treated with the deglycosylation enzyme Endo H or PNGase F (bottom). (b) CFTR detection by the monoclonal antibody to CFTR M3A7 in a healthy control and F508del CFTR organoid co-stained with phalloidin-FITC (actin) and DAPI (nucleus). DIC and fluorescence were imaged using confocal microscopy. Scale bars, 20  $\mu\text{m}$ . CF, cystic fibrosis. The arrowheads indicate the apical membrane. (c) Quantification of forskolin-induced healthy control organoid swelling after preincubation with DMSO, CFTRinh-172, GlyH-101 or both CFTRinh-172 and GlyH-101 (mean  $\pm$  s.e.m.). (d) Forskolin-induced swelling of rectal organoids derived from three individual healthy controls, two individuals with a mild cystic fibrosis genotype (F508del A455E) and nine individuals with a severe cystic fibrosis genotype (one individual with E60X 4015del/ATTTdel, one with F508del G542X, one with F508del L927P and six with F508del F508del). The average swelling in the different groups is indicated in black (mean  $\pm$  s.e.m.). (e) FIS responses of organoids from healthy controls or subjects with cystic fibrosis expressed as the absolute area under the curve (AUC) calculated from the time periods shown in d (baseline = 100%, t = 60 min). Each bar represents AUC values averaged from at least three independent experiments per individual (mean  $\pm$  s.e.m.). (f) Comparison of CFTR activity measured by FIS of organoids from healthy controls and subjects with cystic fibrosis or by ICMs of the corresponding rectal biopsies. ICM bars of the different indicated groups represent forskolin-induced cumulative chloride secretion ( $\mu\text{A cm}^{-2}$ ) relative to the average healthy control response (set at 100%). FIS bars represent FIS expressed as the AUC averaged from at least three independent experiments per individual as shown in f relative to the average healthy control response (100%). (Healthy controls, n = 3; mild cystic fibrosis, n = 2; severe cystic fibrosis (F508del F508del), n = 5; severe cystic fibrosis (other; E60X 4015del/ATTTdel and F508del G542X), n = 2; mean  $\pm$  s.d.). All results are representative of at least three independent experiments. ICMs were performed on four rectal biopsies.

## RESULTS

### Quantification of forskolin-induced organoid swelling

We first assessed whether forskolin, which raises the amount of intracellular cyclic AMP (cAMP) and thereby activates CFTR, could mediate fluid secretion into the lumen of small intestinal organoids derived from wild-type mice. Using live-cell microscopy, we observed a rapid expansion of both the lumen and total organoid surface area after the addition of forskolin, whereas DMSO-treated organoids were unaffected (Fig. 1a and Supplementary Video 1). Removal of the forskolin reversed the organoid swelling (Supplementary Fig. 1a).

We then quantified these responses by automated image analysis. We found excellent cell labeling (>100 times that of the background) using calcein green, a cell-permeable dye that gains fluorescence and is retained within living cells after metabolic conversion. We quantified forskolin-induced swelling (FIS) of organoids using live-cell confocal microscopy and imaging software that calculated the relative increase in the total area of all fluorescent objects per well for each time point after the addition of forskolin (Fig. 1b,c and Supplementary Fig. 1b). The majority of the organoids responded to forskolin stimulation (Fig. 1d). Approximately 5–10% of organoids that were either very small or irregularly shaped and nonviable did not respond to forskolin (Supplementary Fig. 1c,d), but their inclusion did not affect the FIS measurements (Supplementary Fig. 1e). A time-dependent surface area increase in three independent wells showed limited variation (Fig. 1e) and a dose-dependent relationship with forskolin (Fig. 1f). We present the FIS of mouse organoids during the first 10 min, as some wild-type mouse organoids burst and collapsed during longer stimulations (Supplementary Fig. 2a–c). Together these results show that forskolin-induced organoid swelling can be quantified by automated fluorescent image analysis.

### Forskolin-induced swelling of mouse organoids

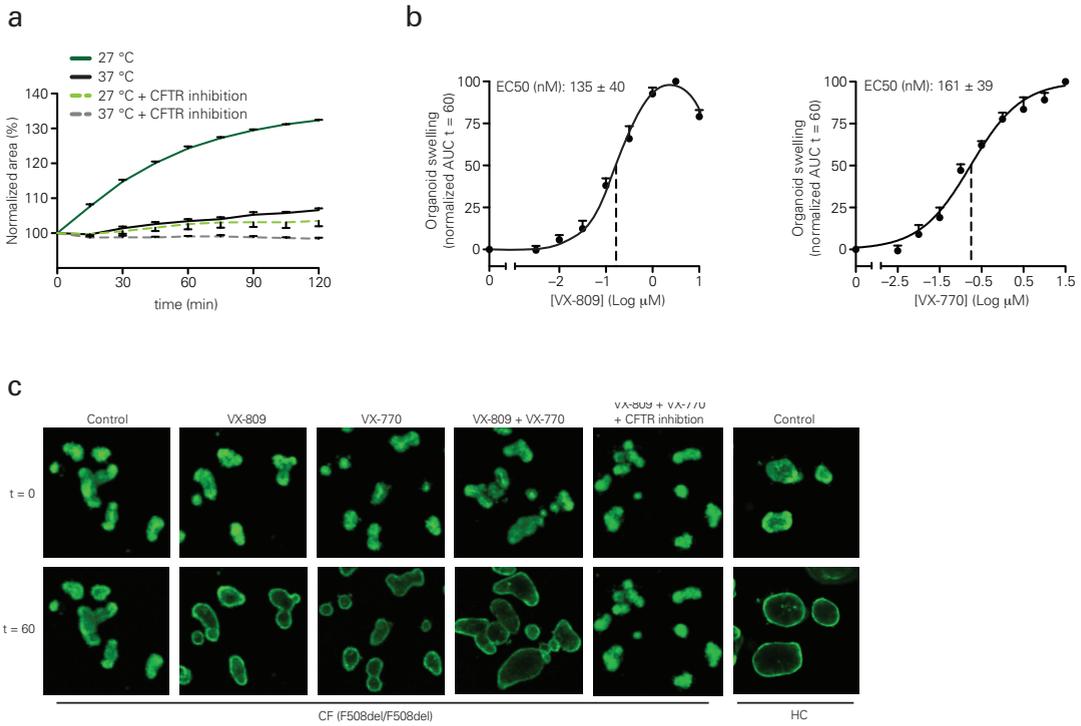

High levels of *Cftr* mRNA in the organoids

supported a role for *Cftr* in FIS (Supplementary Fig. 2d). To demonstrate that FIS is *Cftr* dependent, we used chemical inhibitors of CFTR [22, 23] and *Cftr*<sup>-/-</sup> [24] or *Cftr*<sup>m1eur</sup> (harboring *Cftr* F508del) mice [25, 26]. Preincubation (2 h) with the CFTR inhibitor CFTR<sub>inh</sub>-172 [22] or GlyH-101 [23] reduced FIS by ~90% and ~75%, respectively, and their combination fully prevented FIS (Fig. 2a). In addition, FIS was absent in the organoids of *Cftr*<sup>-/-</sup> mice (Fig. 2b,c and Supplementary Video 1). Calcein green labeling was comparable in wild-type and mutant organoids, indicating that the *Cftr*<sup>-/-</sup> organoids were viable. Organoids of mice harboring the *Cftr* F508del mutation displayed low but detectable FIS (Fig. 2d,e and Supplementary Video 1) that was sensitive to CFTR<sub>inh</sub>-172 (Fig. 2f), suggesting residual *Cftr* activity, as has been observed previously [25, 26]. Together these data demonstrate that FIS in mouse organoids is completely *Cftr* dependent.

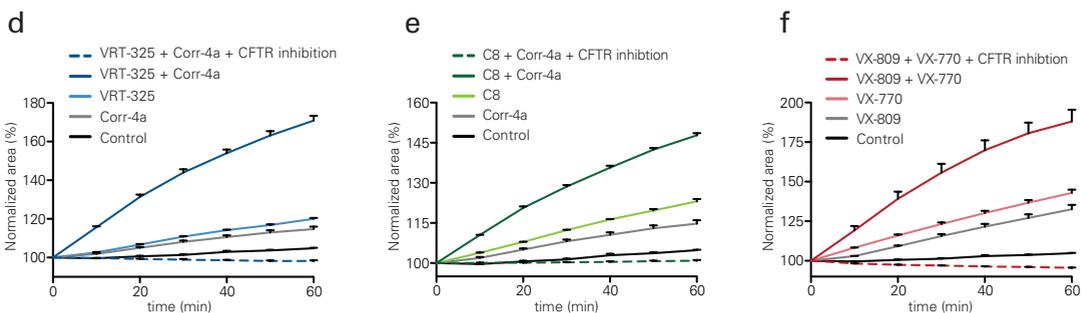

To show that FIS can detect *Cftr* correction, we performed temperature-rescue experiments, which is a widely accepted method to increase the function of CFTR F508del mutant protein [27]. Misfolding of F508del CFTR is reduced at 27 °C, leading to enhanced amounts of functional CFTR at the plasma membrane. Indeed, we observed increased FIS after overnight incubation of F508del *Cftr* organoids at 27 °C (Fig. 2f). We next used the chemical correctors VRT-325 [28] and Corr-4a [29] to restore the function of F508del *Cftr* (Online Methods). Preincubation (24 h) with VRT-325 enhanced FIS, whereas preincubation with Corr-4a only slightly improved FIS, and the effect of Corr-4a was additive to that of VRT-325 (Fig. 2g). CFTR inhibitors prevented FIS after *Cftr* correction (Fig. 2f,g). Collectively these results demonstrate that FIS of mouse organoids can reveal functional restoration of F508del *Cftr* by correction approaches.

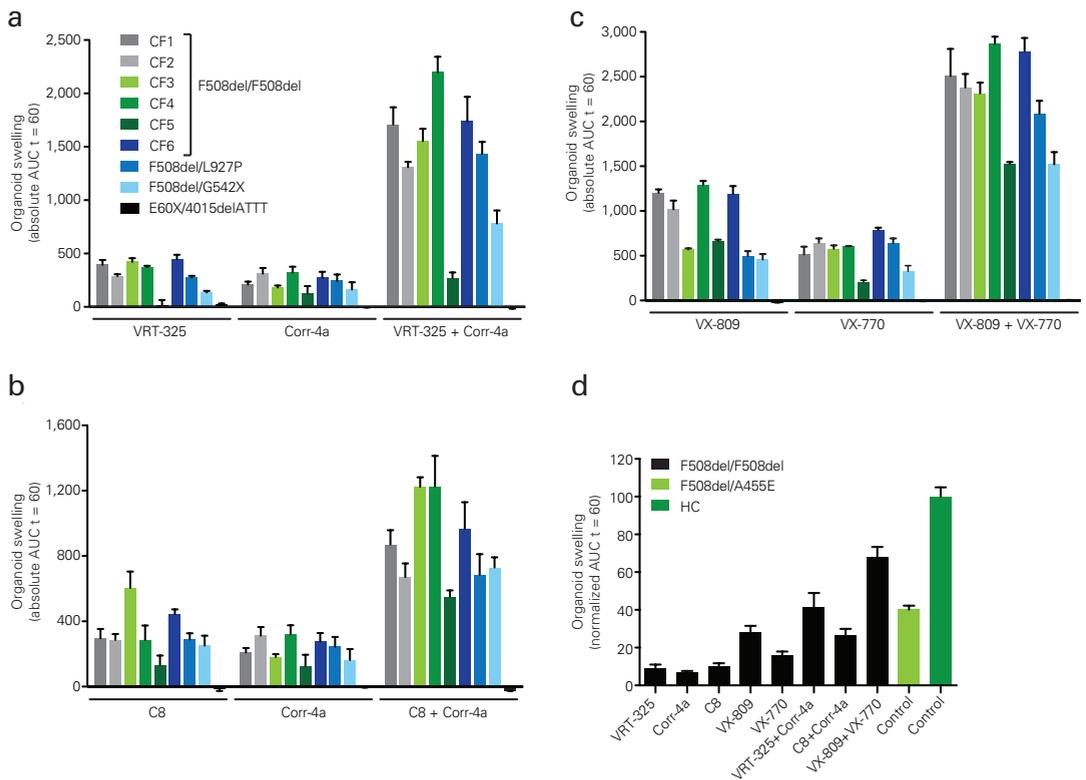

### Forskolin-induced swelling of human organoids

We next assayed human intestinal organoid cultures. Using western blot analysis, we detected mature CFTR (C band, 170 kDa) and immature CFTR (B band, 130 kDa) in human

**Figure 4. Chemical CFTR correction in human rectal organoids from subjects with cystic fibrosis.** (a) Normalized swelling of forskolin-induced calcein green-labeled F508del CFTR organoids cultured for 24 h at 37 °C or 27 °C with or without CFTR inhibition (mean  $\pm$  s.e.m.). (b) EC50 values of F508del organoids for VX-809 or VX-770. The lines represent FIS expressed as the AUC (baseline 100%, t = 60 min) calculated from the time periods shown in d–f relative to DMSO-treated (0%) and VX-809-treated (log(0.5)  $\mu$ M) or VX-770-treated (log(1.5)  $\mu$ M) (100%) organoids (n = 6 F508del homozygous organoids; mean  $\pm$  s.e.m.). (c) Representative confocal microscopy images of calcein green-labeled healthy control and F508del CFTR organoids in response to forskolin after pharmacological restoration of CFTR. Scale bars, 100  $\mu$ m. (d–f) Time lapse analyses of normalized forskolin-induced swelling of F508del CFTR organoids pretreated for 24 h with DMSO, VRT-325 (10  $\mu$ M), Corr-4a (10  $\mu$ M) or both correctors with or without CFTR inhibition (d), with DMSO, C8 (10  $\mu$ M), Corr-4a (10  $\mu$ M) or both correctors with or without CFTR inhibition (e) or stimulated with the corrector VX-809 (24 h pretreatment; 3  $\mu$ M), the potentiator VX-770 (simultaneously with forskolin; 3  $\mu$ M) or a combined compound treatment with or without CFTR inhibition (f) (mean  $\pm$  s.e.m.).

**Figure 5. Differential FIS between organoids from subjects with cystic fibrosis after chemical CFTR restoration.**

(a–c) Quantification of FIS in organoids derived from nine individuals with cystic fibrosis pretreated for 24 h with VRT-325 (10  $\mu$ M), Corr-4a (10  $\mu$ M) or both correctors (a), with C8 (10  $\mu$ M), Corr-4a (10  $\mu$ M) or both correctors (b) or stimulated with VX-809 (24 h pretreatment; 3  $\mu$ M), VX-770 (simultaneously with forskolin; 3  $\mu$ M) or both compounds (c). The bars correspond to the bars shown for the ‘severe CF’ group in Figure 3e. Each bar represents FIS expressed as the AUC calculated from the time periods shown in Figure 4d–f (baseline = 100%, t = 60 min) corrected for the FIS of DMSO-treated organoids and averaged from at least three independent experiments performed at weekly intervals (mean  $\pm$  s.e.m.). (d) Average FIS responses of compound-treated F508del F508del organoids (n = 6 from a–c) and DMSO-treated F508del A455E organoids (n = 2) relative to the average FIS of DMSO-treated healthy control organoids (n = 3) expressed as the AUC calculated from the time periods shown in Figure 4d–f (baseline = 100%, t = 60 min; mean  $\pm$  s.e.m.).

healthy control organoids, but we detected only the B band in F508del CFTR organoids (Fig. 3a). We found no CFTR B or C band in organoids carrying E60X [30] and a previously unreported allele that induces a frame shift in nucleotide-binding domain 2 (NBD2) at residue 1295 (4015delATTT). We further showed the specificity of the CFTR B and C bands using treatment with Endoglycosidase H (Endo H) and PNGase F [5], respectively. CFTR colocalized with apical actin in healthy control organoids but not F508del CFTR organoids

(Fig. 3b). As observed in mouse organoids, rapid FIS of healthy control organoids was sensitive to chemical inhibition of CFTR (Fig. 3c). Human organoids showed somewhat slower kinetics compared to mouse organoids, rarely collapsed and required a longer preincubation time with CFTR inhibitors (3 h) (Fig. 3c, Supplementary Fig. 2c and Supplementary Video 2).

