Abstract

In this work, we analyze a pair of one-dimensional coupled reaction-diffusion equations known as the Gray–Scott model, in which self-replicating patterns have been observed. We focus on stationary and traveling patterns, and begin by deriving the asymptotic scaling of the parameters and variables necessary for the analysis of these patterns. Single-pulse and multiple-pulse stationary waves are shown to exist in the appropriately-scaled equations on the infinite line. A (single) pulse is a narrow interval in which the concentration $U$ of one chemical is small, while that of the second, $V$, is large, and outside of which the concentration $U$ tends (slowly) to the homogeneous steady state $U \equiv 1$, while $V$ is everywhere close to $V \equiv 0$. In addition, we establish the existence of a plethora of periodic steady states consisting of periodic arrays of pulses interspersed by intervals in which the concentration $V$ is exponentially small and $U$ varies slowly. These periodic states are spatially inhomogeneous steady patterns whose length scales are determined exclusively by the reactions of the chemicals and their diffusions, and not by other mechanisms such as boundary conditions. A complete bifurcation study of these solutions is presented. We also establish the non-existence of traveling solitary pulses in this system. This non-existence result reflects the system’s degeneracy and indicates that some event, for example pulse-splitting, ‘must’ occur when a pair of pulses moving apart from each other (as has been observed in simulations); these pulses evolve towards the non-existent traveling solitary pulses. The main mathematical techniques employed in this analysis of the stationary and traveling patterns are geometric singular perturbation theory and adiabatic Melnikov theory.

Finally, the theoretical results are compared to those obtained from direct numerical simulation of the coupled partial differential equations on a ‘very large’ domain, using a moving grid code. It has been checked that the boundaries do not influence the dynamics. A subset of the family of stationary single pulses appears to be stable. This subset determines the boundary of a region in parameter space in which the self-replicating process takes place. In that region, we observe that the core of a time-dependent self-replicating pattern turns out to be precisely

1 Introduction

Self-replicating patterns have recently been observed in a reaction-diffusion system [20Γ16Γ21]. Numerical simulations show that the irreversible Gray-Scott model exhibits a broad array of new patterns including spots that self-replicate in a self-sustaining fashion and develop into a variety of time-dependent and time-independent asymptotic states in two dimensions [20Γ16Γ21] as well as pulses that self-replicate in one dimension [21]. The two-dimensional self-replicating spots have also been observed experimentally in a ferrocyanide-iodate-sulfite reaction [16]. See [15] for more details of the setup. Moreover, those same experiments led to the discovery of other new patterns such as annular patterns emerging from circular spots [16].

The irreversible Gray-Scott model governs the chemical reactions \( U + 2V \rightarrow 3V \) and \( V \rightarrow \mathcal{P} \) in a gel reactor where \( V \) catalyzes its own reaction with \( U \) and \( \mathcal{P} \) is an inert product. See [8Γ9Γ10]. The gel reactor is coupled to a reservoir in which the concentrations of \( U \) and \( V \) are maintained constant. This coupling also results in both chemicals being removed from the reactor in a concentration-dependent fashion. Furthermore, the diffusivities \( D_U \) and \( D_V \) of the chemicals \( U \) and \( V \) respectively can be any chemically-relevant positive numbers. For example, in the one-dimensional work [21] pulse-splitting was observed when \( D_U = 1 \) and \( D_V = \delta^2 = 0.01 \). By contrast, in the two-dimensional numerical simulations [20] the spot-replication was observed with \( D_U = 2D_V = 2 \times 10^{-5} \) and other studies have focused on the case of equal or nearly equal diffusivities [see for example [19Γ23Γ28]].

Letting \( U = U(x, t) \) and \( V = V(x, t) \) denote the concentrations of the two chemical species \( U \) and \( V \), the pair of coupled reaction-diffusion equations governing these reactions is:

\[
\begin{align*}
\frac{\partial U}{\partial t} &= D_U \nabla^2 U - UV^2 + A(1 - U), \\
\frac{\partial V}{\partial t} &= D_V \nabla^2 V + UV^2 - BV.
\end{align*}
\]

Here, \( A \) denotes the rate at which \( U \) is fed from the reservoir into the reactor (and this same feed process takes \( U \) and \( V \) out in a concentration dependent way) and the concentration of \( V \) in the reservoir is assumed to be zero and \( B \) is the sum of \( A \) and the rate constant \( k_2 \) fixed by the rate at which \( V \) is converted to inert product.

