Although previous studies have documented a bottleneck in the transmission of mtDNA genomes from mothers to offspring, several aspects remain unclear, including the size and nature of the bottleneck. Here, we analyze the dynamics of mtDNA heteroplasmy transmission in the Genomes of the Netherlands (GoNL) data, which consists of complete mtDNA genome sequences from 228 trios, eight dizygotic (DZ) twin quartets, and 10 monozygotic (MZ) twin quartets. Using a minor allele frequency (MAF) threshold of 2%, we identified 189 heteroplasmies in the trio mothers, of which 59% were transmitted to offspring, and 159 heteroplasmies in the trio offspring, of which 70% were inherited from the mothers. MZ twin pairs exhibited greater similarity in MAF at heteroplasmic sites than DZ twin pairs, suggesting that the heteroplasmy MAF in the oocyte is the major determinant of the heteroplasmy MAF in the offspring. We used a likelihood method to estimate the effective number of mtDNA genomes transmitted to offspring under different bottleneck models; a variable bottleneck size model provided the best fit to the data, with an estimated mean of nine individual mtDNA genomes transmitted. We also found evidence for negative selection during transmission against novel heteroplasmies (in which the minor allele has never been observed in polymorphism data). These novel heteroplasmies are enhanced for tRNA and rRNA genes, and mutations associated with mtDNA diseases frequently occur in these genes. Our results thus suggest that the female germ line is able to recognize and select against deleterious heteroplasmies.

Heteroplasmy (intra-individual variation) in mitochondrial DNA (mtDNA) plays an important role in mtDNA-related diseases and has also been implicated in aging and cancer (Greaves et al.

2012; Wallace 2012; Chinnery and Hudson 2013; Lombès et al. 2014). Most mtDNA mutations that cause diseases due to defects in mitochondrial function exist as heteroplasmies and only cause

disease symptoms when the frequency of the mutant allele exceeds a particular threshold (Wallace and Chalkia 2013). Below this threshold, individuals are asymptomatic, presumably because there are sufficient functional mitochondria for normal metabolism. Changes in the frequency of pathogenic mutations during the transmission of heteroplasmies from mothers to offspring can thus play an important role in the disease risk of the offspring. However, most of our knowledge concerning the dynamics of heteroplasmy transmission comes from studies of pathogenic mutations (Monnot et al. 2011; Shen et al. 2012; de Laat et al. 2013; Wallace and Chalkia 2013), which in blood have been shown to decrease over time and hence may not accurately reflect the overall level of such pathogenic mutations within an individual (Poulton and Morten 1993; 't Hart et al. 1996; Rahman et al. 2001; Rajasimha et al. 2008). Mouse models have also been utilized (Cree et al. 2008; Fan et al. 2008; Freyer et al. 2012; Ross et al. 2013), but to date, there have been only a few studies of normal patterns of heteroplasmy transmission in humans (Sekiguchi et al. 2003; Goto et al. 2011; Sondheimer et al. 2011; Guo et al. 2013; Rebolledo-Jaramillo et al. 2014), including studies of oocytes and placenta (Marchington et al. 1997, 2002; Jacobs et al. 2007), and several questions remain.

For example, although it is clear that a bottleneck occurs during the transmission of mtDNA genomes from mothers to offspring, the size of the bottleneck remains a contentious issue. Previous estimates of the effective number of transmitted mtDNA genomes range widely, from eight to 200 (Brown et al. 2001; Guo et al. 2013; Rebolledo-Jaramillo et al. 2014). However, all previous studies have assumed a constant size for the bottleneck across individuals; the effect of allowing the bottleneck size to vary among individuals has not been investigated. Moreover, it has been suggested that mtDNA genomes may not behave as independent entities but instead are organized into discrete units called “nucleoids,” each of which contains 5–10 mtDNA genomes (Jacobs et al. 2000; Cao et al. 2007; Khrapko 2008), although recently it has been suggested that the number may be much smaller, on the order of one mtDNA genome per nucleoid (Kukat et al. 2011). Each nucleoid is thought to be homoplasmic for mtDNA genome sequences; thus, mtDNA heteroplasmy at the cellular level would reflect nucleoids that are homoplasmic for different sequence variants. Nucleoid structures within cells have been studied microscopically and biochemically (Bogenhagen 2012), and nucleoid-based models have been found to provide a better fit to the segregation of heteroplasmic mtDNA genomes in cell lines than do simple bottleneck models in some studies (Cao et al. 2007; Khrapko 2008), but not in others (Cree et al. 2008). However, to date, nucleoid-based models have not been investigated in the transmission of mtDNA heteroplasmy from mothers to offspring.

Another issue is the degree to which negative (or purifying) selection may act on deleterious variants during the transmission of mtDNA heteroplasmy. There are conflicting results and views as to whether changes in the frequency of a heteroplasmic mutation from mother to offspring are governed solely by genetic drift, or whether there is an additional role for negative (purifying) selection (Jenuth et al. 1997; Durham et al. 2006; Stewart et al. 2008a,b; Wonnapijit et al. 2008; Wallace and Chalkia 2013; Rebolledo-Jaramillo et al. 2014). Negative selection during heteroplasmy transmission, as evidenced by a decrease in the frequency of presumably deleterious heteroplasmic variants in offspring compared to mothers, must operate on the female germ line and/or early in development after fertilization, and hence differs from negative selection operating on homoplasmic variants that reduce viability or

fertility (Holt et al. 2014). The opportunities for, and extent of, such negative selection during heteroplasmy transmission in humans remain largely unknown.