We analyzed FIS in a large number of intestinal organoids derived primarily from the rectum but

also from the duodenum, ileum and colon. We observed strong FIS in organoids derived from healthy control subjects (Fig. 3d and Supplementary Fig. 3a). Rectal organoids derived from individuals compound heterozygous for F508del and A455E [31], a genotype that is associated with mild cystic fibrosis [32], clearly showed reduced amounts of FIS compared to healthy control organoids (Supplementary Video 2). Subjects with severe cystic fibrosis genotypes (homozygous for F508del or compound heterozygous for F508del and L927P [33] or G542X [31]) showed much less FIS that was variable between individual subjects (Fig. 3e and Supplementary Video 2). We observed no FIS in E60X 4015delATTT organoids (Supplementary Video 2). Chemical inhibition of CFTR abolished all FIS responses of organoids from subjects with cystic fibrosis (Supplementary Fig. 3b).

FIS measurements of *in vitro*-expanded organoids derived from healthy controls or individuals with cystic fibrosis, subdivided into severe and mild genotypes, correlated tightly with forskolin-induced intestinal current measurements (ICMs) performed on rectal suction biopsies [34, 35] from which these organoids originated (Fig. 3f). Most ICM tracings of biopsies from individuals with cystic fibrosis showed residual forskolin-induced anion currents that corresponded to a quantitatively similar CFTR-dependent forskolin response in the FIS assay (Supplementary Fig. 4a–c). Together these data indicate that FIS in human organoids can accurately measure CFTR function and show that residual CFTR function in rectal organoids may differ between individuals homozygous for the CFTR F508del mutation.

### CFTR restoration in cystic fibrosis organoids

We next assessed functional restoration of F508del CFTR in human organoids using either low temperature or the chemical correctors VRT-325, Corr-4a, C8 (<http://cftrfolding.org>) and VX-809 [36] and the potentiator VX-770 [9]. Incubation of CFTR F508del homozygous organoids at low temperature (27 °C) increased FIS (Fig. 4a). We next established

dose-response curves for a single treatment of VX-809 (preincubated for 24 h) or VX-770 (added simultaneously with forskolin) in organoids from six subjects homozygous for CFTR F508del (Fig. 4b) and measured half-maximal effective concentration ( $EC_{50}$ ) values of  $135 \pm 40$  nM (mean  $\pm$  s.d.) and  $161 \pm 39$  nM for the two treatments, respectively. These dose responses are within the ranges reported in human bronchial epithelial cells [9, 36]. VX-809 combined with VX-770 induced increased FIS, which was abolished by chemical CFTR inhibition (Fig. 4c). We next assayed FIS after 24 h of preincubation with multiple correctors in F508del homozygous organoids. All correctors increased FIS, albeit with different efficacies (Fig. 4d–f, Supplementary Video 3 and Supplementary Fig. 5a). We observed that VRT-325 and Corr-4a or C8 and Corr-4a synergistically increased FIS, which was in contrast to the additive effect of VRT-325 and Corr-4a in mouse organoids (Fig. 2g). Restoration of the function of F508del CFTR by temperature and chemicals were all sensitive to CFTR inhibitors (Fig. 4a,c–f). These data indicate that FIS can reliably measure correction or potentiation of F508del CFTR.

We next studied FIS responses to a panel of CFTR-restoring drugs in rectal organoids derived from nine individuals harboring various severe CFTR mutations, including six F508del homozygous organoids. We observed different amounts of drug-induced FIS between various F508del homozygous organoids (Fig. 5a–c and Supplementary Fig. 5b). FIS was variable between organoids after incubation with single drugs, and the distribution of high and low responders was unique for a restoration approach (Fig. 5a–c). The CF5 organoid seems to be a low responder to any corrector or to VX-770 but showed an exceptionally small response to VRT-325. The CF3 and CF5 organoids showed similar responses to VX-809 but differed in their responses to C8. The measured FIS over the expected FIS (additive values of single treatment; Supplementary Fig. 6) indicated stronger synergy between VRT-325 and Corr-4a than between C8 and Corr-4a and was relatively constant between

most organoids. All F508del compound heterozygous organoids also responded to correction, but no correction or potentiation was observed in E60X 4015delATTT organoids (Fig. 5a–c). We next compared the efficacy of approaches to restore the function of F508del CFTR by comparing the amount of FIS to that in mock-treated F508del A455E organoids or healthy control organoids (Fig. 5d). This comparison indicated that VX-809 is the most potent corrector and combined treatment with VX-809 and VX-770 induced FIS beyond the amounts in F508del A455E organoids, reaching ~60% of the FIS in healthy controls. Together these results demonstrate that the potency of CFTR-targeting compounds to restore CFTR function varies widely between organoids from individuals with cystic fibrosis, including CFTR F508del homozygous organoids.

## DISCUSSION

Our results collectively indicate that FIS of mouse and human intestinal organoids is CFTR dependent. Rapid FIS probably results from the near-physiological characteristics of intestinal organoids. Previous data have indicated that forskolin can increase luminal expansion in organoid-like structures grown from renal MDCK cells, colonic LIM1863 cell lines or mouse intestinal spheroids [20, 37, 38], but the larger amplitude and rate of the FIS probably results from higher CFTR expression levels in the primary tissue culture model used here.

Fluid transport measured by FIS in rectal organoids correlated to the ICMs performed on the corresponding rectal suction biopsies. The FIS assay can therefore be a valuable supplement to the electrical measurements of CFTR function currently carried out in cystic fibrosis treatment and research centers and may complement ICM data. Using ICMs and FIS, we found that most subjects harboring CFTR F508del showed some residual CFTR function, suggesting that F508del CFTR is expressed at low levels at the apical surface [39, 40]. This is also supported by the induction of FIS by the potentiator VX-770 in the absence of correctors, as was previously reported for human

bronchial epithelial cells [9]. Clinical data also support low apical expression of F508del CFTR in subjects homozygous for F508del [41]. The paired FIS and ICM allows for the comparison of fluid secretion rates and ion fluxes as measured by ICM. On the basis of the geometry of organoids during FIS and the assumptions that the average organoid lumen is a sphere and the average swelling is similar in all three dimensions and is linear during an experiment, we calculated an initial fluid secretion rate of  $26 \pm 23 \mu\text{l} (\text{mean} \pm \text{s.d.}) \text{h}^{-1} \text{cm}^{-2}$  in healthy control organoids (corresponding to an estimated current of  $1.0 \times 102 \mu\text{A} \text{cm}^{-2}$  on the basis of isotonic chloride secretion). When we assumed isotonic chloride secretion during ICM, we estimated that the measured currents would correspond to an approximate fluid secretion rate of  $12 \mu\text{l} \text{h}^{-1} \text{cm}^{-2}$ . This rate largely exceeds the values reported previously for cysts from MDCK cells [42] and airway epithelium [43].

We demonstrate that FIS can measure functional restoration of CFTR by drugs. Notably, we observed that drug responses between organoids derived from subjects with cystic fibrosis are variable, even between CFTR F508del homozygous organoids. This raises the possibility that this *in vitro* assay may predict *in vivo* drug responsiveness of individual subjects. An ideal therapeutic model for cystic fibrosis would be to screen the effectiveness of available CFTR-restoring drugs directly after diagnosis to optimize treatment at the personal level before disease onset. Personalized medicine approaches may also facilitate the development and approval of drugs to which only subgroups of subjects respond and limit the economic risks associated with drug research. Furthermore, FIS of organoids can be used for approval of drugs in subjects that are genotypically mismatched with drugs that have been validated for a specific *CFTR* genotype. Interim phase 2 results of a current trial published on websites of the North American Cystic Fibrosis Foundation (<http://www.cff.org/>) and Vertex (<http://www.vrtx.com/>) indicate that drug responses to VX-809 and VX-770 together or to VX-770 alone are highly variable between subjects harboring

CFTR F508del. However, the predictive potential of organoid-based measurements of CFTR function for *in vivo* drug responsiveness remains to be established.

Individual drug responses may be predicted currently using *ex vivo* rectal biopsies [44] or primary airway tissue culture models [45]. Compared with these techniques, organoid cultures seem superior in generating large data sets from individual subjects. CFTR function analysis in organoid cultures is relatively easy, fast and robust. The organoids autodifferentiate into tissue-recapitulating structures in 96-well plates, allowing for the measurement of up to 80 organoids per well and up to 96 conditions per experiment. In this format, dose-response curves measured in triplicate for multiple drugs per individual can be easily generated at multiple culture time points, as we demonstrate here.

Using our image analysis approach, higher throughput approaches to identify new compounds that restore CFTR function may be developed. When we compare the drug responses in organoids with the limited clinical data that have been published in subjects homozygous for CFTR F508del [13, 14] (<http://www.cff.org/>), only the combination of VX-809 and VX-770 has been reported to improve lung function in approximately 50% of these individuals. This combination induces approximately 1.5-fold more FIS in CFTR F508del homozygous organoids as compared to untreated F508del A455E organoids and up to 60% of the FIS seen in healthy controls. It is not uncommon that treatment effects in *in vitro* models are superior to the effects measured *in vivo*, but the correction in the FIS assay also exceeds the correction in cultured human bronchial epithelium by approximately twofold [9, 36]. This might indicate that tissue-specific factors may control corrector efficacy. It is also probable that FIS rates are underestimated in healthy control organoids when CFTR expression is no longer rate limiting for FIS beyond a particular threshold by, for example, basolateral ion transport. These data suggest that new CFTR-restoring drugs may have clinical impact when FIS reaches up to ~60% of the FIS in

wild-type organoids.

Two important aspects of organoid cultures render this technology highly suitable for follow-up studies. First, organoids can be greatly expanded while maintaining intact stem cell compartments during long-term culture (over 40 passages) [16]. The generation of large numbers of cells will aid cell biological and biochemical studies of CFTR-dependent cellular alterations and is a prerequisite for high-throughput screens. Second, primary cell banks from individuals with cystic fibrosis can be generated by storage of organoids in liquid nitrogen. These can be used to identify and study cellular factors associated with clinical phenotypes and would allow for the analysis of newly developed drugs at the individual level using materials that have been acquired previously.

In addition, this assay may be suitable for the development of drugs to treat secretory diarrhea, a life-threatening condition that results from CFTR hyperactivation by pathogenic toxins such as cholera toxin [46] (Supplementary Fig. 7), and for electrolyte homeostasis studies in general.

We describe a quick and robust assay for the quantification of CFTR function using a primary intestinal culture model that recapitulates essential features of the *in vivo* tissue architecture. This relatively simple assay will facilitate diagnosis, functional studies, drug development and personalized medicine approaches in cystic fibrosis.

## METHODS

### Mice

*Cftr*<sup>tm1Cam</sup> knockout (*Cftr*<sup>-/-</sup>) mice [24] were backcrossed with FVB mice, and *Cftr*<sup>tm1eur</sup> (*Cftr* F508del) [25, 26] were backcrossed with C57BL/6 (F12) mice. Congenic FVB *Cftr*<sup>-/-</sup> mice (male) or C57BL/6 *Cftr* F508del mice (male and female) were used with their wild-type littermates. The mice were maintained in an environmentally controlled facility at Erasmus MC Rotterdam, and the animal

studies were approved by the Erasmus MC ethical committee.

### Human material

Approval for this study was obtained by the ethics committees of the University Medical Centre Utrecht and Erasmus MC Rotterdam. Informed consent was obtained from all subjects participating in the study. Rectal organoids from healthy controls and subjects with cystic fibrosis were generated from four rectal suction biopsies after ICMs obtained (i) during standard cystic fibrosis care (one individual each harboring E60X 4015ATTTdel, F508del G542X or F508del L927P and five individuals harboring F508del F508del), (ii) for diagnostic purposes (one healthy control) or (iii) during voluntary participation in studies approved by the University Medical Center Utrecht and Erasmus MC ethics committees (two healthy controls and one individual harboring F508del F508del). Material from an individual homozygous for F508del CFTR and a healthy control was derived from proximal ileum rest sections after surgery for meconium ileus. Four duodenal biopsies were obtained from two subjects with cystic fibrosis by flexible gastroduodenoscopy to generate F508del F508del and F508del exon17del organoids. The same procedure was used to obtain four biopsies from two subjects with suspected celiac disease. The biopsies were macroscopically and pathologically normal and used to generate healthy control organoids.

### Crypt isolation and organoid culture from mouse intestine

Mouse organoids were generated from isolated small intestinal crypts and maintained in culture as described previously [15]. R-spondin 1 (Rspo1)-conditioned medium (stably transfected Rspo-1 HEK293T cells were kindly provided by C.J. Kuo, Department of Medicine, Stanford, CA) was used instead of recombinant Rspo-1 and was added to the culture medium at a 1:10 dilution. *Cftr*<sup>-/-</sup> and *Cftr* F508del organoids were obtained from proximal and distal small intestinal segments, respectively. Organoids from passages 1–10 were used for confocal imaging.

### Crypt isolation and organoid culture from human biopsies

Crypt isolation and culture of human intestinal cells has been described previously [16]. In short, biopsies were washed with cold complete chelation solution and incubated with 10 mM EDTA for 30 (small intestine) or 60 (rectum) min at 4 °C. The supernatant was harvested, and EDTA was washed away. Crypts were isolated by centrifugation and embedded in Matrigel (growth factor reduced, phenol free; BD bioscience) and seeded (50–200 crypts per 50 µl Matrigel per well) in 24-well plates. The Matrigel was polymerized for 10 min at 37 °C and immersed in complete culture medium consisting of advanced DMEM/F12 supplemented with penicillin and streptomycin, 10 mM HEPES, Glutamax, N2, B27 (all from Invitrogen), 1 µM N-acetylcysteine (Sigma) and the following growth factors: 50 ng ml<sup>-1</sup> mouse epidermal growth factor (mEGF), 50% Wnt3a-conditioned medium (WCM) and 10% noggin-conditioned medium (NCM), 20% Rspo1-conditioned medium, 10 µM nicotinamide (Sigma), 10 nM gastrin (Sigma), 500 nM A83-01 (Tocris) and 10 µM SB202190 (Sigma). The medium was refreshed every 2–3 d, and organoids were passaged 1:4 every 7–10 d. Organoids from passages 1–10 were used for confocal live-cell imaging. For production of WCM and NCM, Wnt3a-producing L Cells (ATCC, CRL-264) were selected for high-expressing subclones, and human full-length noggin was stably transfected into HEK293T cells, respectively. Amounts and activity of the expressed factors in each batch were assessed using dot blots and luciferase reporter plasmids (TOPflash and FOPflash; Millipore) as described previously [47, 48].