A pulse in one space dimension (and similarly a spot in two space dimensions) may loosely be defined as an interval (region) of high \( V \) and low \( U \). Outside of such an interval (region) \( U \) is near one and \( V \) is nearly zero. A pulse widens (a spot grows) when the flux of \( U \) into it is high enough to sustain the first reaction and replenish the amount of the chemical \( V \) that leaves the pulse (spot) through diffusion and the coupling to the reservoir. Moreover, as a pulse widens (or a spot grows) the middle can quickly cave in (the spot gets pinched into two) when insufficient amounts of \( U \) reach the middle to sustain a high \( V \). Thus, a pulse (spot) can undergo a division process and the two pulses (spots) can move away from each other using up the \( U \) from adjacent intervals (regions). This initial splitting is stationary in the sense that the center of the pattern stays at the middle of
the domain. Further dynamic pulse-splitting occurs when there is enough $U$ behind the moving pulse and a new pulse emerges on the trailing edge.

In order to study this rich pulse dynamics mathematically we analyze the irreversible Gray–Scott model in one space dimension ($x \in \mathbb{R}$ and $\nabla^2 = \frac{\partial^2}{\partial x^2}$) on the infinite line:

\[
\begin{align*}
\frac{\partial U}{\partial t} &= \nabla^2 U - UV^2 + A(1 - U), \\
\frac{\partial V}{\partial t} &= \delta^2 \nabla^2 V + UV^2 - BV,
\end{align*}
\]

where $0 < \delta^2 \ll 1$. The choice of $D_U = 1$ and $D_V = \delta^2 \ll 1$ here follows that of [21] where it is explained that this singular limit “clarifies which physical processes are dominant as the system evolves.”

The numerical simulations of [21] and of this work (see section 6) suggest that neither $U$ nor $V$ are $O(1)$ throughout the whole pattern. For instance, during a peak in $V$ it is observed that $V$ is ‘large’ ($\gg 1$) while $U$ becomes ‘small’ ($\ll 1$). Therefore, we first perform a detailed scaling analysis that results in a scaled system in which the variables and parameters are $O(1)$. Based on geometrical arguments these scalings enable us to deduce that $A$ must be $O(\delta^2)$ in (1.1) in order for the patterns we find to exist. They also lead us to the correct asymptotic scalings for the variables and the other parameter $B$.

Our main results are then the following: First, we prove the existence of single-pulse and multiple-pulse stationary states for (1.1) on the infinite line. The detailed asymptotic scalings are derived specifically for this result and are shown to be essential. As remarked above, $A$ must scale with the small parameter $\delta^2$ in order for these pulses to exist. Moreover, we show that the relevant scalings for a pulse are $U = O(\delta^2)$ and $V = O(\delta^{-\alpha/3})$ and $B = O(\delta^{2\alpha/3})$ where $\alpha \in [0, 3/2)]$. In between the pulses of a multi-pulse solution $V$ becomes $\ll 1$ but not too small; whereas in the semi-infinite intervals surrounding the pulses $V$ becomes exponentially small. Also, we are able to construct these solutions for each (rescaled) $A$ and $B$ and $\alpha \in (0, 3/2)$.

Second, we establish the existence of a plethora of periodic stationary states for (1.1) on the infinite line (equivalently for (1.1) on a finite interval with periodic boundary conditions). These periodic states consist of an infinite array of narrow, equally-spaced pulses. The same scalings derived for the above stationary multiple-pulse states are also central to the analysis here. During a pulse event the dependent variables $U$ and $V$ scale exactly as in the above multiple-pulse states. However, $V$ is exponentially small in the intervals between pulses. Most importantly, these periodic states are observed to form the core regions of the time-dependent self-replicating pulse patterns on finite domains and it is found that their intrinsic length scale is determined exclusively by the reaction and diffusion of the chemicals and not by boundary effects.