Here, we utilize the Genomes of the Netherlands (GoNL) project (Boomsma et al. 2014; Genome of the Netherlands Consortium 2014), consisting of whole-genome sequence data from blood samples from 250 families, to carry out the largest study to date (to our knowledge) of the dynamics of heteroplasmy transmission across the entire mtDNA genome. We utilize the data on changes in minor allele frequency (MAF) from mothers to offspring at heteroplasmic sites to compare different models for the inheritance of mtDNA genomes, and we analyze the data for evidence of negative selection during heteroplasmy transmission.

## Results

### Heteroplasmy characteristics

After quality filtering, there were data from 246 families representing 228 trios, eight DZ twin quartets, and 10 MZ twin quartets (total of 254 independent transmissions of mtDNA from mother to offspring, assuming independent transmissions of mtDNA to the DZ twins), sequenced to an average mtDNA coverage of approximately 1200× (Supplemental Table S1; Supplemental Fig. S1). We first used strict criteria, requiring all heteroplasmies in each individual to pass the quality control measures (including a minimum minor allele frequency [MAF] of 2%) to identify heteroplasmies. These quality control measures also include criteria for detecting contamination and the potential influence of nuclear inserts of mtDNA (NUMTs), as discussed in detail elsewhere (Li et al. 2012; Li and Stoneking 2012). We then called additional heteroplasmies in mothers or offspring if the same two alleles were detected in both (regardless of frequency) and if the heteroplasmy at that position in either the mother or the offspring had passed the quality control measures. With these criteria, we identified 189 heteroplasmies at 163 positions in the 228 trio mothers and 159 heteroplasmies at 137 positions in the 228 trio offspring (Table 1; Supplemental Table S1); the heteroplasmy data for the twin quartets are considered separately (Supplemental Tables S2, S3). A list of all of the heteroplasmies identified and associated MAF can be found in Supplemental Data Set S1. We also analyzed a subset of these heteroplasmies (Supplemental Tables S4, S5) with a different detection method, namely droplet digital PCR (ddPCR), and found a very high and significant correlation (Pearson's correlation = 0.998,  $P < 0.00001$ ) between MAF estimated from sequencing versus MAF estimated from ddPCR (Supplemental Fig. S2). Even for low frequency heteroplasmies (MAF < 0.05), the

**Table 1.** Summary of the heteroplasmy data for trios

Category	Number of individuals	Number of heteroplasmies	Average MAF at heteroplasmic sites
Mothers	228	189	0.109
Nontransmitted		77 (41%)	0.072
Transmitted		112 (59%)	0.134
Offspring	228	159	0.120
Noninherited		47 (30%)	0.077
Inherited		112 (70%)	0.137
Total	456	348	0.107

(MAF) Minor allele frequency; the data for MZ and DZ twins are in Supplemental Tables S2 and S3, respectively.

correlation is still quite high (Pearson's correlation = 0.890,  $P < 0.00001$ ). Thus, the heteroplasmy identified by our criteria in the sequencing data are reproducible by a different method.