### Stimulation assays

Human or mouse organoids from a 7-day-old culture were seeded in a flat-bottom 96-well culture plate (Nunc) in 5 µl Matrigel commonly containing 20–80 organoids and 100 µl culture medium. One day after seeding, organoids were incubated for 60 min with 100 µl standard culture medium containing 10 µM calcein green (Invitrogen). For optimal CFTR inhibition, organoids were preincubated for 2 (mouse) or 3

h (human) with 50  $\mu$ M CFTRinh-172, 50  $\mu$ M GlyH-101 or their combined treatment (both from Cystic Fibrosis Foundation Therapeutics, Inc). After calcein green treatment (with or without CFTR inhibition), 5  $\mu$ M forskolin was added, and organoids were directly analyzed by confocal live-cell microscopy (LSM710, Zeiss,  $\times 5$  objective). Three wells were used to study one condition, and up to 60 wells were analyzed per experiment. For CFTR correction, organoids were preincubated for 24 h with 10  $\mu$ M VRT-325, 10  $\mu$ M Corr-4a, 10  $\mu$ M C8 (all from Cystic Fibrosis Foundation Therapeutics, Inc), 3  $\mu$ M VX-809 (Selleck Chemicals LLC, Houston, USA) or combinations thereof, as indicated. For CFTR potentiation, 3  $\mu$ M VX-770 (Selleck Chemicals LLC) was added simultaneously with forskolin. Dilutions of VX-809 and VX-770 were used as indicated in Figure 4b.

#### Quantification of organoid surface area

Forskolin-stimulated organoid swelling was automatically quantified using Volocity imaging software (Improvision). The total organoid area (xy plane) increase relative to that at  $t = 0$  of forskolin treatment was calculated and averaged from three individual wells per condition. The AUC was calculated using Graphpad Prism.

#### Statistical analyses

A Kolmogorov-Smirnov test was used to test whether the ICM and FIS data were normally distributed. A paired Student's  $t$  test was used to compare FIS with or without preselection of responding organoids (Supplementary Fig. 1e). A Spearman's rank correlation test was used to correlate ICM measurements with organoid swelling (Supplementary Fig. 4c).  $P < 0.05$  was considered statistically significant. All data were analyzed in SPSS statistics version 20.0 for Windows.

#### RNA isolation and quantitative PCR

RNA was isolated with the RNeasy minikit (Qiagen) and quantified by optical density from human duodenal organoids that were cultured for  $>12$  weeks. cDNA was synthesized from 1  $\mu$ g of RNA by performing RT-PCR (Invitrogen). From mouse small intestinal organoids that were cultured for  $>6$  weeks, RNA was isolated

using TRIzol (Invitrogen) and quantified by optical density. cDNA was generated from 500 ng using the iScript cDNA synthesis kit (Bio-Rad). mRNA levels of human *CFTR* and mouse *Cftr* were determined by quantitative real-time RT-PCR with the SYBR Green method (Bio-Rad). Glyceraldehyde-3-phosphate dehydrogenase (*GADPH*) or  $\beta 2m$  mRNA abundance was used to measure cDNA input.

#### Western blot analysis

For CFTR protein detection, organoids from healthy controls or subjects with cystic fibrosis were lysed in Laemmli buffer supplemented with complete protease inhibitor tablets (Roche). Lysates were analyzed by SDS-PAGE and electrophoretically transferred to a polyvinylidene difluoride membrane (Millipore). The membrane was blocked with 5% milk protein in TBST (0.3% Tween, 10 mM Tris, pH 8, and 150 mM NaCl in  $H_2O$ ) and probed overnight at 4  $^{\circ}C$  with a combination of the mouse monoclonal CFTR-specific antibodies 450, 570 and 596 (1:5,000, Cystic Fibrosis Folding consortium) followed by incubation with goat mouse-specific horseradish peroxidase (HRP)-conjugated secondary antibodies (1:3,000, Jackson ImmunoResearch, 115-035-146) and enhanced chemiluminescence (ECL) development. For CFTR deglycosylation, healthy control organoids were lysed in RIPA buffer (50 mM Tris, pH 8.0, 150 mM NaCl, 0.1% SDS, 0.5% sodium deoxycholate and 1% Triton) supplemented with complete protease inhibitor tablets (Roche) and incubated with PNGase F and Endo H for 3 h at 33  $^{\circ}C$  (both from New England BioLabs).

#### Immunocytochemistry

Complete organoids from a 5-day-old culture were incubated with methanol (Sigma) for 10 min at  $-20^{\circ}C$ . Organoids were probed with the mouse monoclonal CFTR-specific antibody M3A7 (1:25, Abcam, AB4067) for 16 h at 4  $^{\circ}C$  followed by simultaneous incubation of Alexa Fluor 649-conjugated secondary antibodies (1:500, Jackson ImmunoResearch, 115-495-205) and phalloidin-FITC for 1 h at 4  $^{\circ}C$  (1:200, Sigma). Organoids were embedded in Mowiol

containing DAPI (1:10,000) and analyzed by confocal microscopy as described previously [49].

## ICM

Trans-epithelial chloride secretion in human rectal suction biopsies (four per subject) was measured as described previously [34] using a recent amendment (repetitive prewashing) [35], which better accentuates forskolin-induced anion current responses by reducing basal cAMP levels. In short, the biopsies were collected in PBS on ice and directly mounted in adapted micro-Ussing chambers (aperture. 1.13 or 1.77 mm<sup>2</sup>). After equilibration, the following compounds were added in a standardized order to the mucosal (M) or serosal (S) side of the tissue: amiloride (0.01 mM, M), to inhibit amiloride-sensitive electrogenic Na<sup>+</sup> absorption; carbachol (0.1 mM, S), to initiate cholinergic Ca<sup>2+</sup>-linked and protein kinase C-linked Cl<sup>-</sup> secretion; DIDS (0.2 mM, M), to inhibit DIDS-sensitive, non-CFTR Cl<sup>-</sup> channels such as the Ca<sup>2+</sup>-dependent Cl<sup>-</sup> channels; histamine (0.5 mM, S), to reactivate the Ca<sup>2+</sup>-dependent secretory pathway and measure the DIDS-insensitive component of Ca<sup>2+</sup>-dependent Cl<sup>-</sup> secretion; and forskolin (0.01 mM, S), to fully activate CFTR-mediated anion secretion. Crude short circuit current values (μA) were converted to μA cm<sup>-2</sup> on the basis of the surface area of the aperture.

## ACKNOWLEDGMENTS

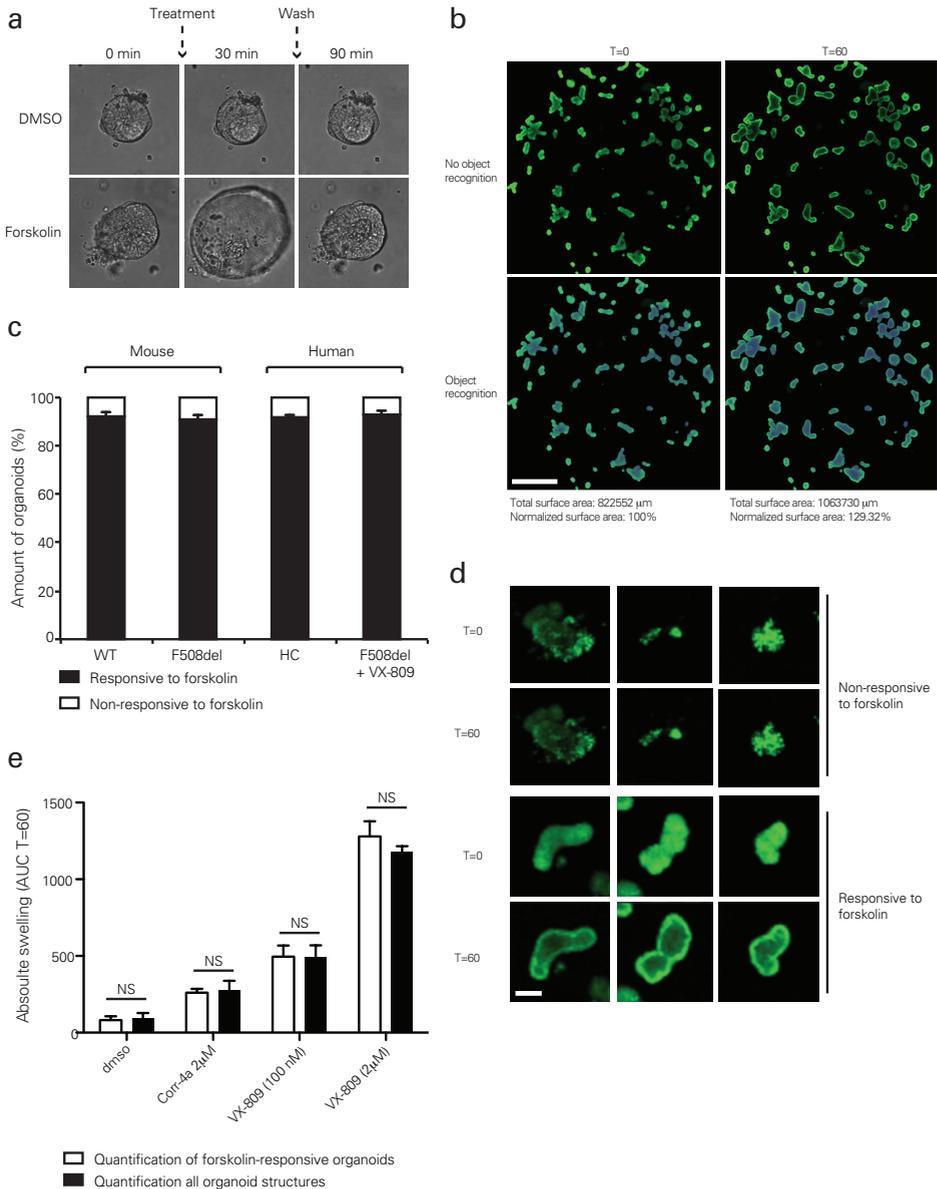

We thank K. Schneeberger for technical assistance, the Department of Pediatric Gastroenterology of the Wilhelmina Children's Hospital for performing gastroduodenoscopy to obtain intestinal biopsies, K. Tenbrock (Department of Pediatrics, Rheinisch-Westfälische Technische Hochschule (RWTH) Aachen University) and J.C. Escher (Department of Pediatric Gastroenterology, Erasmus MC–Sophia Children's Hospital) for providing intestinal rest-material, C.J. Kuo (Department of Medicine, Stanford) for providing the R-spondin 1-producing cell line, J. Riordan (Department of Biochemistry and

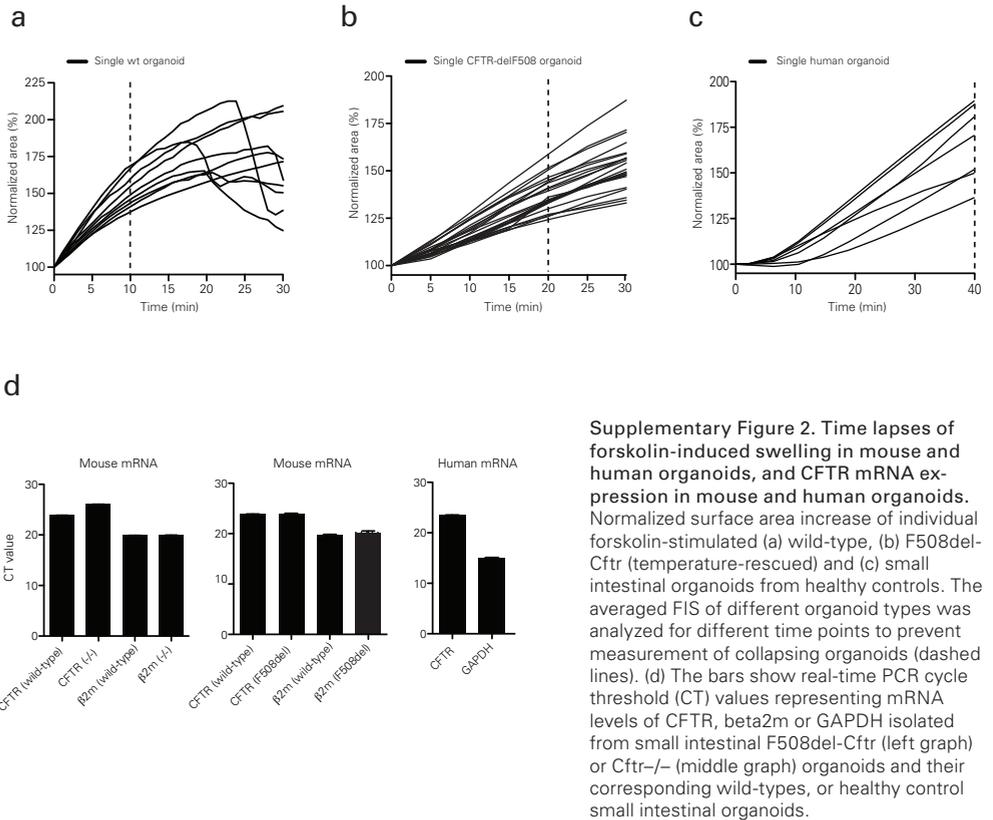

Biophysics, University of North Carolina at Chapel Hill) for CFTR-specific monoclonal antibodies, R. Bridges (Department of Rosalind Franklin University of Medicine and Science) and Cystic Fibrosis Foundation Therapeutics for providing CFTR-restoring compounds, P.W. van Leeuwen for assistance with statistical analyses and C.B.M. ten Brink for assistance with Volocity software. This research was partly funded by a grant from the WKZ research fund (OZF-2010) and the Dutch Cystic Fibrosis society (NCFS).

## ABSTRACT

Celiac disease is caused by an aberrant immune response to gluten in patients with genetic susceptibility. T-helper cells take center stage in the pathogenesis of the disease by recognizing gluten-derived peptides and promoting a pro-inflammatory environment, for example by inducing interferon gamma ( $\text{IFN}\gamma$ ) production. Additionally, T-helper cells aid B-cells to produce gluten- and transglutaminase 2 (TG2)-specific antibodies and increased serum levels of TG2-antibodies are indicative for active celiac disease.

Nonetheless, enterocytes might also be involved in celiac disease, since enterocytes from patients with celiac disease show alterations in gene expression, such as increased expression levels of  $\text{IFN}\gamma$ -responsive genes and *TGM2*, the gene encoding TG2. However, it is not known if these enterocytic changes are programmed intrinsically, induced directly by the antigen or indirectly by external factors. Therefore, we have generated epithelial organoid cultures from patients with celiac disease and healthy individuals and compared mRNA expression profiles after long-term culture with their respective biopsies. Our data show that differentially expressed genes in biopsies from patients with celiac disease were normalized upon long-term culture compared to controls. However, these genes were similarly induced in both healthy and celiac organoids upon stimulation with either  $\text{IFN}\gamma$  or retinoic acid (RA), a metabolite of vitamin A, which has been shown to have a critical role in the induction of intestinal regulatory responses [1-3]. In conclusion, our data suggest that the intestinal epithelium of patients with celiac disease is not intrinsically different from healthy control epithelium. Despite the fact that the intestinal epithelium might not have a primary role in celiac disease, patient-specific organoids could provide a useful model for understanding epithelial transport of gliadins or for co-culturing with immune cells to better comprehend celiac disease pathophysiology.