Third, the traveling pulses observed in the simulations of [21] and of this work are for large time intervals more or less stationary in a co-moving frame. Hence, it is natural to try to construct traveling pulses of the same type as the stationary pulses. However, we prove that these traveling solutions cannot exist. Therefore, this non-existence result shows that while the numerically-observed moving pulses begin to resemble the non-existing traveling solitary pulses more and more, they must undergo some transformation such as pulse-splitting. Moreover, we note that the analysis needed to obtain this result while again depending on the above scaling is delicate since the non-existence of traveling waves violates simple generic counting arguments (see section 5).
Finally we present the results of some numerical simulations of (1.1) on finite but sufficiently large domains with various types of boundary conditions using a moving grid code. These simulation results corroborate our analytical results and confirm that the patterns do not form in response to boundary conditions. In the (rescaled) \((A, B)\)-parameter plane we determine a transition region which distinguishes two regions: a trivial one where \((U, V)\) tend to the asymptotically stable homogeneous ‘pattern’ \(U \equiv 1Tv \equiv 0\) and the so-called self-replicating pulse region. In this transition region we observe the stationary single pulse patterns described above. Above the transition region namely in the self-replicating pulse region one does not expect, a priori, stationary behavior. Nevertheless we observe that (after quite a long time) the self-replicating patterns on an unbounded domain evolve towards a stationary periodic pulse pattern that grows at both sides by a self-replication process which only involves the two traveling ‘boundary pulses’ and their most recently created ‘images’. The periodic ‘core’ is once again of the type described above. We have made a quantitative check between the observed patterns and those we constructed analytically and found a very good agreement. Note that the periodic core itself turns out to be the asymptotically stable pattern if one considers a finite domain with periodic boundary conditions (see figure 1 in [21]). Moreover the simulations reveal some other essential components of the pulse-splitting process and provide an important guide to further analysis. In the discussion we suggest some ideas for future work.

Our analysis begins with the traveling wave Ansatz: \(U = u(x - ct)\) and \(V = v(x - ct)\) where \(c \in \mathbb{R}\) is the wave speed and \(c = 0\) corresponds to stationary states. Plugging this Ansatz into (1.1) yields the following system of four ordinary differential equations:

\[
\begin{align*}
    u' &= p \\
    p' &= -cp + uv^2 - A(1 - u) \\
    \delta v' &= q \\
    \delta q' &= -c\delta q - uv^2 + Bv,
\end{align*}
\]

where \('\) denotes the derivative with respect to the independent variable \(\xi \equiv x - ct\). Note that the fourth component of the vector field (1.2) is \(O(\frac{1}{\delta})\) if \(c = O(1)\) therefore we introduce \(\gamma\) by

\[c = \delta \gamma.\]  

Rescaling the independent variable \(\xi \equiv \delta \eta\) yields:

\[
\begin{align*}
    \hat{u} &= \delta p \\
    \hat{p} &= \delta \left[ -\delta \gamma p + uv^2 - A(1 - u) \right] \\
    \hat{v} &= q \\
    \hat{q} &= -\gamma q - uv^2 + Bv,
\end{align*}
\]

where \('\) denotes the derivative with respect to the new independent variable \(\eta\).

Equation (1.4) possesses two time scales: \(u\) and \(p\) are slow variables and \(v\) and \(q\) are fast variables. Hence the system (1.4) may be split into reduced slow and fast subsystems in a natural fashion. The reduced slow subsystem is defined only on the invariant plane \(\{u, p, v = 0, q = 0\}\) and is given by \(u'' + \delta \gamma u' + A(1 - u) = 0\) which has an equilibrium at \((u = 1, u' = 0)\). The reduced fast subsystem is the nonlinear planar oscillator \(\dot{v} + \gamma \dot{v} + uv^2 - Bv = 0\) which the variable \(u\) is treated as a fixed parameter and where this oscillator possesses an orbit homoclinic to \((v = 0, \dot{v} = q = 0)\) when \(\gamma = 0\) (equivalently \(c = 0\)).
This analytical splitting has a natural geometric analog that manifests itself in the various types of observed pulse solutions and that will be exploited throughout this work. Indeed, based on the structure of the pulse solutions observed in our numerical simulations and those reported in figures 1 and 2 of [21T3], we construct solutions which consist of alternating distinguished slow ($\approx \mathcal{O}(\delta)$) and fast ($\approx \mathcal{O}(1)$) parts. The slow part of the solution is guided by a particular slow trajectory on the invariant manifold \( \mathcal{M} = \{ u, p, v = 0, q = 0 \} \) while \( |v|, |q| \ll 1 \) in (1.4). By contrast, the fast part of the solution is guided by a particular homoclinic orbit of the reduced fast system since \( u \) and \( p \) will change by an \( \mathcal{O}(\delta) \) amount during a fast excursion through \((v, q)\)-space.