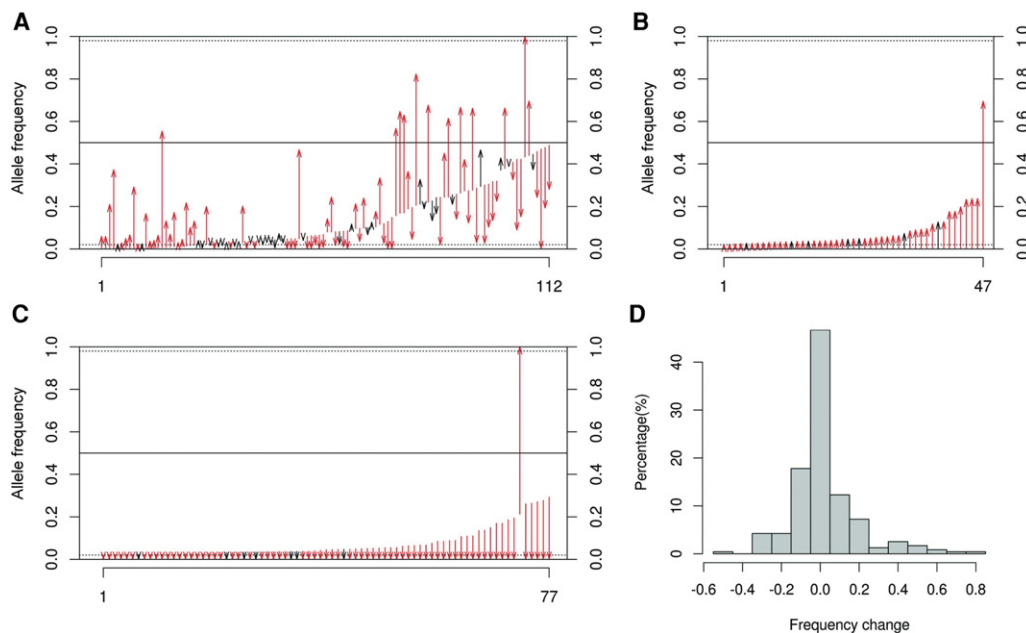

We first compared the number of heteroplasmy in the parents and offspring, using only those heteroplasmy that had passed all quality control measures so as not to introduce a bias when comparing mothers or offspring to fathers. There were significantly fewer heteroplasmy in the offspring than in the parents ( $P = 0.0179$ , Mann-Whitney  $U$  test), which presumably reflects the age-related accumulation of heteroplasmy (Liu et al. 1998; Sondheimer et al. 2011; Williams et al. 2013). Indeed, there is a small but significant correlation between age and number of heteroplasmy in the parents (Spearman's  $\rho = 0.139$ ,  $P = 0.000236$ ). The number of heteroplasmy identified in the offspring is significantly correlated with the number of heteroplasmy in mothers ( $\rho = 0.328$ ,  $P = 3 \times 10^{-7}$ ), but not with that in fathers nor with parental age at conception. The number of heteroplasmy per individual (using only unrelated individuals, e.g., the parents) does not differ significantly from a Poisson distribution ( $\chi^2$  test,  $P = 0.63$ ) (Supplemental Fig. S3), indicating that there is no evidence to indicate that heteroplasmy occur preferentially in some individuals; the mean number of heteroplasmy per individual was 0.7 (range 0–5). Finally, the MAF distribution across heteroplasmy sites did not differ significantly between mothers and fathers ( $P = 0.10$ , Mann-Whitney  $U$  test).

The average shift in heteroplasmy MAF between mothers and offspring was 0.108 (regardless of direction), with a maximum of 0.787 (Fig. 1). Although the MAF at all heteroplasmy sites did not differ significantly between mothers and offspring ( $P = 0.08$ , Mann-Whitney  $U$  test) (Table 1), the transmitted heteroplasmy in mothers had a significantly higher MAF than the nontransmitted heteroplasmy ( $P = 5 \times 10^{-15}$ ) (Table 1). Similarly, the inherited heteroplasmy in offspring had a significantly higher MAF than the noninherited (i.e., de novo) heteroplasmy ( $P =$

$1 \times 10^{-8}$ ) (Table 1), suggesting that heteroplasmy with higher MAF are more likely to be transmitted to the next generation and also have a higher mutant allele frequency than de novo mutations (Table 1). Differences in coverage could potentially explain these results; however, we did not find any significant coverage differences between transmitted versus nontransmitted heteroplasmy in mothers or between inherited versus noninherited heteroplasmy in offspring (Supplemental Fig. S4).

We observe a higher concordance (i.e., smaller difference in MAF) in transmitted heteroplasmy in MZ than in DZ twins. For the 10 sets of MZ twins, the MAF differs significantly between the members of a twin pair at just one of seven heteroplasmy sites (Supplemental Table S2), whereas for the eight sets of DZ twins, the MAF differs significantly at six of nine heteroplasmy sites (Supplemental Table S3). MZ twins are therefore more concordant for MAF than are DZ twins, although this result is of borderline significance ( $P = 0.06$ , Fisher's exact test).

The major alleles at 18 positions differed between mothers and offspring (Supplemental Table S6). The biggest change was observed at np 15152, where the A allele increased from a frequency of 21.3% in the mother to fixation in the offspring. Interestingly, the observed G > A mutation at this position is a nonsynonymous mutation, resulting in a change from Gly to Ser at amino acid position 136 in the *MT-CYB* gene. This amino acid change is predicted to have a high risk of a functional effect (Reva et al. 2011) and has only been reported previously in the Acadian population (Secher et al. 2014) and in a patient with type 2 diabetes mellitus (Ohkubo et al. 2000). Only one of the shifts in the major allele from mother to offspring involved a putative de novo mutation (i.e., the mutant allele could not be detected in the mother): the mutant allele at np 8405, which had a frequency of 69.5% in the offspring (Supplemental Table S6). All the other putative de novo mutations had a frequency of <30% in the offspring (Fig. 1C). We emphasize that all of these putative de novo mutations

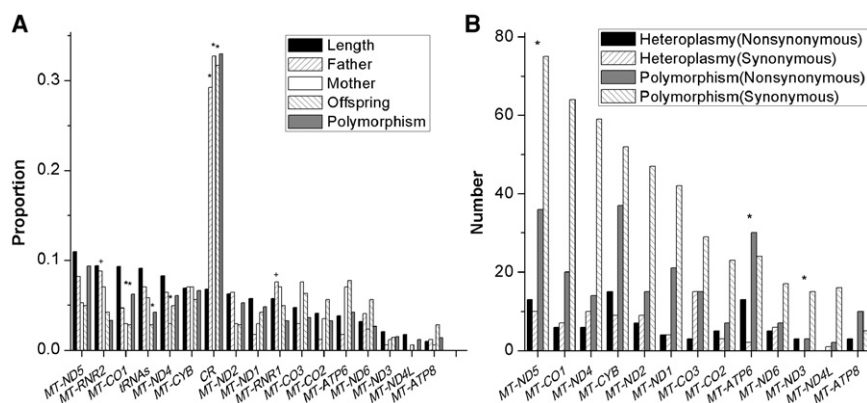

**Figure 1.** Minor allele frequency (MAF) changes between mothers and offspring. Red arrows indicate cases in which the MAF changed significantly between mother and offspring ( $P < 0.00001$ , Fisher's exact test). (A) MAF change for heteroplasmy detectable in both mothers and offspring. (B) MAF change for heteroplasmy detected in offspring but not in mothers. (C) MAF change for heteroplasmy detected in mothers but not in offspring. (D) Summary of the MAF changes observed for all heteroplasmy sites.

could still reflect heteroplasmies that were actually transmitted from the mothers but were present in the mothers at too low a frequency for our methods to detect. Therefore, these results should be interpreted as providing an upper bound for the incidence and frequency shifts of de novo mutations.