## INTRODUCTION

Celiac disease is an immune-mediated disorder caused by an abnormal inflammatory response to gluten in genetically susceptible patients. The prevalence of the disease is estimated to be ~1% in Europe [4]. In a small percentage of the people carrying the celiac disease-associated DQ2 or DQ8 HLA types, the ingestion of mainly wheat gluten leads to massive small-bowel mucosal inflammation, crypt hyperplasia, villous atrophy and clinical symptoms, such as failure to grow, abdominal pain and/or malabsorption problems. Other secondary symptoms, such as fatigue, vitamin deficiency and anemia are also commonly reported [5, 6]. The only current therapy that reverses this phenotype is a gluten free diet (GFD). Although a small group of patients suffers from refractory celiac disease and maintain their symptoms despite refraining from gluten [7-9].

Gluten is a protein found in wheat and contains the 'toxic' gliadin [10]. Barley and rye have similar prolamins, hordeins and secalins, which are able to elicit the same response [11]. These storage proteins are highly enriched in the amino acids proline and glutamine. Due to resistance of proline to digestion by intestinal proteases [12], long fragments remain undigested in the intestinal lumen. It was suggested that these fragments are transported to the lamina propria due to increased intestinal permeability [13], although more recent studies show evidence of epithelial transcytosis as the main mechanism [14-16]. Subsequently, glutamine is deamidated (converted to glutamate) by TG2 and negatively charged, which increases binding affinity with the HLA-DQ2/8 molecules that are present on antigen presenting cells [17, 18]. Gliadin fragments are presented to T-helper cells, which help to create a pro-inflammatory environment, after surpassing a minimal threshold of antigen presentation [19]. The pro-inflammatory environment, marked by high IFN $\gamma$  levels [20], is important for two reasons. First, IFN $\gamma$  increases expression of HLA-DQ molecules, therefore enhancing T-cell recognition of gluten peptides [21]. Second, IFN $\gamma$  induces cytotoxic T-cell activation that

promotes intestinal damage [22]. This in turn increases release and activation of TG2 and thus improves deamidation and sustains antigen presentation of gluten peptides [23]. Moreover, T-helper cells promote B cell differentiation into plasma cells [24], which produce TG2 antibodies, one of the main serum markers for celiac disease [6, 25]. The discovery of gluten-specific T-helper cells that were only present in celiac patients explains the major role of these cells in the development of celiac disease [26, 27].

The haplotype HLA-DQ2 and/or HLA-DQ8 that is associated with celiac disease is present in ~30% of the population. However, only ~1% of the people develop celiac disease [4]. This suggests that other factors than HLA and gluten-specific T cells must be involved in developing celiac disease. One of the factors that is suggested and debated in literature is the intestinal epithelium. Although it seems quite unlikely that the intestinal epithelium plays a role in the pathogenesis of this clearly immune-mediated disease, the epithelium is an important barrier between gliadin peptides in the intestinal lumen and the T-helper cells in the lamina propria. Moreover, several studies have shown that enterocytes of patients with celiac disease show aberrant expression of several genes in biopsies or in response to gliadin challenge.

One study revealed an increased expression of interleukin 15 (IL15) in enterocytes, even after eight years of GFD [28]. Another study showed increased crypt enterocyte proliferation in biopsy samples of GFD-treated celiac patients [29] and suggests that this is an intrinsic property of celiac enterocytes. Furthermore, gliadin and its p31-49 derived peptide were shown to induce *in vitro* protein expression of MICA, a type of MHC class I molecule, in intestinal epithelial cells from celiac patients on GFD [30]. Interferon regulatory factor-1 (IRF1) and signal transducer and activator of transcription 1 (STAT1), both IFN $\gamma$ -responsive genes, were upregulated in both lamina propria cells and epithelium upon *in vitro* gliadin exposure in active and GFD-treated celiac patients [31].

Although these and other studies have shown that enterocytes of celiac patients are affected, the majority of these studies were performed on whole biopsies or with freshly isolated enterocytes from biopsies. In this way, it is not possible to determine if these effects are programmed intrinsically, caused by an aberrant response to antigen or are induced by environmental factors, such as cytokines.

As such, it is to our knowledge not yet established whether the enterocytic alterations in intestinal epithelial cells of patients with celiac disease are primary or secondary effects. We hypothesized that the reported enterocytic alterations are secondary effects mediated by inflammatory cytokines such as IFN $\gamma$  and RA, which have been shown to upregulate the gene encoding TG2, TGM2, one of the major initiators of celiac disease [32-37]. We addressed this hypothesis by establishing pure epithelial cell cultures, so-called organoids, from both celiac patients and healthy control subjects with the same HLA-DQ haplotype. We determined if the expression of epithelial genes, which were up- or down regulated in biopsy material of celiac patients, were maintained after long-term culture in absence or presence of IFN $\gamma$  and RA.

## METHODS

### Patient material

Duodenal biopsy material was obtained from patients with a positive HLA-DQ2.5 genotype who were suspected for celiac disease. All participants (and/or parents) were informed about the study and signed written informed consent. The study protocol was examined and approved by the local medical ethics committee of the University Medical Centre Utrecht. Biopsy material was utilized for real-time polymerase chain reaction (RT-PCR) or organoid establishment. Healthy control subjects (5 female, 1 male, median age 5 years old, range 3-9 years) were selected on serum immunoglobulin A (IgA) anti-tissue transglutaminase antibodies (IgA-TG2) of 0 U/ml, combined with a Marsch criteria of 0 and no other pathologic features on histology. Celiac

disease patients (4 female, 1 male, median age 12 years old, range 4-15 years) had a minimum of Marsch 3a criteria on histology and elevated serum levels of IgA- endomysial antibodies and IgA-TG2.

### Organoid culture

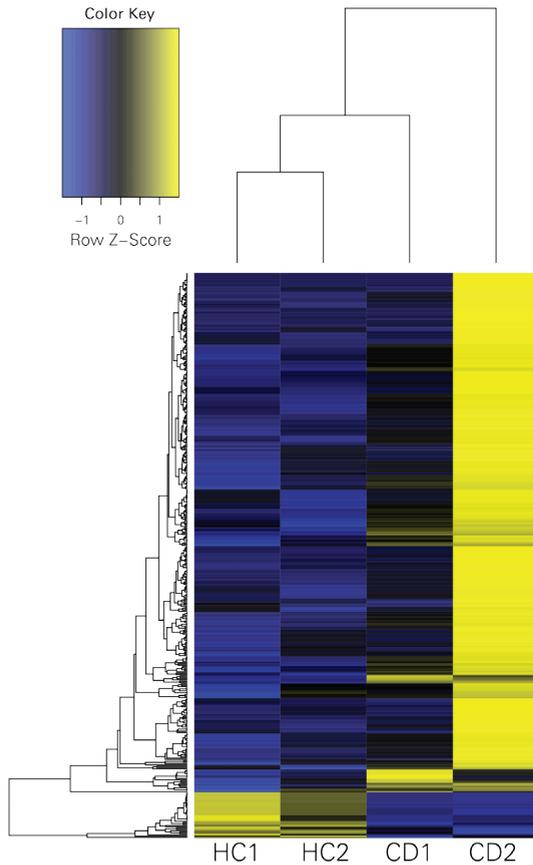

Crypts were isolated from patients' biopsies and cultured as described previously [38]. Duodenal organoids were cultured in expansion medium (containing WNT3A, epidermal growth factor, noggin, R-spondin1, A83-01, N-actylcysteine, B27, SB202190 and nicotinamide) and passaged weekly. Per experiment, organoids (passages varied from 6-14) were cultured with one batch of expansion medium. Differentiation was induced in cultures that were grown in expansion medium for 2 days, followed by 5 days in differentiation medium (expansion medium without WNT3A, nicotinamide and SB202190). For stimulation IFN $\gamma$  (eBioscience, 1000 IU/ml dissolved in DMSO) was added to the culture medium for 48 hours before harvesting. Retinoic acid (Sigma, 15  $\mu$ M in DMSO) was added to the organoids 5 hours before harvesting. Unstimulated organoids were treated with similar amount of DMSO as vehicle control. Organoids were photographed with an EVOS-microscope, representative pictures of healthy and celiac organoids are depicted in Supplementary Figure 2.

### RNA isolation, mRNA sequencing and real-time PCR

RNA isolation, mRNA sequencing and real-time PCR was performed as described previously [39]. The mRNA sequencing data were analyzed using R with the DESeq package [40]. For real-time PCR data were Data were analyzed in GraphPad Prism, expressed as median, and analyzed for significant differences using the Mann Whitney test.  $P < 0.05$  was considered statistically significant. Supplementary Table 2 shows an overview of the primers we have used. *ACT11N* mRNA abundance was used to normalize the data.

## RESULTS

Literature about differentially expressed genes

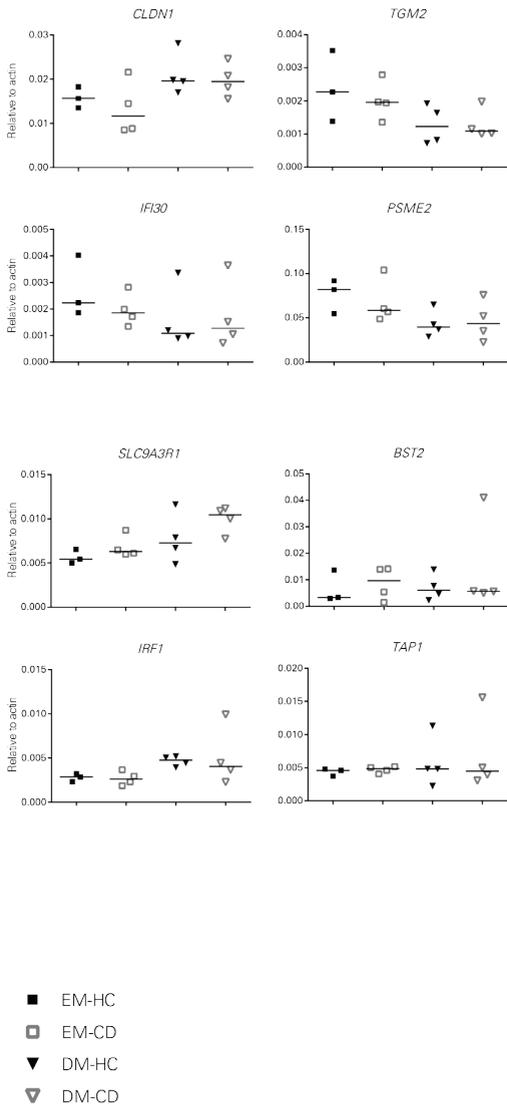

**Figure 1. Differential gene expression in biopsies of celiac patients compared to healthy controls.** mRNA sequencing was performed on biopsies derived from healthy controls (n=2) and celiac patients (n=2). Yellow indicates maximal expression and blue indicates zero expression. In each compartment, genes are sorted by chromosomal location.

in celiac disease is extensive and sometimes contradictory [23, 31, 41-51]. Therefore, we first performed mRNA sequencing on a selection of duodenal biopsies of celiac patients and healthy controls. Two biopsies per group were sequenced and all differentially expressed genes with  $>0.6$  fold difference and a p-value  $<0.05$  were selected, resulting in a list of 450 genes (Figure 1A and Suppl. Table 1), from which 300 genes were unique values and 150 duplicates. Of these 450 genes, 34 genes

were downregulated in celiac biopsies (Suppl. Table 1A) and 416 genes were upregulated in celiac biopsies (Suppl. Table 1B). Notably, CD3 gene expression, a lymphocyte marker, was significantly upregulated in celiac biopsies, which was in agreement with Marsch 3 criteria.

We cross-checked our list of candidate genes with literature to select previously identified genes that were shown to be different in celiac patients compared to controls [23, 31, 41-46, 52, 53]. From our list, 25 genes were identified in other studies, from which ten correlated with the literature and were upregulated in celiac patients. In contrast, we have found 12 genes that were negatively correlated with literature [42, 45]. For example, FABP1 and GSTA1 were both found downregulated in celiac patients by proteomics [45], while they were upregulated in our biopsies. Additionally, three genes were shown to be contradictory in different studies: *DEFA6*, *MUC2* and *FBP1* [47-49, 51], of which we found *FBP1* and *MUC2* to be upregulated in our cohort of celiac patients. One explanation for these discrepancies could be that the studies were performed in adults, while our study is performed in children. Previously, discrepancies between adult and pediatric celiac patients have been described [54, 55]. Nonetheless, our data did correlate with one of the adult studies [41], therefore a heterogeneous celiac population is a more probable explanation for these discrepancies.