More precisely, we employ adiabatic Melnikov theory [18T22T30] directly on the scaled version of (1.4) to determine where the stable and unstable manifolds of the invariant slow plane intersect. This theory is particularly simple when \( c = 0 \) since (the scaled version) of (1.4) has a nice symmetry then. The case \( c > 0 \) is much more involved and it is necessary to calculate the asymptotic expansions for the location of the intersection out to a fairly high order. Furthermore, for both cases \( c = 0 \) and \( c > 0 \) it is also necessary to calculate the asymptotic expansions for the base points of the fast stable and unstable fibers lying in the transverse intersection of the slow plane's stable and unstable manifolds; again to sufficiently high order when \( c > 0 \). In this respect, we make use of the fundamental work [6] in geometric singular perturbation theory to study how the fast and slow dynamics ‘hook up’ to each other.

By constructing fast–slow periodic and homoclinic solutions of the type just described to a version of (1.4) in which the variables and parameters are properly scaled, we obtain our first and second main results. In particular, the locally–unique homoclinic orbits of (1.4) that we find—which are biasymmetric to the equilibrium point \((u = 1, u' = 0)\) of the slow subsystem and which are comprised of one or more fast excursions into the \( v - q \) space—immediately imply the existence of single-pulse and multiple-pulse stationary states of (1.1) on the infinite line. In addition, each of the periodic orbits of (1.4)—consisting of slow segments near \( \mathcal{M} \) and fast excursions away from \( \mathcal{M} \) into the \( v - q \) space—whose existence we prove is precisely a periodic stationary state of (1.1). These \( c = 0 \) periodic orbits are locally unique and lie exponentially close to the above transverse intersections by a modified version [25] of the exchange lemma with exponentially small error [12]. Finally, the dynamics of (1.4) also holds the key to our proof of the non-existence of traveling waves.

The periodic patterns we observe are Turing patterns because they are found to have an intrinsic chemical wave length as described above. However, they are not formed by the bifurcation mechanism Turing proposed [27] because they do not appear to emerge from small inhomogeneities in linearly–unstable homogeneous steady states. Rather, the initial data taken for most of our simulations are localized large-amplitude perturbations from the linearly–stable homogeneous steady state \((U = 1, V = 0)\). See [13] for a recent review of Turing patterns and spiral waves in reaction–diffusion systems and note that [29] show that \( D_U / D_V \) must exceed a critical ratio for supercritical bifurcations to occur.

The work here on the irreversible Gray–Scott model involving equations (1.1) fits into the larger problem area of the reversible Gray–Scott model see for instance [10] or equation (5) in [28]. The work reported in [28] shows that steady spatial patterns may form from finite-amplitude perturbations of a stable homogeneous steady state when the diffusion coefficients of all three species are equal. Also, in [23] it is shown under the same assumption of equal diffusivities that the presence of external gradients leads to Hopf bifurcations from spatially–
homogeneous states to periodic states as well as transitions to other patterns including multi-hump branches and fronts. In [7] patterns that develop from finite-amplitude perturbations to linearly stable homogeneous states are studied by a FitzHugh-Nagumo model. Multi-peak and periodic patterns have also recently been observed in models of the Belousov-Zhabotinsky reaction [1, 24], respectively.

Equations of the form (1.1) with $A, B = 0$ are also of interest. The recent work [17] investigates the dynamics of propagating fronts in this autocatalytic reaction. There a new phenomenon dubbed biscale chaos is reported and analyzed that occurs under the same condition imposed here, namely that the diffusivity of the ‘fuel’ $U$ is sufficiently larger than the diffusivity of the ‘autocatalyst’ $V$ although with qualitatively different initial data. Finally we remark that other localized phenomena are reported in [4] for a system of reaction–diffusion equations related to (1.1) but with a small parameter in front of the term $\partial V / \partial t$.

The paper is organized as follows. In section 2 we perform the scaling analysis that puts (1.4) into the form suitable for the analysis presented in the remainder of the paper. The global geometry of the rescaled system is studied in section 3 where we explicitly identify distinguished fast and slow orbit segments. In section 4 we use the results from section 3 to construct stationary single-pulse and multiple-pulse homoclinic solutions as well as a plethora of periodic steady state solutions. The nonexistence of traveling waves is shown in Section 5. The theoretical results of sections 4 and 5 are compared to those of numerical simulations in section 6. Finally we discuss a variety of issues related to our results and suggest further work in Section 7.