The distribution of heteroplasmies across different regions of the mtDNA genome did not differ among fathers, mothers, and offspring, but overall heteroplasmies were not distributed at random across the mtDNA genome (Fig. 2). Instead, heteroplasmies occurred preferentially in the noncoding control region (CR), as observed previously (He et al. 2010; Li et al. 2010; Rebolledo-Jaramillo et al. 2014; Ye et al. 2014), whereas *MT-CO1*, *MT-ND4*, and tRNAs had fewer heteroplasmies than expected based on gene length (Fig. 2). The heteroplasmies incidence is significantly correlated with the estimated mutation rate for each site (Pearson's  $\rho = 0.421$ ,  $P = 7 \times 10^{-14}$ ), as observed previously (Li et al. 2010), which is in accordance with expectations under neutrality. However, compared to polymorphisms observed among the consensus mtDNA genome sequences from the same individuals, heteroplasmic mutations are enriched for nonsynonymous (NS) mutations relative to synonymous (SS) mutations (NS:SS ratio is 1.09 for heteroplasmies and 0.46 for polymorphisms,  $P = 2 \times 10^{-6}$ , Fisher's exact test; the details for each gene are shown in Fig. 2). Moreover, the NS:SS ratio decreases with increasing MAF (Supplemental Fig. S5), and the proportion of mutations that are predicted to have a high or medium risk of a functional effect is significantly higher in low frequency (MAF < 5%) than in high frequency (MAF > 5%) heteroplasmies (73% versus 31%,  $P = 0.0017$ , Fisher's exact test) (Supplemental Fig. S6).

### Negative selection

Overall, there is no evidence for nonrandom shift in the MAF (either increasing or decreasing) from mother to offspring ( $P = 0.903$ , Wilcoxon signed-rank test). In addition, as shown in Figure 3A,

**Figure 2.** Distribution of heteroplasmies in different mtDNA gene regions. (A) Overall distribution of heteroplasmies. Black bars represent the expected heteroplasmies frequency for each gene region based purely on length. Uphill-striped, white, and downhill-striped bars represent the observed proportion of heteroplasmies identified in fathers, mothers, and offspring, respectively. Gray bars represent the polymorphism frequency for each gene region (inferred from PhyloTree Build 15 [van Oven and Kayser 2009]). Asterisks indicate significant differences ( $P < 0.01$ ) between the observed and expected proportion of heteroplasmies based on gene region length, and the plus signs indicate significant differences between the observed and expected proportion of heteroplasmies based on polymorphism frequency. There were no significant differences observed between fathers and mothers, fathers and offspring, or mothers and offspring in the distribution of heteroplasmies across gene regions. (B) Number of nonsynonymous (NS) and synonymous (SS) heteroplasmies and polymorphisms observed in different genes. Asterisks indicate that the NS:SS ratio for heteroplasmies is significantly greater than the NS:SS ratio for polymorphisms in the respective gene ( $P < 0.05$ ).

the average MAF was lower for NS heteroplasmies than for SS or noncoding (NC) heteroplasmies in both mothers and offspring (MAF = 0.174 for NS heteroplasmies versus 0.275 for SS-NC heteroplasmies in the mothers; MAF = 0.169 for NS heteroplasmies versus 0.249 for SS-NC heteroplasmies in the offspring). However, these differences in MAF between NS and SS-NC heteroplasmies are not significant in either the mothers ( $P = 0.127$ , Mann-Whitney  $U$  test) or the offspring ( $P = 0.317$ , Mann-Whitney  $U$  test).

NS heteroplasmic mutations were further categorized, based on the likelihood of having a functional impact, into high risk, medium risk, low risk, and neutral (Reva et al. 2011). Although high risk mutations had a lower frequency and were more likely to be eliminated in the next generation (Fig. 4), the difference between the high risk and other categories was not significant ( $P = 0.26$ ). Overall, these results do not provide compelling evidence for negative selection against NS mutations during transmission from mothers to offspring.

However, we do find significant differences in the transmission of polymorphic heteroplasmies (heteroplasmies for which both the major and minor alleles have been previously observed as polymorphic variants in comparisons among mtDNA sequences from worldwide individuals) (van Oven and Kayser 2009) versus novel heteroplasmies (heteroplasmies for which the alleles have not been reported previously as polymorphic variants). Novel heteroplasmies had a significantly lower MAF than polymorphic heteroplasmies in both mothers (novel MAF: 0.074; polymorphic MAF: 0.310;  $P = 0.0001$ , Mann-Whitney  $U$  test) and offspring (novel MAF: 0.056; polymorphic MAF: 0.286;  $P = 4 \times 10^{-6}$ ). Moreover, the MAF decreased in frequency from mothers to offspring more often for novel heteroplasmies than for polymorphic heteroplasmies (84.4% of novel heteroplasmies versus 68.0% of polymorphic heteroplasmies;  $P = 0.049$ ) (Fig. 5A). Consequently, a significantly larger proportion of novel heteroplasmies were eliminated in the offspring (71.1% of novel heteroplasmies versus 27.9% of polymorphic heteroplasmies,  $P = 2.2 \times 10^{-6}$ ) (Fig. 5A).

This difference in the disappearance of novel versus polymorphic heteroplasmies remains significant even when controlling for the lower average MAF of novel heteroplasmies (Supplemental Fig. S7). Interestingly, novel heteroplasmies are overrepresented in ribosomal RNA (rRNA) and transfer RNA (tRNA) genes (Fig. 5B,C): These genes account for 58% of the novel heteroplasmies versus just 5% of the polymorphic heteroplasmies ( $P = 5 \times 10^{-13}$ , Fisher's exact test). Moreover, 88% of the novel mutations in rRNA and tRNA genes decreased in frequency in the offspring, and 77% disappeared entirely, compared to 67% of polymorphic mutations in rRNA and tRNA genes decreasing in frequency in the offspring and 33% disappearing entirely. As discussed subsequently, disease-associated mtDNA mutations often occur in the rRNA/tRNA genes; these results thus suggest that negative selection is occurring against novel heteroplasmies in the rRNA and tRNA genes that are likely to be deleterious.