We have focused on genes that were differentially expressed in epithelial cells and were in concordance (ten genes) and contradictory (two genes) with previous literature. From this list of 12 genes, we selected eight genes for further validation by real-time PCR. One of the selected genes is *TGM2*, since it is the most prominent marker for celiac disease and is increased in biopsies from patients with celiac disease [6, 23, 56]. Ezrin-Radixin-Moesin-Binding Phosphoprotein 50 (EBP50), which is encoded by *SLC9A3R1*, was selected as an important member of the protein complexes that form the brush border of epithelial cells [44, 57, 58]. More importantly, EBP50 was shown to bind to TG2 and as such may have an important role in celiac disease [59]. And

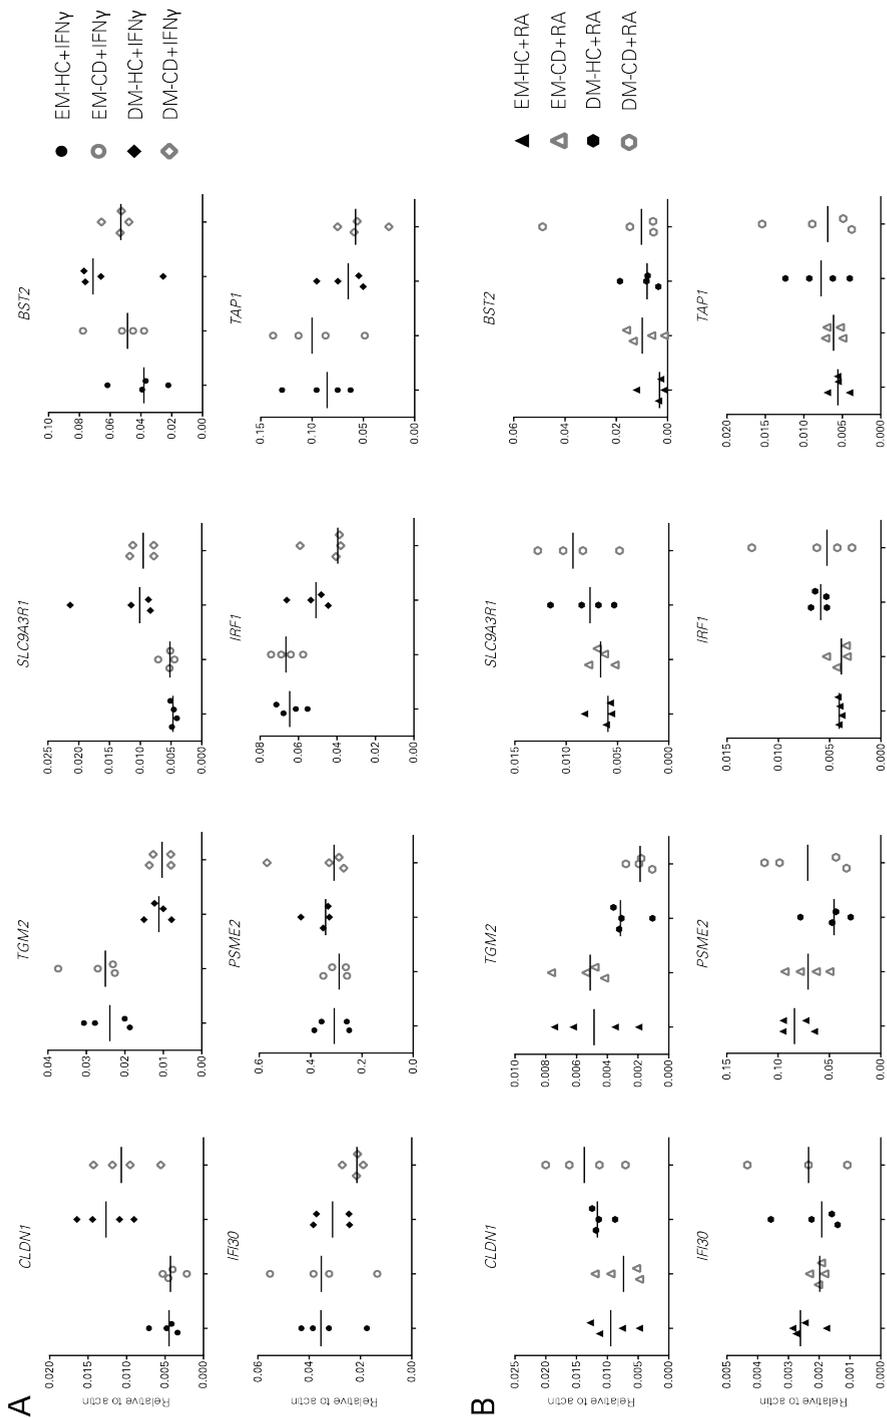

**Figure 2. Similar mRNA expression in epithelial cultures derived from celiac patients and healthy controls.** Relative expression of differentially expressed genes in organoids derived from healthy controls (n=3) and celiac patients (n=4). Organoids were generated from human duodenal biopsies and maintained in EM for a minimum of 6 weeks. Differentiation was induced by incubation in DM for 5 days. Quantitative reverse transcription PCR was performed to measure relative expression of the mentioned genes. Data were normalized to *ACTIN* housekeeping mRNA levels and are represented as median; \*, p<0.05. HC, healthy control; CD, celiac disease; DM, differentiation medium; EM, expansion medium.

although not described in literature, the tight junction protein claudin 1, encoded by *CLDN1*, was clearly downregulated in celiac biopsies in our study and was therefore selected for further analysis. Isolated enterocytes of celiac patients expressed levels of bone marrow stromal cell antigen 2 (*BST2*) and therefore added to our list of candidate genes [41]. Next to these epithelial-specific genes, we added several IFN $\gamma$ -responsive genes to our list of candidate genes: Proteasome activator complex subunit 2 (*PSME2*), IFN $\gamma$  inducible protein 30 (*IFI30*), transporter 1-ATP-binding cassette (*TAP1*) and IFN $\gamma$  regulatory factor 1 (*IRF1*) [31, 43].

mRNA sequencing data showed that these selected genes were indeed differentially expressed in biopsies from celiac patients compared to controls (Figure 1a).

Next, we determined expression of our selection of genes in organoids, which were derived from four celiac patients and four healthy controls and were cultured for a minimum of six weeks. Before analysis, proliferation and differentiation status were assessed by light microscopy, and real-time PCR. Light microscopy did not reveal macroscopic differences between healthy and celiac organoids (Suppl. Figure 1A). We determined mRNA expression of *LGR5* as a marker for crypt-like organoids (cultured in expansion medium, EM) and sucrase-isomaltase (*SI*) for villus-like organoids (cultured in differentiation medium, DM). As such, *LGR5* is expressed in EM and lost upon differentiation, while *SI* was not detected in EM and was upregulated in DM (Suppl. Figure 1B). As expected, the expression levels of *LGR5* and *SI* were similar between celiac organoids and controls, indicating that both organoid cultures behaved identical in terms of proliferation and differentiation.

Furthermore, the expression levels of the selected set of genes, which were differentially expressed in *ex vivo* biopsies, showed no significant differences between healthy and celiac derived organoids after long-term culturing (Figure 2). These data indicate that the

**Figure 3. Organoids from celiac patients respond similarly to IFN $\gamma$  and RA as healthy controls.** Relative expression of differentially expressed genes in organoids stimulated with IFN $\gamma$  (A) or RA (B). Healthy controls (n=4) and celiac patients (n=4) were derived from duodenal biopsies from organoids were either stimulated with 1000 IU/ml IFN $\gamma$  for 48 hours (A) or with 15  $\mu$ M RA for 5 days. Quantitative reverse transcription PCR was performed to measure relative gene expression. Data were normalized to ACTIN housekeeping mRNA levels and are represented as median; \*, p < 0.05. HC, healthy control; CD, celiac disease; DM, differentiation medium; EM, expansion medium; IFN $\gamma$ , interferon gamma; RA, retinoic acid.

differentially expressed genes in biopsies are not intrinsically programmed in epithelial cells and normalize upon long-term culture.

To assess if the differences in biopsies were dependent on changes in the external environment, we stimulated the organoids with IFN $\gamma$ , the main active cytokine in celiac disease. First, the efficiency of IFN $\gamma$  stimulation was validated by analysis of the expression levels of the IFN $\gamma$ -responsive genes *PSME2*, *IFI30*, *TAP1* and *IRF1*. As expected, these genes were significantly upregulated in organoids that were incubated with 1000 IU/ml IFN $\gamma$  compared to vehicle control (Suppl. Figure 2A), indicating sufficient response to IFN $\gamma$ .

Second, we determined expression levels of our selection of genes that were differentially expressed in celiac biopsies. We found that most genes, including *TGM2*, were upregulated upon IFN $\gamma$  stimulation, while *CLDN1* was downregulated (Figure 3A). However, gene expression levels did not differ between the samples, indicating that both healthy and celiac organoids respond similarly to IFN $\gamma$ .

Next, we assessed the response of organoids to exogenous RA, one of the other main mediators of celiac disease. Previously, it has been shown that RA induces the activity of *TGM2* in Caco-2 cells [34]. In concordance, we detected increased levels of *TGM2* after 5 hours of RA exposure (Suppl. Figure 2B). Again, no significant differences were observed between organoids from celiac patients and controls after RA stimulation (Figure 3B), strengthening our hypothesis that epithelial changes in celiac disease are caused by exogenous stimulants.

In conclusion, we did not find any differences in gene expression in organoids derived from patients with celiac disease or healthy controls. Furthermore, stimulation with either IFN $\gamma$  or RA resulted in similar induction of gene expression in both celiac and healthy organoids. Our data indicate that epithelial cells derived from patients with celiac disease, at least for the selected genes, are not intrinsically different and respond similarly to the external stimuli

IFN $\gamma$  and RA.

We conclude that differentially expressed genes in biopsies from patients with celiac disease are probably caused by the inflammatory microenvironment in the lamina propria, consisting of e.g. IFN $\gamma$  and RA, which are produced by activated immune cells upon recognition of deamidated gliadin.

## DISCUSSION

In the pathophysiology of celiac disease, a leading role has been attributed to lymphocytes in response to gluten in genetically susceptible patients [22, 60]. Yet, our current knowledge does not clarify why some genetically susceptible patients do not develop celiac disease, suggesting other factors could be involved. One of these factors mentioned in the literature is the intestinal epithelium, although, its role in celiac disease is debated [29, 60-62]. Recently, a pure epithelial intestinal model was established [63], we used this model to assess if the epithelium from patients with celiac disease is intrinsically different from controls.

In this study, we compared gene expression in *ex vivo* biopsies and long-term epithelial cell cultures derived from patients with celiac disease compared to healthy controls. We found 450 genes that were differentially expressed in biopsies from celiac patients. From this list of genes, we selected eight genes on basis of epithelial specificity and complementary results in literature-based evidence, which renders them as potential candidate genes that could have a primary role in the epithelial component of celiac disease. However, we did not detect differences in mRNA expression of these nine genes in organoids derived from patients or controls. In addition, stimulation with either IFN $\gamma$  or RA resulted in similar induction of these genes in both celiac and control organoids.

One of the limitations of this study is that our gene selection was primarily based on mRNA sequencing of only two biopsies per group. To

prevent selecting coincidentally up- or down-regulated genes in celiac biopsies, we cross-checked all differentially expressed genes with known literature to select the most promising epithelial derived candidates genes. Obviously, our strict selection does not exclude the possibility that other genes might play a role in epithelial cells of celiac disease patients.

Although we cannot discard the epithelium from having a prominent role in celiac disease based on detailed analysis of only eight genes, we think it will be unlikely that other genes will show differential expression in organoids. This assumption is supported by the systematic analysis of genetic loci associated with celiac disease and open chromatin regions from more than 350 human tissue/cell samples (Mokry et al. submitted). While the open chromatin regions from immune cells are enriched around the celiac disease susceptibility loci, open chromatin from intestines does not show any enrichment (Suppl. Figure 3).

Our findings indicate that epithelial cells from patients with celiac disease are not intrinsically different from healthy controls. However, to strengthen this negative finding, further studies are needed in a larger number of patients. Although we suggest that epithelial differences in celiac patients are induced by exogenous factors and probably not caused by intrinsic defects, the organoid model could still be useful to assess gliadin transport in a model that resembles the *in vivo* epithelium. Additionally, co-culture studies could be performed to clarify the pathogenesis of celiac disease by studying the interaction of the epithelium with other cells, such as gliadin-specific T-cells, dendritic cells or fibroblasts.

## ACKNOWLEDGMENTS

We thank the gastroenterologists of the Wilhelmina Children's Hospital for obtaining biopsies and René Eijkemans from the Julius Center of the UMC Utrecht for statistical advice.

**Suppl. Figure 1. Morphology and validation of organoid culture.**

Organoids derived from patients with celiac disease or healthy controls were cultured for 7 days in EM or 2 days in EM, followed by 5 days in DM to induce differentiation. (A) Representative pictures by bright field microscopy showed similar morphology. (B) Relative expression of the stem cell marker *LGR5* and the differentiation marker *SI* were validated by real time PCR. Data were normalized to *ACTIN* housekeeping mRNA levels and are represented as median; \*,  $p < 0.05$ . HC, healthy control; CD, celiac disease; DM, differentiation medium; EM, expansion medium, *SI*: sucrase isomaltase.

**Suppl. Figure 2. Validation of IFN $\gamma$  and RA stimulation.**  
Organoids from celiac patients (n=4) and healthy controls (n=3-4) were maintained in EM for a minimum of 6 weeks before differentiation was induced by incubation in DM for 5 days. Organoids were stimulated with 1000 IU/ml IFN $\gamma$  for 48 hours or 15  $\mu$ M RA for 5 hours. Quantitative reverse transcription PCR was performed to determine relative expression of (A) IFN $\gamma$  upon stimulation with IFN $\gamma$  and (B) TGM2 in response to IFN $\gamma$  and RA. Data were normalized to ACTIN housekeeping mRNA levels and are represented as median; \*, p < 0.05. DM, differentiation medium; EM, expansion medium, IFN $\gamma$ , interferon gamma; RA, retinoic acid.

Suppl figure 3. Enrichment of open chromatin near susceptible celiac loci (PMID: 20190752) compared to random loci.  
 Open chromatin data was derived from Roadmap Epigenomics project (PMID: 20944595).  
 SI: small intestine.

## THE ORGANOID

The noun 'organoid' broadly means resembling an organ (see box 1; from Lancaster & Knoblich, Science 2014[1]). Although, after reading this thesis, we assume the term organoid is now well-known, some Japanese manga anime fans associate this term with something entirely different: a fictional mechanical creature that fights and protect the people that command it. Still, both organoids might share some similarities: can they both protect people? In our case, increase knowledge about intestinal diseases to prevent or treat diseases? And can they be commanded/manipulated by people for good use?

The aim of this thesis was to use organoids as a model for intestinal diseases. The biggest question is how valuable these organoids are for patients, doctors and scientists. To evaluate this, we have to address the following questions: are there other intestinal models available? Do the organoids genuinely recapitulate the *in vivo* intestine? For which applications could organoids be useful? And what future research could be conducted and recommended from a clinical point of view? In short: how valuable are these organoids as intestinal disease models and what clinical potential do they have?

Box 1 (from Lancaster and Knoblich, Science, 2014)[1]

Defining organoids.

ORGANOID n. Resembling an organ.

This implies:

1. Multiple organ-specific cell types
  2. Capable of recapitulating some specific function of the organ (eg. excretion, filtration, neural activity, contraction)
  3. Grouped together and spatially organized similar to an organ
- Organoid formation recapitulates both major processes of self-organization during development: cell sorting out and spatially restricted lineage commitment

Definition:

A collection of organ-specific cell types that develops from stem cells or organ progenitors and self-organizes through cell sorting and spatially restricted lineage commitment in a manner similar to *in vivo*.

## INTESTINAL MODELS: WHICH OTHER MODELS EXIST?

To evaluate the use of organoids as an intestinal *in vitro* model, it is essential to have an overview of the currently used models to study the intestine. These models could roughly be divided into three categories: a) *in vivo* models (in a living organism); b) *ex vivo* models (outside a living organism for a short period of time); c) *in vitro*

models (cells/tissue cultured in a dish). *In vivo* models encompass animal models, such as mice or pigs, which are beneficial for studying disease pathophysiology and determining the role of certain genes or cells within a living organism. The major downside of animal models is the fact that they are not human and therefore these data are not always translatable to patients. Other models that are also considered to represent *in vivo* are cultured cells that are transplanted back into an organism. For example, intestinal organoids derived from embryonic or pluripotent stem cells that have been transplanted into the kidney capsule of mice or engraftment of small intestinal organoids into the colon [2, 3]. Both studies show that intestinal organoids maintain their cell types and function in an *in vivo* model.

The main source of *ex vivo* tissue is the intestinal biopsy; helpful in the diagnosis and understanding of pathology of many intestinal diseases. Biopsies are often directly fixed after endoscopy, which preserves the *in vivo* architecture. It is also possible to mount biopsies immediately into an Ussing chamber to detect and quantify transport and barrier functions. However, epithelial cells do not survive for a long time outside the body [4]. The downside of using intestinal biopsies is the limited availability of material and limited survival of the cells when not immediately fixed for pathology.

Next to *in vivo* and *ex vivo* models, there are also several *in vitro* models to study intestinal cells, which are summarized in Table 1 (adapted from [5]).