2 Scaling

A priori it is not clear that it is necessary to introduce new scales in (1.4). However we shall show in this section that the patterns observed in the numerical simulations ([21] and those reported in section 6 of this work) correspond to solutions of (1.4) in which most quantities are not of $O(1)$ at least not for all $\eta$. In the derivation of the appropriate scalings we focus on the construction of solutions homoclinic to the saddle point $S = (1, 0, 0, 0)$ of (1.4). See figure 1.a for a sketch of a one-pulse homoclinic orbit. These solutions correspond to solitary traveling “pulses” which do not change shape. Note that $\lim_{x \to -\infty} u(x, t) = 1$ and $\lim_{x \to -\infty} v(x, t) = 0$ for these homoclinic solutions: this agrees with the numerical observations. This restriction to homoclinic solutions is not essential in the derivation of the new scalings; and the same scalings will be used in section 4.2 in which we study periodic solutions [see figure 1.b. In order to keep the derivation as concise as possible we will sometimes use some foreknowledge about the flow induced by (1.4); a rigorous analysis of the flow will follow in the subsequent sections. The reader desiring to omit this derivation at first should start with equation (2.8).

The saddle point $S$ of (1.4) has 2-dimensional stable and unstable manifolds $W^S(S)$ and $W^U(S)$. The flow induced by (1.4) restricted to $\mathcal{M}$ is linear therefore the intersections $W^S(S) \cap \mathcal{M}$ and $W^U(S) \cap \mathcal{M}$ are straight lines in $\mathcal{M}$ (see also figure 1 and section 3.1):

$$\ell^{U,S} \equiv \{ p = \frac{1}{2} (\pm \sqrt{A + \delta^2 \gamma^2 - \delta \gamma}) (u - 1) \},$$

(2.1)

where $\ell^U \subset W^S(S)$ corresponds with the + sign and $\ell^S \subset W^U(S)$ with the − sign. The desired homoclinic solution $\Gamma_{h}(t) \subset W^S(S) \cap W^U(S)$ consists of three parts: first a slow part close to $\ell^U \Gamma$
then there is a fast excursion followed by the third part close to $\ell S$ which is again slow. See figure 1.a. The fast excursion ‘jumps’ from $\ell U$ to $\ell S$; and hence $\ell U$ and $\ell S$ need to be $O(\delta)$ close to each other at the “take off” and “touch down” points of the fast excursion. It follows from (2.1) that the jump must occur $O(\delta)$ near $S$ (and thus $1-u=O(\delta)$). However the numerically observed patterns show that $u$ is not close to 1 during the excursion. By (2.1) we observe that an $O(\delta)$ jump from $\ell U$ to $\ell S$ through the fast field for $1-u \neq O(\delta)$ is only possible if $A=O(\delta^2)$: then $\ell U$ and $\ell S$ are $O(\delta)$ close for all $u$ of $O(1)$. Thus we introduce $u$ by

$$A = \delta^2 u. \quad (2.2)$$

This scaling of $A$ agrees completely with the numerical values chosen in [21]; there $\delta^2 = 0.01$ and $A = 0.02$.

Next it is clear from the fast subsystem of (1.4) that $\gamma$ cannot be $O(1)$: a solution which leaves the slow manifold $\mathcal{M}$ will follow the unstable manifold of the point $(0, 0)$ of this subsystem $O(\delta)$ close. This orbit cannot return $O(\delta)$ close to $\mathcal{M}$ due to the strong ‘friction’ term $-\gamma q$. Furthermore numerical simulations suggest that $u \neq O(1)$ during the excursion through the fast field see section 6. Thus we scale:

$$u = \delta^\alpha \hat{u} \quad \text{and} \quad \gamma = \delta^\beta \hat{\gamma}, \quad (2.3)$$

where $\alpha \geq 0$ and $\beta > 0$ are free parameters. This scaling establishes that $\hat{u}$ cannot be smaller than $O(1)$ during the excursion through the fast field: $\delta^\alpha \hat{u}$ is the leading order part of $u$ during a ‘jump’; $\hat{\gamma}$ has a similar interpretation. Either $\hat{\gamma} = 0$ which corresponds to stationary waves or $\hat{\gamma}$ is $O(1)$ and not smaller. This property of $\hat{u}$ and $\hat{\gamma}$ will be essential in the proof of the non-existence result of section 5.