**Figure 3.** Frequency of the mutant allele (relative to the revised Cambridge Reference Sequence [rCRS]) and frequency change of the mutant allele for different mutation types. (A) Frequency of the mutant allele for: NS mutations in the mother [NS(M)]; SS and NC mutations in the mother [SS-NC(M)]; NS mutations in the offspring [NS(O)]; and SS and NC mutations in the offspring [SS-NC(O)]. (B) Distribution of the frequency change of NS and SS-NC mutations during transmission from mothers to offspring. The same results were obtained when the analyses were done for the minor allele at each position rather than the non-rCRS allele.

### Bottleneck models

We used the distribution of the changes in MAF between mothers and offspring at heteroplasmic sites (Fig. 1D) to investigate the size and nature of the transmission bottleneck. We used one offspring and one heteroplasmic position per family so as to avoid any complications due to potential non-independence of heteroplasmy within families. The specific positions used are identified in Supplemental Data Set S1; similar results were obtained when different sets of positions were used. Previous studies of the bottleneck size have assumed a constant size for the bottleneck across individuals and treated each mtDNA genome as an independent unit (Guo et al. 2013; Rebolledo-Jaramillo et al. 2014); neither variable-size bottleneck models nor nucleoid models have been investigated. We therefore fit four models to the data: a constant-size bottleneck, a variable-size bottleneck, a constant-size bottleneck with nucleoids, and a variable-size bottleneck with nucleoids (see Methods). We took into account the observed coverage and associated sequencing error rate for each position in the analysis (see Methods). Under the constant-size bottleneck model, the maximum-likelihood estimate (MLE) of the number of transmitting mtDNA genomes was eight (Fig. 6A); and under the variable-size bottleneck model, the MLE was a mean of nine transmitted mtDNA genomes (Fig. 6B). For both nucleoid models, we assumed an average of 7.5 mtDNA genomes per nucleoid, in accordance with empirical data (Cao et al. 2007; Khrapko 2008; Bogenhagen 2012). The MLE was seven nucleoids for the constant-size bottleneck model (Fig. 6C); and for the variable-size bottleneck model, the MLE was a mean of nine transmitted nucleoids (Fig. 6D). The Akaike Information Criterion (AIC) for the various models (Supplemental Table S7) indicates that the variable-size bottleneck model with mtDNA as independent entities provides the best fit to the data (the smaller the AIC value, the smaller the loss in information when fitting the model).

### Discussion

This study of the transmission of human mtDNA heteroplasmy across the entire mtDNA genome is one of the largest to date and provides several important insights. However, before discussing these insights, it is necessary to consider the accuracy of the data. First, we note that since the GoNL data were originally aligned and mapped to the hg19 reference, a newer reference (GRCh38)

has become available; remapping the data to GRCh38 in theory might change the results. However, the mtDNA reference sequence has not changed, so the only difference that could arise would be in the identification of NUMTs. We therefore did a BLAST search of the mtDNA genome against hg19 and GRCh38; there is a ~3% increase in the number and total length of NUMTs in GRCh38 compared to hg19. Because additional steps are taken in the pipeline to remove potential NUMT sequences, as discussed in detail in Li et al. (2012), and the additional confirmation by ddPCR indicates that NUMTs are not being misidentified as heteroplasmy, it is highly unlikely that remapping reads to GRCh38 would result in any significant differences in the conclusions of our study.

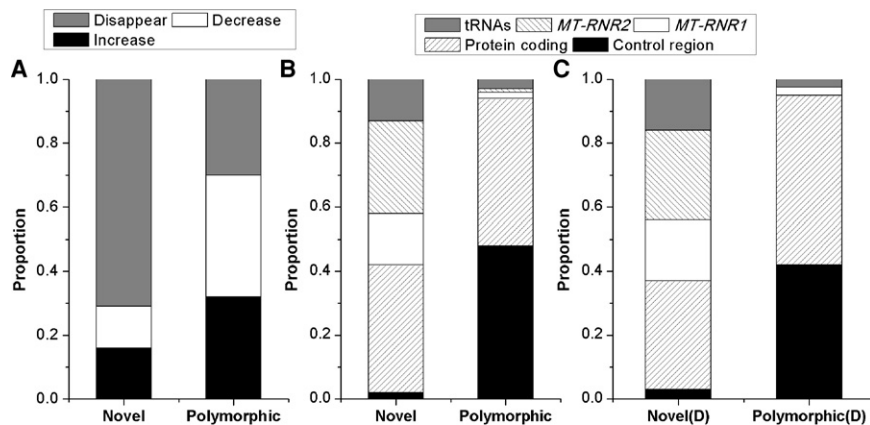

Although next-generation sequencing platforms are extremely useful for detecting low-level heteroplasmy, rigorous criteria are needed to call heteroplasmy in order to avoid false positives due to sequencing errors (Bandelt and Salas 2012). Moreover, contamination with another sample can lead to the false appearance of heteroplasmy (Just et al. 2014). The pipeline we have implemented for calling heteroplasmy includes strict criteria for avoiding false positives due to sequencing errors, as well as for detecting contamination and avoiding the influence of NUMTs (Li et al. 2012; Li and Stoneking 2012). In addition, contamination was previously assessed independently in the GoNL genomic sequence data that we analyzed (Genome of the Netherlands Consortium 2014). Most importantly, a subset of the heteroplasmy identified by our pipeline from the Illumina sequence data were verified by an independent method (Supplemental Fig. S2; Supplemental Table S5); it is thus highly unlikely that the heteroplasmy we identified are sequencing errors, artifacts due to NUMTs, or contamination.