Organ	Cellular input	Culture format	Refs*
Small intestine	Cell line (for example, Caco-2)	2D culture	[11, 12]
	Organ slice	Mechanically supported	[4, 11]
	Tissue organoid	3D-embedded culture	[12-16]
	Stem cell organoid (LGR5+)	3D-embedded culture	[9, 10, 13]
	Stem cell organoid (iPS cells)	3D-embedded culture	[14]
Colon	Organ slice	Mechanically supported	[11, 20]
	Tissue organoid	3D-embedded culture	[3, 10, 15-17]
	Stem cell organoid (LGR5+)	3D-embedded culture	[3, 10]

**Table 1: Cellular and molecular techniques for three-dimensional culture**

\*Where possible, the original reference for the approach is included and is supplemented with additional recent references that highlight major technical advances. 3D, three-dimensional; iPS, induced pluripotent stem; LGR5, Leucine-rich repeat-containing G protein-coupled receptor 5.

Cell lines such as Caco2, derived from human colon carcinoma, have been extensively used for pharmacological and absorption studies, as they can be differentiated towards an enterocyte-like state [6-8]. Recently, stem cell organoid cultures derived from embryonic, pluripotent or intestinal adult stem cells have been reported. The adult stem cell intestinal organoid technique was developed by the Clevers group in 2009. Organoids are derived from intestinal crypts that contain the Lgr5-expressing stem cells and Paneth cells [9, 10]. In this thesis, we have used the adult stem cell-derived organoid *in vitro* model to study intestinal disease. However, the question that remains is how well these human organoids recapitulate the *in vivo* intestine. To answer this, we will evaluate different aspects of the organoids, such as culture conditions, the pure epithelial properties, functional properties and their role in complex intestinal diseases.

## DO ORGANOID RECAPITULATE THE IN VIVO INTESTINE? CULTURE CONDITIONS

A good *in vitro* model needs to resemble the *in vivo* organ as much as possible. Essential for this is that culture conditions approximate the *in vivo* signals. The intestine is an organ with plasticity as stem cells specialize to certain cell types depending on the signals they receive. The crypts, containing the stem cells, are cultured in medium with several growth factors to maintain stemness. For example, Wnt and the Wnt-agonist R-spondin maintain crypt cells and the BMP-inhibitor Noggin inhibits differentiation. A small change in medium composition is already able to drive the cell fate to a different direction. In the human intestinal organoid model, one can drive stem cells into differentiation by withdrawal of Wnt, SB202190 and nicotinamide.[10] Furthermore, differentiation into purely enterocytes is achieved by adding extra compounds, such as valproic acid (VPA) and Wnt-inhibitor IWP-2 to the medium [18]. And incubation with RANKL will induce differentiation into M-cells, a cell-type that is normally only situated in the epithelial sheet overlying Peyer's patches in the intestine [19].

Organoids are cultured in matrigel to provide them with an extracellular matrix, consisting of collagens and laminins that resemble the *in vivo* basal lamina. The extracellular matrix helps the epithelial cells to maintain their apical to basal cell polarity, both in matrigel or when cultured on transwells ([10, 20] and this thesis chapter 3 and 4), where the basolateral side is directed towards the matrigel. Overall, the culture conditions seem to reflect the *in vivo* situation, however, caution must be maintained, as the selected growth factors might not be sufficient for exact modeling of the *in vivo* intestine. As the culture system relies on medium that comprises multiple growth factors, including several conditioned media, batches should be well monitored to achieve stable culture conditions.

## ORGANOIDS: EPITHELIAL CELL CULTURES

While we are addressing the human organoids as a model for intestinal diseases, one has to bear in mind that the organoids are only in part representing the intestine. The adult stem cells in the crypt are epithelial cells, indicating that the organoid model system falls short on interactions with other cells such as fibroblasts, lymphocytes or glial cells. In complex intestinal diseases, such as inflammatory bowel disease, often multiple cell types are involved in the pathogenesis of the disease and therefore this disease might not be well represented in this model.

On the other hand, organoids provide an excellent model for intestinal diseases that are based on epithelial defects such as microvillus inclusion disease. The histological phenotype found in biopsies from patients with microvillus inclusion disease is retained in biopsy derived organoid cultures (chapter 3 and 4 of this thesis).

## FUNCTIONAL PROPERTIES OF ORGANOIDS

Not only is the histological phenotype maintained in organoids, also the functional phenotype of intestinal organoids is preserved, as demonstrated in organoids derived from patients with cystic fibrosis (CF) in chapter 5. Intestinal organoids from CF patients show reduced organoid swelling in response to forskolin, which activates the CFTR channel through cAMP, compared to healthy controls. This indicates that CFTR function/dysfunction is still represented in these organoids.

In conclusion, intestinal organoids at least partially recapitulate the intestine of patients (this thesis), which has been confirmed by others as well [21]. As such, organoids are patient-specific *in vitro* models of disease, which is by far not achieved by *in vitro* colon cancer-derived cell models such as Caco2 cells.

## COMPLEX INTESTINAL DISEASES

In complex intestinal diseases, where the pathogenesis is dependent on multiple cell types within the intestine, such as inflammatory bowel disease (IBD), the organoid *in vitro* model will not suffice to mimic all aspects of the disease. Nonetheless, organoids could be helpful to elucidate the role of the epithelium in these multifactorial diseases, since they enable the study of the epithelium of these diseased patients without interference from other non-epithelial cells.

In this thesis we used organoids from celiac patients and healthy controls to test our hypothesis that the differential expression of genes in biopsies of celiac patients are not intrinsically programmed in the epithelial cells (chapter 6). Similar studies could be performed for other multifactorial diseases, such as inflammatory bowel disease, to clarify the role of the epithelium in these diseases. In

addition, co-culture studies of organoids with fibroblast or lymphocytes could shed light on their direct effect on the epithelium.

Beyond the use of organoids as an *in vitro* model of disease, they are also helpful to study healthy epithelial intestine. For this purpose organoids were used to identify if location-specific intestinal properties, such as bile acid uptake in ileum and iron uptake in duodenum, are imprinted in the epithelial stem cells (chapter 2). Understanding the healthy and diseased epithelium is necessary to advance our knowledge on pathogenesis of intestinal diseases.

## APPLICATION OF ORGANOIDS

The value of organoids does not solely rely on recapitulating the diseased/healthy epithelial intestine to improve our comprehension of intestinal diseases. Additionally, this model could aid in diagnostics and therapy for patients suffering from intestinal diseases.

### ORGANOIDS AS A PATIENT-SPECIFIC DISEASE MODEL FOR DIAGNOSTIC PURPOSES

To date, diagnosis of many intestinal diseases is often based on either the pathological analysis of biopsies or genetic make-up of the patient. For most diseases this suffices for an accurate diagnosis, nonetheless the measure of intestinal function or dysfunction is more difficult in this manner. Here organoids could assist in assessing patient-specific functional properties of epithelial cells, as is applied in cystic fibrosis patients (chapter 5). Patients with rare congenital enteropathies would also benefit from better functional studies, since the mutations found in for example *myo5b* are very heterogenous and could affect patients and thus treatment differently [22]. A mutation in a certain domain will have a different effect on the phenotype of microvillus inclusion disease patients, which is also evident in phenotypic analysis of two STX3-deficient patients (chapter 3).

In addition, organoids could play a role in improved diagnosis of rare congenital enteropathies. Intestinal biopsies are often difficult to obtain from these newborns, while correct diagnosis depends almost entirely on histology. If biopsies are unsatisfactory, endoscopy has to be repeated and accurate diagnosis, and therefore therapy might be delayed. Organoids provide almost unlimited material and could be used to understand diseases and determine multiple intestinal functions. Congenital enteropathies have been categorized in four groups: 1) defects in absorption or transport of nutrients and electrolytes; 2) defects in enterocyte differentiation and polarization; 3) defects in enteroendocrine differentiation; and 4) dysregulation of the intestinal immune response [23, 24]. It would be desirable to have a set of functional *in vitro* tests that could quickly identify the functional defects and determine the category of disease. Furthermore, organoids could be used as a model for diagnosis and

even for testing tailor-made medicine, as is currently being done for patients with CF (chapter 5). Eventually, this could lead to an improved understanding of the pathogenic mechanism and, hopefully, patient-specific drug development.

## THE ROLE OF ORGANOIDS IN TREATMENT STRATEGIES

Testing patient-specific drug response in organoids has already been shown for patients with cystic fibrosis (chapter 5 this thesis).

Currently, this assay is used in clinical trials to assess if *in vitro* drug response is in concordance with the patient's response *in vivo*.

Preliminary data show that a patient with a unique CFTR mutation responded well to the drug that showed the most optimal *in vitro* response (Dekkers *et al.*, unpublished).

Taking into account that in some congenital enteropathies partial uptake of nutrients is possible, specific dietary conditions could also be tested *in vitro* and could help in development of a personalized diet.

Recently, Schwank *et al.* showed that it is possible to repair a single-gene mutation by CRISPR/CAS9 genome editing in organoids of a CFTR patient, resulting in full recovery of CFTR function [25, 26]. This opens up possibilities for gene editing in patients with single-gene diseases. However, the corrected cells still need to be delivered to the right location. In case of intestinal diseases, one would have to transplant gene-edited intestinal cells into the intestine of patients. The ability to repair the intestine and, possibly transplant the repaired intestinal cells into a patient sounds incredible. Although colon organoids were successfully transplanted in dextran sulfate sodium (DSS) induced colitis in mice, to date no successful method for transplanting the small intestine has been shown. Even if this will work in mice, it will be challenging to have everything approved for clinical practice and scaled up in such a way that the patient benefits. It was estimated that at least 20% of the intestinal surface should be replaced to become independent of total parental nutrition in microvillus inclusion disease. If you add up the cost, work and sensible outcome of transplanting organoids, currently the burden still outweighs the benefits and small intestinal transplantation is the preferred and only treatment option in case of failure of venal access for nutrition. An overview of possible applications of stem cells for clinical purposes is given in Figure 1 [1].

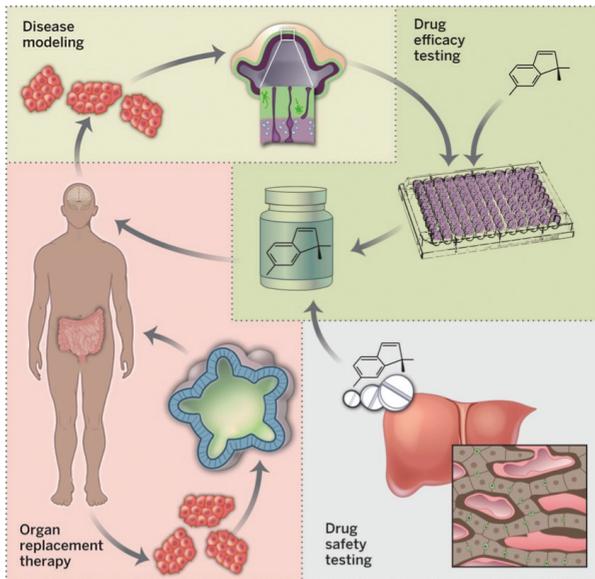

Figure 1.  
Possible applications of organoids  
(adapted from [1])

## CONCLUSION

Organoid cultures at least partially represent the *in vivo* epithelium of a patient quite well, as shown in both functional and histological studies. In addition, mesenchymal or other cells present in a biopsy are not surviving in the epithelial culture conditions, therefore resulting in a simplified model of the intestine. As the culture system relies on medium that comprises multiple growth factors, including several conditioned media, media batches should be well monitored. Nonetheless, it is a useful tool to study intestinal diseases, improve diagnosis and eventually test various treatment regimens for patients suffering from intestinal diseases. Does this imply that we should make organoids of every patient with intestinal disease that visits the clinic? In my opinion, organoids should only be established from a select group of patients, since organoids remain an expensive and laborious *in vitro* model. However, patients with rare intestinal monogenetic traits, a pure epithelial defect and/or expensive, inefficient current treatments, such as is the case in patients with cystic fibrosis and congenital enteropathies, could benefit immensely from organoids as diagnostic or therapeutic tool.

## SUMMARY CHAPTER 1 - GENERAL INTRODUCTION

You are what you eat. A common saying that indicates that your physical or mental state can be influenced by your choice of food. Unfortunately, not all people have the luxury to choose what to eat; this can be related to place of birth, social, economic state, or the physical inability of the diseased intestine to take up certain food. A cell layer, the epithelium, covers the intestine, and harbors the main functions of the intestine: uptake, digestion of food, and a barrier against unwanted guests from outside the body. The intestinal epithelium consists of protrusions (villi) and invaginations (crypts) and all cells are renewed every four to five days. This renewal is possible because the stem cell, residing in the crypt, multiplies and produces all specialized epithelial cells. The group of Hans Clevers discovered a method to isolate these crypts, including the stem cells, and by adding growth factors, they were able to maintain these cells in a culture dish for weeks. These mini-intestines, which are grown in the lab, are called organoids and can be made from a small part (biopsy) of the intestine from a patient. The aim of this thesis was to make these organoids from patients with intestinal diseases, and to see if they recapitulate the patient's intestine and are a useful model for studying intestinal diseases.

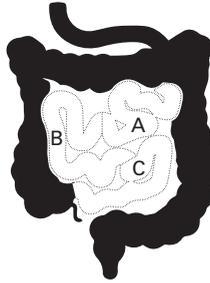

Je bent wat je eet. Deze bekende uitspraak geeft aan dat je fysieke of mentale staat kan worden beïnvloed door je keuze van voedsel. Helaas heeft niet iedereen de luxe om te kiezen wat men wil eten vanwege geboorteplaats, sociale-, economische status, of door een darmziekte waardoor het fysiek onmogelijk is om bepaalde voedingsstoffen op te nemen of te verteren. De darm is bedekt door een cellaag, het epitheel, die de belangrijkste functies van de darm uitvoert zoals vertering en opname van voedsel. Ook beschermt deze darm laag tegen ongewenste gasten van buitenaf. Darmepitheel bestaat uit uitstulpingen (villi) of instulpingen (crypten) en alle cellen worden bijna elke vier tot vijf dagen vernieuwd. Dit is mogelijk doordat de darmstamcel, die zich in de crypten bevindt, zich steeds blijft vermenigvuldigen en allerlei gespecialiseerde darmcellen kan maken. De groep van Hans Clevers heeft een methode ontdekt om deze crypten, die de stamcellen bevatten, weken lang te kunnen kweken in een plastic schaalpje in het lab. Dit kunnen ze doen doordat ze bepaalde groeifactoren aan de kweek toevoegen. Deze mini-darmpjes, ook wel organoids genoemd, kunnen worden gemaakt van een klein stukje darmweefsel (biopt) van patiënten. Het doel van dit proefschrift was om met behulp van deze methode mini-darmpjes van patiënten met verschillende darmziekten te maken, te bestuderen of dit de echte situatie nabootst, en dit te gebruiken als ziektemodel van de darm.