Due to the above scalings the fast field is the fast $(v, q)$ part of (1.4):

$$\begin{align*}
\dot{v} &= v_0 + q = q \\
\dot{q} &= q_0 - \delta^\beta \hat{\gamma} q - \delta^\alpha \hat{u} v^2 + Bu,
\end{align*} \quad (2.4)$$

becomes linear in the limit $\delta \to 0$ (if $\alpha > 0$) and has no solutions which are homoclinic to the saddle point $(v, q) = (0, 0)$. This is a crucial deficiency of the fast field since this again means that a solution which leaves the neighborhood of $\mathcal{M}$ cannot return to $\mathcal{M}$ (note that $\mathcal{M}$ corresponds to the collection of all saddle points of the fast field in the limit $\delta \to 0$). Thus in order to be able to construct homoclinic solutions to $S\Gamma$ we need scalings of $v\Gamma q$ and $B$ such that the leading order fast field supports homoclinic solutions. In particular we introduce $v = \delta^{\alpha-r} r \Gamma r > 0$ and $q = \delta^s \hat{q}$; here $r$ and $s$ are free parameters which will be determined later on. Note that numerical simulations also suggest that $v$ and $q$ scale with powers of $\delta^{\alpha-r}$ see [21] and section 6. We balance the $\hat{u} v^2$ and $B v$ terms in (2.4) by setting $B = \delta^{(\alpha-s)} b$. We now observe that $\hat{v}_0 = O(\delta^{(r+s)})$ and $\hat{q}_0 = O(\delta^{(\alpha-2r-s)})$. We impose $r + s = \alpha - 2r - s$ since the distinguished limit in the second-order $\hat{v}$ equation occurs when $\hat{v}$ and its derivative $\hat{q}$ evolve on the same time scale. Thus $\Gamma s = \frac{1}{2}(\alpha - 3r)$. Introducing the new independent variable $\hat{q} = \delta^{\frac{1}{2}(\alpha-r)} \eta \Gamma (2.4)$ transforms to:

$$\begin{align*}
\hat{\eta} &= \hat{q} \\
\hat{\eta} &= -\hat{u} \hat{v}^2 + b \hat{v} - \delta^{\frac{3}{2}(2\beta-\alpha+r)} \hat{\gamma} \hat{q}.
\end{align*} \quad (2.5)$$

This equation has all necessary features so that it can serve as fast field in the rescaled version of (1.4). Note that we again have to impose that the ‘friction’ term $\hat{\gamma} \hat{q}$ is $O(1)$ i.e. $2\beta - \alpha + r > 0$. 

When we introduce all the above scalings supplemented with a scaling for $p$: $p = \delta^i \hat{p}$ for some $t > 0$ into the slow part of (1.4) we find that $\hat{u}_t = O(\delta^{1 \over 2(2-\alpha-r)})$ and $\hat{p}_t = O(\delta^{1 \over 2(2+\alpha-3\alpha)})$ $(i.e.$ the `\hat{u}^2` term is the leading order term in $\hat{p}_t$) the other terms in $\hat{p}_t$ are assumed to be $o(1)$.

Since the distinguished limit also occurs when the dependent variable -- here $\hat{u}$ -- varies at the same rate as its derivative we set $t = \alpha - r$. This gives the following rescaled equations:

$$
\begin{align*}
\hat{u}_t &= \delta^{1 \over 2(2-\alpha-r)} \hat{p} \\
\hat{p}_t &= \delta^{1 \over 2(2-\alpha-r)} \left[ \hat{u} \hat{v}^2 - \delta^{1 \over 2+2\alpha} \hat{v} \hat{p} - \delta^{2 \over 2+2\alpha} a + \delta^{2 \over 2\alpha} a \hat{u} \right],
\end{align*}
$$

(2.6)

with the additional assumption $2 - \alpha - r > 0$ so that the $(\hat{u}, \hat{p})$-subsystem remains slow compared to the $(\hat{v}, \hat{q})$-subsystem.

Combining the fast and the slow subsystems (2.5) and (2.6) we note that there are two different leading order perturbation scales: the slow `time'-scale $\delta^{1 \over 2(2-\alpha-r)}$ in (2.6) and the `friction'-term of $O(\delta^{1 \over 2(2+\alpha-3\alpha)})$ in (2.5). In the next section we shall show that the stable and unstable manifolds of the slow manifold $\mathcal{M}$ can only intersect if the leading order term is at most of the same order as the leading order term $\delta^{1 \over 2(2-\alpha-r)}$ in (2.6). Moreover we will find that we need to impose that the friction-term is of $O(\delta^{1 \over 2(2-\alpha-r)})$ for the existence of the desired homoclinic solution $\Gamma_i(t)$. Thus if a homoclinic solution $\Gamma_i(t)$ to $S \in \mathcal{M}$ can only exist if the leading order perturbation in the complete $(\hat{u}, \hat{p}, \hat{v}, \hat{q})$-system is $O(\delta^{1 \over 2(2-\alpha-r)})$. Hence when a solutions makes an excursion through the fast field one expects that both $\hat{u}$ and $\hat{p}$ will change by an amount of $O(\delta^{1 \over 2(2-\alpha-r)})$. Since $p = \delta^{1 \over 2 \alpha} \hat{p}$ this implies that an excursion through the fast field modifies $p$ by an amount of $O(\delta^{1 \over 2(2+\alpha-3\alpha)})$. The homoclinic solution $\Gamma_i(t)$ must `jump' from $\ell^U$ to $\ell^S$ (2.1) by such an excursion through the fast field. Due to the scaling (2.2) we know that $\ell^U$ and $\ell^S$ are $O(\delta)$ apart; thus we have to choose $r$ such that it satisfies the following `jump condition':