### MZ versus DZ twins

We also find fewer heteroplasmy exhibiting significant differences in MAF in MZ twin pairs than in DZ twin pairs (Supplemental

**Figure 4.** Frequency change during transmission for different types of NS mutations. NS mutations were categorized in terms of likely functional impact on the protein as high risk, medium risk, low risk, or neutral (Reva et al. 2011). Other: SS and NC mutations.

**Figure 5.** Transmission characteristics of heteroplasmies for novel versus polymorphic heteroplasmies. (A) Proportion of minor alleles observed in mothers that disappear entirely, decrease in frequency, or increase in frequency in the offspring for novel versus polymorphic heteroplasmies. (B) Distribution across genic regions of all heteroplasmies involving novel versus polymorphic heteroplasmies. (C) Distribution across genic regions for novel heteroplasmies that disappeared in the offspring [Novel(D)] compared to polymorphic heteroplasmies that disappeared in the offspring [Polymorphic(D)]. The *MT-RNR1* and *MT-RNR2* genes and the tRNA genes are overrepresented in the novel heteroplasmies.

Tables S2, S3), which would not be expected if these reflected sequencing errors. This result suggests that for inherited heteroplasmies, the MAF in the offspring is largely influenced by the MAF in the oocyte at the time of fertilization rather than subsequent drift and/or selection during development. We note that a previous study did not report a higher concordance in heteroplasmy in MZ versus DZ twin pairs (Andrew et al. 2011); however, this study used a probe-based assay to interrogate a limited number of positions in the control region and hence only evaluated the presence/absence of heteroplasmy at a site, not the MAF. Another study, which utilized Sanger sequencing of PCR products of the control region, did find higher concordance in MAF for MZ than DZ twins (Bendall et al. 1996). Still, our observations are based on a relatively small number of twin pairs (10 MZ and eight DZ), and therefore need further evaluation in a larger data set.

### Bottleneck models

We used the shifts in heteroplasmy MAF from mothers to offspring to estimate the size of the bottleneck that occurs during the transmission of mtDNA genomes. The size of the bottleneck was estimated under four models: a constant-size bottleneck model, in which each mtDNA genome is a segregating unit and the bottleneck size does not vary between individuals; a variable-size bottleneck model, in which each mtDNA genome is a segregating unit and the bottleneck size is allowed to vary between individuals; a constant-size nucleoid model, in which a nucleoid containing a variable number of homoplasmic mtDNA genomes is the segregating unit and the bottleneck size

does not vary between individuals; and a variable-size nucleoid model, in which a nucleoid containing a variable number of homoplasmic mtDNA genomes is the segregating unit and the bottleneck size is allowed to vary between individuals. The best fitting model (as determined by AIC values) was a variable-size bottleneck, with an estimated mean of nine individual mtDNA genomes transmitted from mothers to offspring.

This number is smaller than a recent estimate of 30–35 mtDNA genomes transmitted, based on 39 mother-offspring pairs (Rebolledo-Jaramillo et al. 2014). Although this previous study assumed a constant-size bottleneck model, our estimate for a similar constant-size bottleneck model is also smaller, about eight mtDNA genomes transmitted (Fig. 6; Supplemental Table S7). The reason for this discrepancy is probably because we do not assume that the observed

MAF in the offspring is identical to the MAF at transmission, as is usually assumed. Instead, we model the replication process from the bottleneck to the actual mtDNA population in the offspring, thereby allowing for genetic drift during the replication process (see Methods). Doing so allows for substantial changes in MAF during the replication process, but such changes will only be substantial if the bottleneck size is small. Incorporating drift in this way has two consequences: First, the same bottleneck model can be consistent with the few variants in the data set that have

**Figure 6.** Likelihood curves for the observed data (changes in MAF from mothers to offspring) under different models for the transmission of mtDNA. (A) Likelihood curve for the constant-size bottleneck model with mtDNA genomes as segregating units. (B) Likelihood curve for the variable-size bottleneck model with mtDNA genomes as segregating units. (C) Likelihood curve for the constant-size nucleoid model. (D) Likelihood curve for the variable-size nucleoid model.

drastic changes in allele frequency and with the large set of variants in the data set that show a smaller change; second, small MAF in the offspring do not require very large bottleneck sizes. Consider that without a drift model, the smallest nonzero allele frequency possible is  $1/n$ , where  $n$  is the bottleneck size. Hence, without modeling drift, all descendants with a very low MAF provide strong evidence for a large bottleneck size. However, by including drift, the final MAF in the offspring can be substantially smaller than the frequency at the bottleneck. As drift can only have substantial effects if the bottleneck size is small, this explains the estimate of a relatively small number of transmitted mtDNA genomes.

A variable-size bottleneck with each mtDNA genome as a segregating unit fit the data better than models involving nucleoids. However, this is not necessarily evidence against nucleoids, as we assumed an average of 7.5 mtDNA genomes per nucleoid, in accordance with some observations (Cao et al. 2007; Khrapko 2008; Bogenhagen 2012). If instead the number of mtDNA genomes per nucleoid is smaller, then the results based on nucleoids will approach the results based on mtDNA genomes as segregating units; in the limit, if each nucleoid contains exactly one mtDNA genome, as suggested by some studies (Kukat et al. 2011), then both models will give identical results. Our results therefore argue against the existence of nucleoids with several mtDNA genomes, but not necessarily against nucleoids with smaller numbers of mtDNA genomes. The most important conclusion is that the size of the bottleneck varies among individuals, whereas all previous attempts to model the size of the bottleneck have assumed that it is constant among individuals. Identifying the factors that influence this between-individual variation in bottleneck size would be of great interest and might have consequences for understanding the transmission of mtDNA-related diseases.