## SUMMARY CHAPTER 2 – ADULT STEM CELLS IN THE SMALL INTESTINE ARE INTRINSICALLY PROGRAMMED WITH THEIR LOCATION-SPECIFIC FUNCTION

We first inspected the organoids in healthy intestines. The small intestine, which mainly digests and takes up nutrients, can be divided in three parts: the duodenum, the jejunum and the ileum. Each part has its own function such as; uptake of iron in the duodenum, milk in the jejunum, and bile acids/salts that help digestion in the intestine, are reabsorbed in the last part of the small intestine, the ileum, and returned to the liver. We were wondering if these functions are specific for the stem cell of each part, or if these functions were influenced by external factors such as the cells around the intestine. To answer this question we made organoids from these three different parts of the intestine, from both mice and human intestine, and studied if these functional properties were maintained over time (~10 weeks of culture). We noticed that organoids (containing the stem cells) from the duodenum remained specific for iron uptake and continued to be different from jejunal and ileal organoids. This confirms that each segment in the small intestine has its own specific stem cell that keeps its own functional properties.

Eerst hebben we gekeken naar gezonde organoids. De dunne darm, die met name voeding verteert en opneemt, kan opgedeeld worden in drie delen: het duodenum, het jejunum en het ileum. Elk deel heeft zijn eigen functie, zo wordt in het duodenum met name ijzer opgenomen, in het jejunum melk, en in het laatste stukje van de dunne darm, het ileum galzouten (die helpen bij het verteren van voedsel en die worden weer teruggegeven aan de lever). We vroegen ons af of deze functies intrinsiek zijn ingebed in de stam cel uit dit segment of dat deze functies aange-stuurd worden door externe factoren zoals andere cellen rondom de darm. Om deze vraag te kunnen beantwoorden hebben we organoids gemaakt van alle drie de delen, van zowel muizen als mensen darm, en hebben we bekeken of deze eigenschappen nog steeds in de stamcellen zaten na deze ~10 weken te kweken in het lab. We zagen dat organoids uit het eerste deel van de dunne darm, het duodenum, nog steeds hun functie voor ijzeropname behielden en niet de functies van het jejunum of het ileum overnamen. Dit bevestigt dat elk deel van de dunne darm een eigen specifieke stamcel heeft, met zijn eigen functies.

## SUMMARY CHAPTER 3 - LOSS OF SYNTAXIN 3 CAUSES VARIANT MICROVILLUS INCLUSION DISEASE

A severe, but rare, disease in which the intestine hardly functions at all is microvillus inclusion disease. This disease manifests itself in the first three months of life with diarrhea and total dependency on tube feeding. 90% of these children have a mutation in the *MYO5B* gene (part of the DNA). In this chapter we identified that a mutation in another gene Syntaxin 3 (*STX3*) also caused this disease. Two patients with microvillus inclusion disease had mutations in *STX3*, and cell lines, in which the same mutations were inserted, also showed the same diseased phenotype. Furthermore, organoids, made from the intestine of one of these patients, recapitulated the pathology that was present in patient's biopsies. This implies that organoids could be useful as a model to study this disease.

Een ernstige, maar zeldzame, ziekte waarbij de darm nauwelijks functioneert is microvillus inclusion disease. Deze ziekte presenteert zich in de eerste drie maanden van het leven met diarree en totale afhankelijkheid van voeding via een infuus. 90% van deze kinderen heeft een mutatie in het *MYO5B* gen (deel van het DNA). In dit hoofdstuk hebben wij een nieuwe mutatie ontdekt in een ander gen, Syntaxin 3 (*STX3*), die ook deze ziekte kan veroorzaken. Twee patiënten met microvillus inclusion disease hadden een mutatie in *STX3*, ook zagen we dat, als we dezelfde mutaties in een cellijn inbrachten, die cellen ook hetzelfde zieke fenotype lieten zien. Organoids gemaakt van de darm van één van deze patiënten lieten ook dezelfde afwijkingen zien als de darmbiopten. Kortom, organoids lijken een goed model te zijn om deze ziekte te kunnen bestuderen.

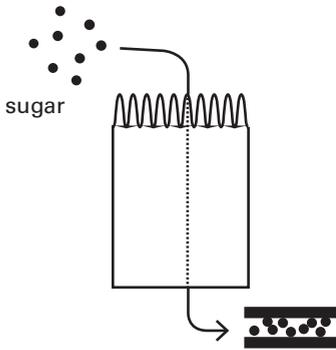

## SUMMARY CHAPTER 4 - APICAL AND INTRACELLULAR TRAFFICKING PROTEINS ARE MISLOCALIZED IN ENTEROCYTES FROM SYNTAXIN 3-MUTANT PATIENTS WITH VARIANT MICROVILLUS INCLUSION DISEASE

In this chapter we looked more in depth at the function of Syntaxin 3, *STX3*, in patients with microvillus inclusion disease. In this disease one cell type in the intestine is especially affected: the enterocyte. This cell main function is to digest and take up nutrients with small hair-like protrusions on the villi, called microvilli. Uptake of nutrients is possible because there are enzymes/proteins located on the luminal side of the intestine on these microvilli. For example sugar can be digested by the enzyme sucrase-isomaltase (SI) on the apical (luminal) side of the cell and transferred to the blood on the basolateral side. We know these patients have difficulties in taking up food that is why they are dependent on tube feeding. *STX3* is known for directing these enzymes/proteins to the membrane of the cell. We studied if these enzymes or proteins, in these *STX3* mutant patients, were still localized correctly. We noticed that in organoids and biopsies from these patients some apical proteins were maintained on the apical side, while others were mislocalized and accumulated just under the cell membrane. Other proteins, that were supposed to be on the basolateral side, remained at the right location in these patients.

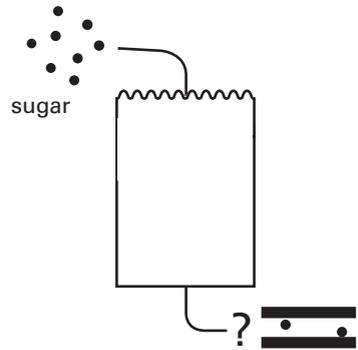

In dit hoofdstuk hebben we meer in de diepte gekeken naar de functie van Syntaxin 3, *STX3*, in patiënten met microvillus inclusion disease. Bij deze ziekte is met name één type darmcel aangedaan: de enterocyt. De voornaamste functie van deze cel is vertering en opname van voeding in de darm door middel van kleine haarachtige uitstulpingen op de villi, ook wel microvilli genoemd. Opname van voedsel is mogelijk doordat er op deze microvilli eiwitten/enzymen zitten die contact maken met voedsel en dit kunnen opnemen in de cel. Zo wordt suiker klein geknipt door het enzym sucrase-isomaltase (SI) op de apicale (of luminale) zijde van de cel. De geknipte suiker wordt vervolgens opgenomen door andere eiwitten op de celmembraan en uiteindelijk doorgegeven aan het bloed via de basolaterale zijde. We weten dat deze patiënten moeite hebben met het verteren en opnamen van voedsel, dit is de reden dat ze voeding via een infuus krijgen. *STX3* is bekend als een eiwit dat ervoor zorgt dat enzymen en eiwitten op de celmembraan terecht komen. We zagen dat in organoids en biopten van deze patiënten sommige apicale eiwitten op de goede plek zaten, terwijl andere ophoopten onder de celmembraan. Eiwitten die op de basolaterale zijde moesten zitten, zaten wel op de goede plek bij deze patiënten.

## SUMMARY CHAPTER 5 - A FUNCTIONAL CFTR ASSAY USING PRIMARY CYSTIC FIBROSIS INTESTINAL ORGANIDS

Another rare disease is cystic fibrosis. In this disease mainly the lungs are affected, often in combination with the pancreas and the intestine. These organs are clogged with thick mucus, often accompanied by infections. The main cause of this disease is a mutation in the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene, a chloride channel that moves water to the luminal side. In a healthy situation this channel helps in making a thin watery layer of mucus that protects organs from infections. In cystic fibrosis the mucus layer is thick instead of watery. If you add Forskolin, a drug that activates the CFTR channel, to organoids, water moves into the lumen, resulting in swelling of organoids. In organoids from a cystic fibrosis patient, CFTR does not function, therefore no swelling occurs. However, if you add Forskolin in combination with the right drug to an organoid of a cystic fibrosis patient, the CFTR channel will become activated and swelling will occur. The choice of drug and response to it varies per mutation and patient. The organoid model can help in predicting a patient-specific response to a drug by adding different drug combinations to the organoid, and observe if swelling occurs. As these drugs are very expensive and it usually takes weeks before we know if the medicine works in a patient, organoids could be a useful tool to select the right drug for each patient.

Een andere zeldzame ziekte is taaislijmziekte, ook wel cystic fibrosis genoemd. Bij deze ziekte zijn met name de longen aangedaan, vaak in combinatie met andere organen, zoals de alveesklier en de darm. Deze organen raken verstopt door dik taai slijm en dit gaat vaak gepaard met ontsteking van deze weefsels. De oorzaak van deze ziekte is een mutatie in het cystic fibrosis transmembrane conductance regulator (*CFTR*) gen, een chloride kanaal dat water naar het lumen van organen beweegt. In een gezonde situatie zorgt dit kanaal ervoor dat er een dun waterig laagje slijm op de organen ligt die bescherming biedt tegen ontstekingen. Bij taaislijmziekte is deze slijmlaag juist taai in plaats van waterig. Als je Forskolin, een stof die het CFTR kanaal activeert, aan de organoids toevoegt zie je bij gezonde organoids het lumen opzwellen. In organoids van een patiënt met taaislijmziekte, waarbij het CFTR kanaal het niet doet, zwelt het lumen niet. Echter als je, naast Forskolin, ook het goede medicijn toevoegt aan de organoids van een patiënt met taaislijmziekte kan er wel zwelling van de organoids ontstaan. Of een patiënt wel/niet reageert op bepaalde medicatie is afhankelijk van het type mutatie in het *CFTR* gen, dit kan per patiënt verschillen. Om te voorspellen welk medicijn wel of niet werkt kan een patiënt-specifieke organoid gestimuleerd worden met Forskolin en verschillende medicijn combinaties. De mate van zwelling geeft hier bij aan of het medicijn wel of niet aanslaat. Deze medicijnen zijn erg duur en het effect ervan in de patiënt is pas op lange termijn te beoordelen. Organoids zouden daarom een mooi model zijn om het gepaste medicijn te selecteren voor een patiënt.

## SUMMARY CHAPTER 6 - INTESTINAL EPITHELIUM IS NOT INTRINSICALLY AFFECTED IN PATIENTS WITH CELIAC DISEASE

There is a specific intestinal disease, celiac disease, where patients cannot eat a specific type of food such as: gluten. This protein is found in wheat, barley and rye. We know that a certain genetic make-up predisposes people for celiac disease, in combination with a gluten-containing diet, and causes immune cells to become active. The immune cells, located under the intestinal epithelium, make antibodies that damage the intestine. Although 30% of the population has this genetic make-up, only 1% is affected by gluten. That means additional factors play a role, one of these factors could be the intestinal epithelium. To dissect if the epithelium of celiac patients might be different from healthy intestines, we made organoids from both groups. In intestinal biopsies differences in expression of epithelial genes were seen. However, after a few weeks of culturing only the epithelium, organoids derived from healthy and celiac patients did not differ. Even after stimulating the organoids with a protein that induces inflammation in cells, both groups responded similarly. This implicates that the intestinal epithelium of celiac patients does not intrinsically differ from healthy controls.

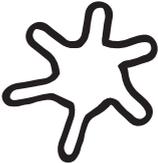

Er is een specifieke darmziekte, coeliakie, waarbij patiënten met name een bepaald type voedsel niet goed kunnen verdragen: gluten. Dit eiwit zit in tarwe, gerst en rogge. We weten dat deze ziekte alleen voorkomt bij mensen met een bepaalde combinatie van genen die, samen met gluten, ervoor zorgen dat afweercellen geactiveerd worden. Deze afweercellen, die net onder het darmepitheel zitten, maken antistoffen die het darmepitheel beschadigen. Alhoewel deze genencombinatie bij 30% van de bevolking voorkomt, krijgt slechts 1% van de bevolking coeliakie. Dit betekent dat er meer factoren zijn die ervoor zorgen dat mensen coeliakie ontwikkelen, het darmepitheel zou hierbij een rol kunnen spelen. Om te onderzoeken of het darmepitheel van coeliakiepatiënten anders is dan dat van gezonde personen hebben wij van beide groepen organoids gemaakt. In darmbiopten zien we verschillen in expressie van bepaalde epitheelgenen. Echter, na het kweken van alleen het darmepitheel, zijn de organoids van patiënten en gezonde personen niet verschillend. Ook na stimulatie van de organoids met een eiwit dat celontsteking activeert, reageren beide groepen hetzelfde. Dit impliceert dat het darmepitheel van coeliakiepatiënten niet intrinsiek anders is dan van gezonde personen.

## DANKWOORD

Wie is Carl Sagan? Misschien kent u hem, misschien niet, ik schaar mijzelf in ieder geval tot de laatste categorie. Toch kom ik zijn naam in verschillende proefschriften tegen, zelfs met verschillende quotes over de wetenschap in algemene zin. Ik veronderstel daarom dat hij vast een bekende mannelijke wetenschapper is. Dit kan ik alleen doen op basis van een aantal aannames: a) hij is hoogstwaarschijnlijk een man (vanwege zijn voornaam) b) hij doet uitspraken over de wetenschap en is daardoor mogelijk zelf een wetenschapper, en c) het feit dat hij in proefschriften wordt geciteerd betekent dat hij vast populair is. Toch wil ik een bevestiging hiervan en begin ik met een simpele search op Google met de zoekterm: "Carl Sagan". Daarbij stuit ik op deze foto:

Subjectief gezien zou hij zowel een acteur van de serie *Love Boat* als een populaire wetenschapper kunnen zijn. Objectief zie ik een aantal andere dingen: dat er bij google ongeveer 12.800.000 resultaten verschijnen in slechts 0,29 seconden. Hij leefde van 1934 tot 1996; was astronoom en is drie keer gehuwd geweest. Zijn grootste wetenschappelijke bijdrage was het ontdekken dat de planeet Venus een temperatuur van 500 °C heeft. Hij is, echter, vooral bekend vanwege zijn zoektocht naar buitenaardse wezens. Voor zijn project SETI (Search for Extra-Terrestrial Intelligence) heeft hij 70 wetenschappers een petitie kunnen laten ondertekenen, waaronder 7 nobelprijs winnaars, die werd gepubliceerd in *Science*. Ook heeft hij de eerste boodschappen de ruimte in gestuurd die te begrijpen zouden zijn voor elke vorm van buitenaards leven. Zijn grote bekendheid heeft hij verworven door het televisieprogramma *Cosmos*, waarin hij in begrijpelijke taal allerlei dingen over het heelal uitlegde.

Nu neem ik aan dat mijn collega's hem niet direct van die tv-programma's kennen, gezien hun leeftijden. Mogelijk kennen ze hem nog van zijn science-fiction boeken. Alleen bij verder onderzoek zie ik dat hij ook makkelijk te vinden is bij Google met de termen "science" en "quote". De eerste site laat al snel vele uitspraken van Carl Sagan zien, tussen andere beroemdheden zoals Kant, Einstein en Hawking. De quotes van Carl Sagan variëren van "Absence of evidence is not evidence of absence" tot "If you wish to make an apple pie from scratch, you must first invent the universe." Na deze korte studie kunnen we concluderen dat hij inderdaad een bekende mannelijke wetenschapper is. Toch zijn er enkele kanttekeningen bij deze studie te plaatsen. De definities voor wetenschapper, bekend en man zijn niet goed uitgelegd. Als bronnen zijn met name Wikipedia en Google gebruikt. Bovendien belicht deze studie maar enkele kanten van Carl Sagan en is dus vrij summier.