$$
{1 \over 2}(2 + \alpha - 3r) = 1 \quad \text{or} \quad r = {1 \over 3} \alpha.
$$

Summarizing we have derived the following scalings for the quantities appearing in (1.4):

$$
\begin{align*}
u &= \delta^{1 \over 2 \alpha} \hat{u}, \quad p = \delta^{1 \over 2 \alpha} \hat{p}, \quad v = \hat{v}, \quad q = \hat{q}, \quad A = \delta^{1 \over 2 \alpha} a, \quad B = \delta^{1 \over 2 \alpha} b, \quad c = \delta^{1 \over 2 \alpha} \gamma,
\end{align*}
$$

(2.7)

Also $\eta = \delta^{1 \over 2 \alpha} \hat{\eta}$. Introducing these scalings into (1.4) and dropping hats we arrive at:

$$
\begin{align*}
\hat{u} &= \delta^{1 \over 2 \alpha - \gamma} \hat{p} \\
\hat{p} &= \delta^{1 \over 2 \alpha - \gamma} \left[ \hat{u} \hat{v}^2 - \delta^{1 \over 2 \alpha - \gamma} \hat{v} \hat{p} - \delta^{1 \over 2 \alpha - \gamma} a + \delta^{1 \over 2 \alpha} a \hat{u} \right] \\
\hat{v} &= q \\
\hat{q} &= -uv^2 + bv - \delta^{1 \over 2 \alpha - \gamma} q,
\end{align*}
$$

(2.8)

with two additional conditions for the free parameters $\alpha$ and $\beta$:

$$
1 - {2 \over 3} \alpha > 0 \quad \text{or} \quad 0 \leq \alpha < {3 \over 2}
$$

(2.9)

$$
\beta - {1 \over 3} \alpha \geq 2 \left( 1 - {2 \over 3} \alpha \right) \quad \text{or} \quad \beta \geq 2 - \alpha > {1 \over 2}.
$$

(2.10)

Based on the numerical simulations of [21] and section 6 one would say that $\alpha$ must be 1 in (2.8). Note that the choice $B = 0.079$ with $\delta^2 = 0.01$ in the numerical simulations of [21] is then related to
the realistic value of $b$ of approximately $0.37 \Gamma$ since $\Gamma B = 0.079 = b \delta^{2/3} \approx 0.366(0.01)^{1/3}$. However $\Gamma$ in section 4 we shall see that there exist stationary pulses (thus $c = \gamma = 0$) for any $\alpha \in [0, \frac{3}{2}]$. Nevertheless the numerical simulations suggest that only those with $\alpha = 1$ can be stable (for certain values of $a$ and $b$; see section 6). If we look for non-stationary (traveling) pulses $\Gamma$ then the value of $\beta$ becomes important as we shall see in section 5. In the simulations illustrated in figures 7–9 we show numerically that the splitting pulses travel with speed $c = \mathcal{O}(\delta^2)$ thus $\Gamma$ by (2.7) $\Gamma \beta = 1$ in (2.8).