One limitation of our approach is that we are using the MAF observed in the mother's blood several years after conception as the estimate for the MAF in the egg at the time of conception. In the absence of data on heteroplasmy in human eggs, this limitation is unavoidable, although one way to improve the estimate would be to utilize heteroplasmy data from multiple tissues, as was recently done elsewhere (Rebolledo-Jaramillo et al. 2014). To further investigate this potential limitation, from a previous study of heteroplasmy variation across different tissues (Li et al. 2015), we calculated the correlation in MAF at heteroplasmic positions in blood and ovarian tissue from the same individual. There were 52 heteroplasms with MAF > 0.02 detected in either blood or ovarian tissue (or both) in individuals with data from both tissues, and the MAF in blood exhibits a modest but nonetheless significant correlation with that in ovarian tissue (Pearson's correlation = 0.62,  $P < 0.0001$ ). This would suggest that the MAF in blood is a reasonable proxy for the MAF in ovarian tissue, although data on heteroplasmy in human eggs would still be desirable.

A significant correlation between the mother's age at conception and the number of heteroplasms detected in the offspring was reported previously (Rebolledo-Jaramillo et al. 2014). However, there is no such correlation in the GoNL data (Pearson's rho = -0.03,  $P = 0.65$ ), although the range of mothers' ages at conception is similar between the two studies (range = 18–44). The reason for this difference is unclear, and further studies are warranted.

### Negative selection

Our results provide additional insights into the role of negative selection on heteroplasmic variants. We first examined nonsynon-

ymous (NS) heteroplasms in the coding region. As found previously (Li et al. 2010; Ye et al. 2014), NS heteroplasms occur proportionally more often (relative to SS heteroplasms) than do NS polymorphisms among individuals. Moreover, the ratio of NS:SS heteroplasms is higher for low-frequency heteroplasms (Supplemental Fig. S5), and low-frequency NS heteroplasms are enriched for NS mutations that are likely to have a functional impact (Supplemental Fig. S6). These results are consistent with the threshold model for deleterious mtDNA mutations (Wallace and Chalkia 2013): Such mutations are tolerated at a low frequency within a cell because there are still sufficient nonmutant mtDNA genomes to carry out normal mitochondrial metabolism. However, above a certain frequency threshold, the deleterious mutations have a negative impact on mitochondrial function and so can never reach "fixation" within an individual. Thus, NS mutations that are likely to be deleterious are observed at heteroplasmic frequencies below the frequency threshold, but are never observed as polymorphisms (i.e., homoplasmic variants among individuals).

However, we do not see any compelling evidence for negative selection acting on NS heteroplasms during transmission from mothers to offspring. The distribution of the average change in MAF from mothers to offspring does not differ for NS heteroplasms versus SS-NC heteroplasms (Fig. 3B). Although there is a tendency for NS heteroplasms with a higher risk of a functional effect to be reduced in frequency or disappear entirely in offspring versus mothers (Fig. 4), the difference between high-risk versus other types of NS heteroplasms is not significant. These results are in contrast to a previous study (Rebolledo-Jaramillo et al. 2014), which reported a significant decrease in the MAF for 11 NS heteroplasms when comparing mothers to offspring. However, we have recomputed (based on a one-tailed sign test) the  $P$ -value associated with the decrease in MAF in this previous study and obtained a higher value (0.033) than that reported by the authors ( $9.54 \times 10^{-7}$ ); with Bonferroni correction for multiple tests, this  $P$ -value is no longer significant. Moreover, in this previous study, the change in MAF for NS sites does not differ significantly from the MAF change for SS or NC sites, which we also found to be the case for the GoNL data. Overall, there does not seem to be any compelling evidence for selection in humans against NS heteroplasms during transmission from mothers to offspring.

This conclusion is in contrast with previous studies based on the mouse mutator mtDNA model (Fan et al. 2008; Stewart et al. 2008a,b), which found evidence for purifying selection against NS mutations. It may be that the purifying selection in the mouse mutator model operates at a different level, as the NS mutations generated in the mouse mutator model may be starting at a much higher frequency than would be observed in the human family data, possibly already above the threshold at which an impact on mitochondrial metabolism could occur. Although the differences do not reach statistical significance, we do see a tendency for NS mutations with a higher risk of functional impact to be reduced in frequency in offspring. Further studies of potential purifying selection against NS mutations during heteroplasmy transmission in humans are warranted.

In contrast to the situation with NS heteroplasms, we do see clear evidence for negative selection acting on heteroplasms for novel mutations versus heteroplasms for polymorphic mutations (Fig. 5). These novel heteroplasms are enriched for mutations in rRNA and tRNA genes; intriguingly, disease-causing mtDNA mutations frequently occur in these genes (Taylor and Turnbull 2005; Tuppen et al. 2010; Wallace and Chalkia 2013). However, none of the observed rRNA/tRNA heteroplasms are

annotated as disease-associated on the MITOMAP website ([www.mitomap.org](http://www.mitomap.org)). Based on criteria developed from conservation of mitochondrial tRNA sequences across species as well as potential for disrupting stem-loop pairing (Kondrashov 2005), three of six novel heteroplasmies and two of three polymorphic heteroplasmies are predicted to be deleterious. However, because ~70% of tRNA mutations are predicted to be deleterious by these criteria, it is not clear how to interpret these numbers; further studies are needed to investigate the functional consequences of these novel heteroplasmies.