Dit is onderzoek in een notendop. Je hebt een onderzoeksvraag, stelt een hypothese, onderzoekt met een bepaalde methode of dit klopt of niet. Hierna wordt een conclusie getrokken, de beperkingen van de studie besproken, besproken hoe deze bevindingen overeen komen/ tegenstrijdig zijn met de huidige literatuur. Soms worden er dan nog suggesties gegeven voor aanvullend onderzoek dat in de toekomst gedaan zou kunnen worden. Simpel zou je zeggen, alleen dan moet je nog proberen dit onderzoek in een goed blad te kunnen publiceren. Dit is het moment dat het echt moeilijk wordt, zeker voor dit stuk omdat er geen nieuwe bevindingen zijn. Dit betekent dat dit onderzoek buiten de scoop van bijna alle bladen valt. Heel misschien valt het nog te publiceren in een studentenblaadje of de buurtkrant, maar om te voorkomen dat dit stuk echt in de prullenbak belandt, publiceer ik het voor de zekerheid maar zelf, in mijn eigen proefschrift.

Dat dit proefschrift hopelijk van iets meer kwaliteit is dan bovenstaande studie, heb ik gelukkig te danken aan heel veel andere mensen die ik bij deze graag zou willen bedanken.

Dat ik niet een heel hoofdstuk heb gewijd aan Carl Sagan heb ik onder andere te danken aan mijn promotor Edward Nieuwenhuis. Edward, dank je voor het helpen met de focus in mijn PhD. Ik kon rustig met vijf ideeën bij jou naar binnen lopen en weer met één naar buiten gaan. Ik heb vooral geleerd van jou dat je beter iets kleins heel goed kan uitzoeken dan iets groots half, de basis van goed onderzoek. Wat was het fijn om af en toe uit te kunnen zoomen van het onderzoek, kleine tegenvallers te kunnen relativiseren, en daarnaast ook andere dingen dan werk te kunnen bespreken. Hopelijk zien we elkaar in Colombia en kunnen we in de toekomst nog eens samenwerken.

Behalve de grote lijnen, heb je ook iemand nodig die de kleine lijnen bewaakt en zorgt dat je de juiste controles meeneemt zoals Sabine Middendorp, mijn co-promotor. Sabine van jou heb ik met name de praktische kant van het onderzoek geleerd. Het zal vast niet altijd

makkelijk voor je geweest zijn om een arts in te moeten wijden in de wetenschap. Vanaf de eerste week heb ik al op het lab mogen staan en daar ben ik je zeer dankbaar voor. Door verschillende technieken te leren kon ik een beter beeld krijgen van de mogelijkheden en alles was ook mogelijk. Elk voorstel kon worden uitgevoerd, met vaak de nodige fouten, maar dat was misschien wel de beste manier om het te leren. Je hebt me veel vrijheid en zelfstandigheid gegeven en je was altijd bereikbaar voor overleg. Dank ook voor het doorploegen van teksten in de laatste fase. Ik ben heel benieuwd naar het verdere onderzoek wat jullie gaan doen.

Daarnaast wil ik de mensen in mijn begeleidingscommissie bedanken voor hun input in de laatste fase van mijn PhD: Roderick Houwen, Marianne Boes en Joost Frenkel. Roderick, dankzij jouw contacten is het STX3 stuk zo mooi geworden. Je was altijd betrokken door kritisch mee te denken over het onderzoek. Je bent *to the point* en dat is prettig om mee te werken. Marianne en Joost ook jullie brachten het onderzoek steeds terug naar de vraagstelling en dachten kritisch mee over wat wel of niet relevant zou zijn voor de stukken in de resterende tijd. Ontzettend leuk dat jullie in mijn commissie willen deelnemen.

Ook in de commissie, Berent Prakken. De rust die jij uitstraalt en de helderheid waarmee je onderzoek vertaalt vanuit de bench naar bedside zijn inspirerend. Ik zal niet vergeten om in de toekomst ook vraagstellingen vanuit patiëntengroepen mee te nemen bij het opzetten van onderzoek. Prof. Dr. P.D. Siersema, dank voor het kritisch lezen van mijn proefschrift, dankzij uw afdeling heb ik ook vele volwassen patienten van de MDL kunnen includeren. Prof. Dr. J.T.A. Knappe dank voor het willen voorzitten van mijn promotie.

Hankje, dank voor je betrokkenheid bij mijn onderzoek. Jij belde/ mailde mij bij elke mogelijke patiënt en alles was altijd goed geregeld in Rotterdam. Ook dankzij jouw inzet hebben we de STX3 stukken kunnen doen. Leuk om naast Edward, ook jou te leren kennen en geweldig dat je straks als professor bij mijn verdediging aanwezig bent.

Frits Koning, heel veel dank voor jouw adviezen omtrent coeliakie onderzoek. Dat het epitheel geen rol speelt in coeliakie voorspelde jij al vanaf het eerste moment. Ik zal de TCR ontwikkelingen in coeliakie in de gaten blijven houden.

Dear Thomas Müller, it has been an honor to work with you, the great Myo5b man, and your group, on STX3. Thank you for coming all the way to the Netherlands for my defense, I promise there will be a good party afterwards.

Hans Clevers, dank je voor jouw ondersteuning en die van de rest van je groep bij al het organoidwerk. Dankzij jullie hulp konden wij ook met deze techniek werken en heb ik wekelijks de kans gehad om

top-science van dichtbij te zien. Everybody from the Hubrecht group thank you for four years of inspiration, input, help and hard-core science including Rob, Mark, Wim, Stieneke, Joyce, Karin, Henner, Gerald, Sina, Valentina and everyone else.

Valentina and Ruben it was great to be able to work together, I wish the best for both of you in, respectively, the editor and the epigenetics field. Desiree dank voor je bijdrage aan STX3 en gezellige koffies. Amani dank voor al je coeliakiekennis, vriendschap en oprechtheid. Fantastisch dat je nu in opleiding bent, hopelijk worden we in de toekomst weer collega's. De afdeling metabole diagnostiek voor hun gastvrijheid om daar de disaccharidase assay te leren, in het bijzonder veel dank aan Nanda Verhoeven, Mirjam van Aalderen en Ans Geboers.

Dan wil ik met name alle patiënten en families bedanken die mee hebben gewerkt aan dit onderzoek, zonder jullie vertrouwen en deelname was dit proefschrift niet mogelijk geweest.

Ook veel dank aan alle kindergastroenterologen die geholpen hebben bij inclusie en biopten in het WKZ: Roderick, Victorien, Freddy, Sarah, Janneke, Anemone, Cathelijne en Renske. Behalve jullie hulp bij inclusies was het erg leuk om iets mee te krijgen van jullie mooie vak, praktische inzichten en humor. Graag wil ik ook alle anesthesisten, OK-personeel en assistenten bedanken voor hun hulp en goede sfeer. Ik ben alle gastroenterologen van het UMC dankbaar voor het kunnen includeren en biopteren van hun patiënten voor het onderzoek, in het bijzonder Herma Fidder, Bas Oldenburg, Karel van Erpecum, de hele dagbehandeling, Janneke ten Brink en de secretaresses die altijd hielpen met inclusie en bloedafnames. Beth en Petra dank voor alle hulp bij METC-amendementen en contracten.

Ook ben ik de kindergastroenterologen en onderzoeksmensen uit andere ziekenhuizen dankbaar die mee hielpen met het materiaal of uitbreiden van de STEM-studie, in het bijzonder: Henkjan Verkade, Edmond Rings, Els Roelofs, Marc Benninga, Merit Tabbers, Luisa Mearin, Yvonne Wijkhuizen, Barbara de Koning, Jessie Hulst, Barbara Sibbles, Katharina Biermann en Merel van Pieterse.

Dear Rüdiger Adam thank you for your hospitality and quick communication about the patient in Mannheim.

Dank ook aan alle overige co-authors voor hun bijdrage bij de stukken. Daarnaast ben ik de rest van de Nieuwenhuisgroep dankbaar voor alle wetenschappelijke input en gezelligheid. Kerstin, trouwe maat, wat had ik toch zonder jou ontmoeten. Ik heb veel van je geleerd als wetenschapper, maar ben vooral blij dat ik een dierbare vriendin erbij heb gekregen. Wat een feest dat wij samen, zij aan zij, deze drie+een jaar konden beleven: successen, failures, koffies, samenwerken, burgers eten, yoga (in die volgorde), reisverhalen, Vancouver, Berlijn en als hoogtepunt onze Husky-tour. We hebben

nog heel veel samen te beleven, wie weet is onze volgende trip in Colombia. Ik ben heel benieuwd naar je volgende stap. Michal, thanks for your positive and relaxed view on everything and your great sense of humor. Sylvia, de rechtvaardige gangmaker en doe-het-zelver, ontzettend fijn dat ik tenminste 3 jaar met je heb kunnen samenwerken (en dansen). Simone, Hans en Anke van jullie alliedrie heb ik het belang van precisie geleerd, alliedrie een andere aanpak, maar jullie waren altijd bereid om mee te denken en geduld op te brengen voor iemand die het liefst snel resultaat heeft. Ook was het fijn om na 2 jaar enkele dokters in de groep te krijgen en niet zomaar dokters maar leading ladies: Sabine F, Caroline en Janneke. Sabine, dank voor je onuitputtelijke enthousiasme, je bent een mooi voorbeeld van iemand die alles kan combineren met een glimlach en hart voor de zaak heeft, heel inspirerend. Caroline, jij stond altijd klaar om bij te springen, zelfs in een kerstweekend voor Wnt maken, terwijl je al druk genoeg was, dank daarvoor. Janneke, wat leuk om met jou samen te werken en zelfs varkensorganoids te maken. Ik wens je veel succes in Eindhoven en dank voor al je steun gedurende mijn PhD en etentjes in Jerusalem. Claartje, de efficiënte onderzoekster en dokter, hopelijk worden we nog collega's in de toekomst. Jorik, dank voor het overnemen van onze projecten, heel veel succes de komende tijd. Ook studenten: Charlotte, dank voor al je hulp bij het IBD project, je inzet, inzicht en spontaniteit. Imre, Layla, Delia, Ronald, Tim, Sin, Lotte, Susanne en overige studenten in het lab, jullie zijn de jonge wetenschappers die ons scherp en enthousiast houden. Susanna dank voor het regelen van alle afspraken en extra zaken rondom de PhD en heel veel succes bij je nieuwe baan.

Niet alleen je directe groep maar ook de grotere groep, eerst CMCI, later LTI, helpen je verder in het onderzoek en voegen vooral veel toe met sparren over allerlei andere dingen dan onderzoek. De Boesers: Ewoud, Thijs, Robert, Arjan S, Annick, Friederike, Lotte en Willemijn. Dank voor alle nespresotalks, gitaarles, (soms ongevraagde) adviezen, hulp, gezelligheid, sticky toffee cakes, koe-bel concerten, Gent en Israel trips. Helmut Trekking en Willy succes met de laatste loodjes, ik kijk uit naar jullie promoties. U-dancers: Maud, Colin, Nina, na de verhuizing kwamen jullie gelukkig toch nog af en toe voor een borrel langs. Maud dank ook voor je FACS tips. Prakkers: Evelien, Theo, Femke, Gerdien, Genoveva, Arjan B, Judith, Sytze, Nienke, Alessandra, Felicitas, Annemieke, Lieke, Ellen, Yvonne, Henk, Bas, Maja, David en Marloes. Dank voor alle leuke borrels, etentjes en pubquizen. De spills van het lab: Lieneke, Rianne, Sigrid, Jenny en Mark. Dank voor alle organisatie zodat het lab goed loopt, jullie hulp en organisatie van goede voetbalgames, etentjes, Derk-dansjes, scherpe humor en relativeringsvermogen. Barbara and Sjors thanks for keeping up the histolab. De Beekmangroep: Jeffrey, Florijn, Dominique, Annelotte, Jennifer, Lodewijk en Evelien, het was fijn om met jullie te kunnen sparren over organoids en letterlijk hulp in nood te krijgen bij het zoveelste mediumprobleem. Florijn en Jeff, dank dat ik mee kon werken aan een mooi stuk met CF organoids, hier heb ik veel van geleerd. Een PhD is niks zonder gezellige kamergenoten:

flexers, Kerstin, Sylvia, Gerdien, Evelien, Willemijn, Sanne, Annemieke, Sandra, Luuk, Florijn, Nadia, Elena, Chiara, Pieter. En nog meer mensen uit andere groepen die wetenschappelijk input of gezelligheid gaven: Kim, Alsya, Tessa, Emmerik, Rina, Sarita, Jorg, Saskia, Yvonne, Erica, Angela, Julia, Hilde, Michiel, Nienke en nog vele anderen van het CMCI en LTI. Ook zijn er mensen die je op late uren inspireren, Achmed, heel veel dank voor alle gesprekken over politiek, Egypte, je kinderen, je bent voor mij een groot voorbeeld die door hard werken zich inzet voor de volgende generatie. Ik weet zeker dat je kinderen een fantastische toekomst dankzij jou krijgen en dat er vast een mooie nieuwe banenkans in het verschiet ligt. Bade, succes met alle drukte thuis en dank voor mijn schone kamer, lab en aanspraak in de avond.

Verder wil ik ook de mensen bedanken voor andere samenwerkingen die niet in dit boekje voorkomen: Carolijn voor het IBD project, Wentao en Peter voor de aanraking met varken en kat organoids.

In addition I would like to thank everybody from the Grand lab for making me enthusiastic about basic science in the first place. De kinderartsen en collega's van Tergooziekenhuizen voor het mij enthousiasmeren voor het vak kindergeneeskunde. Clairetje, wat een feest dat je mee wilt buigen als paranimf op de dag van mijn promotie. Naast studiematen, oud-collega's, jaargenoot, ben je vooral een heel goede vriendin die ik graag naast me zie staan bij dit moment.

Overigens ben ik mijn andere vrienden die alles goed te weten relativeren en klaar stonden buiten werktijden voor leuke dingen ook dankbaar: Eddy, Emma, Linde, Lieke, Laura, Soof, Jos, Claar, Frederique, Rosanne, Mariette, Neel, Maria, Claire L, Claire S, Klaus & co. Ook mijn medische familie Sophie, Melanie en Maarten die altijd geïnteresseerd bleven ondanks specialistische termen.

Lieve familie, pappa, mamma, Nils, Lisa, Roland, Nina, lieve Marie, maar ook mijn schoonfamilie, Kees, Monika en Niels dank dat jullie altijd voor mij klaar stonden en voor alle mooie momenten met jullie de afgelopen jaren, waarbij de komst van Marie toch wel een van de hoogtepunten was.

Lieve Sven, dank voor je hulp bij het mooi maken van dit boekje, je liefde en al je vrolijkheid. Elke dag is weer een feest met jou en ik kijk heel erg uit naar ons buitenland avontuur met zijn tweeën.

## LIST OF PUBLICATIONS