Overall, there is growing evidence for a role of negative selection in decreasing the frequency of potentially deleterious mutations during the transmission of mtDNA genomes from mothers to offspring (Fan et al. 2008; Stewart et al. 2008a). This negative selection could operate during the bottleneck that occurs during transmission of mtDNA from mothers to offspring, as this bottleneck might by chance raise the frequency of deleterious heteroplasmic mutations above the threshold at which impairment of mitochondrial function occurs (Freyer et al. 2012). Alternatively, there may be selective replication favoring nonmutant mtDNA during the amplification that occurs after the bottleneck, as has been recently found in *Drosophila* (Hill et al. 2014). Regardless of the underlying mechanism, it is important to recognize that negative selection during the transmission of deleterious heteroplasmies is not the same as negative selection against homoplasmic deleterious mtDNA mutations that reduce fertility or viability; the latter operates according to the well-known principles of Darwinian natural selection, whereas the former implies the existence of a mechanism in the female germ line for recognizing and preferentially discriminating against such deleterious heteroplasmies, perhaps via impaired mitochondrial function (Holt et al. 2014). Understanding how this putative mechanism operates could be of crucial importance in providing new therapeutic targets for reducing the transmission of disease-associated mtDNA mutations.

## Methods

The characteristics of the study population and the production of the sequence data have been described in detail elsewhere (Boomsma et al. 2014; Genome of the Netherlands Consortium 2014); the sequence data can be accessed at the European Genome-Phenome Archive (study accession number EGAS00001000644). Briefly, genomic DNA was purified from blood samples from 769 individuals from across The Netherlands (consisting of 231 trios, 11 monozygotic [MZ] twin quartets, and eight dizygotic [DZ] twin quartets) and sequenced to an average genomic coverage of ~14× on the Illumina HiSeq 2000 platform. The reads were aligned and mapped, and heteroplasmies called (with MAF > 0.02) as described in detail in the Supplemental Material (Processing mtDNA data). A subset of the inferred heteroplasmies were selected for independent verification via droplet digital PCR, which was performed as described previously (Li et al. 2015), with additional details in the Supplemental Material (Digital Droplet PCR). Potential contamination in the whole-genome sequence data was previously assessed by the GoNL Consortium (Genome of the Netherlands Consortium 2014); additional measures were taken to identify potential contamination as described in the Supplemental Material (Potential contamination). After removal of potential contaminants, there were 756 samples (228 trios, eight DZ twin quartets, and 10 MZ twin quartets) for further analysis.

The relative mutation rate for each heteroplasmic position was estimated as the number of mutations observed at that posi-

tion in PhyloTree Build 15 (van Oven and Kayser 2009). Mutations noted in PhyloTree were defined as polymorphic mutations, whereas mutations that were not reported in PhyloTree were defined as novel mutations.

The size of the bottleneck during transmission of mtDNA genomes from mothers to offspring was estimated using a maximum-likelihood approach for four different models: a constant-size bottleneck model and a variable-size bottleneck model in which each mtDNA genome is the segregating unit; and a constant-size bottleneck model and a variable-size bottleneck model in which a nucleoid containing a variable number of identical mtDNA genomes (with mean = 7.5 genomes per nucleoid) is the segregating unit. The equations used for each model and further details concerning the modeling approach are in the Supplemental Material (Estimating the size of the bottleneck during mtDNA transmission and Modeling the replication process).

## Acknowledgments

This study makes use of data generated by the Genome of the Netherlands (GoNL) Project. Samples were contributed by LifeLines, The Leiden Longevity Study, The Netherlands Twin Register, The Rotterdam Studies, and the Genetic Research in Isolated Populations Program. The sequencing was carried out in collaboration with the BGI. Funding for the GoNL was provided by the Netherlands Organization for Scientific Research under award number 184021007, dated July 9, 2009, and made available as a Rainbow Project of the Biobanking and Biomolecular Research Infrastructure Netherlands (BBMRI-NL). This research was supported by the National Science Foundation, Directorate for Biological Sciences (Graduate Research Fellowship Grant No. DGE 1256260 to R.R.); the Netherlands Bioinformatics Center (M.V. and J.F.J.L.); and the Max Planck Society (M.L., M.W., R.S., and M.S.). The Netherlands Twin Register acknowledges funding from the Netherlands Organization for Scientific Research (NWO) and MagW/ZonMW (grants 904-61-090, 985-10-002, 912-10-020, 904-61-193, 480-04-004, 463-06-001, 451-04-034, 400-05-717, Addiction-31160008, Middelgroot-911-09-032, Spinopremie 56-464-14192); VU University's Institute for Health and Care Research (EMGO+) and Neuroscience Campus Amsterdam (NCA); and the European Research Council (ERC Advanced Award 230374).

**Author contributions:** M.S. and P.d.K. conceived the study; P.I. W.deB., J.A.B., C.M.v.D., G.J.B.v.O., P.E.S., M.A.S., C.W., D.I.B., and G.N.C. organized and oversaw the sampling and the production of the sequence data; M.L., R.R., M.V., J.F.J.L., and M.v.O. analyzed the data with input and supervision from M.K., S.Z., P.d.K., and M.S.; M.W. and R.S. performed the ddPCR experiments; M.L., R.R., P.d.K., and M.S. wrote the manuscript with input from the other authors; all authors read and approved the final manuscript.