In the next sections we will expand the solutions of (2.8) with respect to the leading order perturbation term $\delta(1 - \frac{2}{3} \alpha)$. Especially in section 5 we will study the relative magnitudes of the ‘friction’-term in the fast field and the amplitude of the slow components of the vector field. Therefore we introduce for simplicity $\Gamma \varepsilon$ and $\sigma$ by

$$
\varepsilon = \delta^{1 - \frac{2}{3} \alpha} \quad \text{and} \quad \varepsilon^{2 + \sigma} = \delta^{\beta - \frac{2}{3} \alpha}.
$$

Furthermore we define $\rho = \frac{1}{1 - \frac{2}{3} \alpha} \Gamma$ so that $\delta = \varepsilon^\rho \Gamma$ and transform the $\delta \alpha$ and $\beta$ in (2.8) into $0 < \varepsilon \ll 1$, $\sigma \geq 0$ and $\rho \geq 1$ to obtain the main equations to be analyzed in this paper:

$$
\begin{align*}
\dot{u} &= \varepsilon p \\
\dot{p} &= \varepsilon \left[ uv^2 - \varepsilon^{2/(3 \rho + 1)} a - \varepsilon^{(2 \rho + 1 + \sigma)} \gamma p + \varepsilon^{(3 \rho - 1)} au \right] \\
\dot{v} &= q \\
\dot{q} &= -av^2 + \beta v - \varepsilon^{(2 + \sigma)} \gamma q.
\end{align*}
$$

Note that the critical point $S = (1, 0, 0, 0)$ of (1.4) has been rescaled into $(1/\delta^\alpha, 0, 0, 0)$ in (2.8) and $(1/\delta^{2/(3 \rho - 1)}, 0, 0, 0)$ in (2.12) where we note $(3/2)(\rho - 1) = \alpha \rho$. Also for completeness we note that $\sigma$ is given explicitly by $\sigma = (\beta + \alpha - 2)/(1 - \frac{2}{3} \alpha)$.

**Remark 2.1.** There are three free parameters in the original unscaled system (1.4): $A, B, \gamma$. As a consequence of the scalings there are five $- a, b, \gamma, \alpha, \rho$ in (2.12) (or equivalently $\Gamma a, b, \gamma, \alpha, \beta$ in (2.8)). The main difference is that we introduced $\Gamma$ by the scalings in this section explicit new parameters that fixed the magnitudes of the parameters in (1.4) as order functions in $\delta$ by the scalings. All five parameters in (2.8) and (2.12) are $\mathcal{O}(1)$ which is clearly not the case in (1.4).

**Remark 2.2.** The above scaling respects the fundamental chemistry of the Gray–Scott model. Recall that $B = A + k_2 \Gamma$ where $k_2 > 0$. By our scaling we see that $B$ is always greater than $\mathcal{A} \Gamma$ since $\Gamma B = \delta^{2 \alpha/3} b \gg A = \delta^2 a$ with $\alpha \in [0, \frac{3}{2}]$ (see equation (2.9)) for all $a$ and $b$ of $\mathcal{O}(1)$ and $0 < \delta \ll 1$.

**Remark 2.3.** The scalings in (2.7) still form a one-parameter family. In this section this parameter $\alpha \in [0, \frac{3}{2}]$ has been introduced by the observation that the solution $U$ of (1.1) is not $\mathcal{O}(1)$ during a pulse excursion of $\mathcal{V} \Gamma$ but $\mathcal{O}(\delta^\alpha)$. On the other hand these could also introduce $\alpha$ as the parameter that measures the magnitude of $B$ with respect to $c$: $B = \delta^{2 \alpha/3} b$. From this point of view one can say that the magnitude of $B$ determines the magnitude of $U$ (and $V$) during a pulse excursion (see also sections 6 and 7).
# 3 Global geometry for \( \varepsilon = 0 \) and for \( 0 < \varepsilon \ll 1 \)

The fast subsystem of (2.12) is given by
\[
\begin{align*}
\dot{i} &= q \\
\dot{q} &= -u v^2 + b v - \varepsilon (2 + \sigma) q,
\end{align*}
\] (3.1)
in which \( u \) is constant. See figure 2.a. When \( \varepsilon = 0 \) the equation (3.1) possesses a center equilibrium at \( (v = \frac{b}{u}, q = 0) \) and a saddle equilibrium at \( (v = 0, q = 0) \) connected to itself by a homoclinic orbit:
\[
v_0(t; u_0) = 3b/(2u_0) \text{sech}^2(\sqrt{b}/2)t \quad \text{and} \quad \dot{v}_0(t; u_0) = \dot{i}_0.
\] (3.3)
Moreover when \( \varepsilon = 0 \) the equation (3.1) possesses a center equilibrium at \( (v = \frac{b}{u}, q = 0) \) and a saddle equilibrium at \( (v = 0, q = 0) \) connected to itself by a homoclinic orbit:
\[
v_0(t; u_0) = 3b/(2u_0) \text{sech}^2(\sqrt{b}/2)t \quad \text{and} \quad \dot{v}_0(t; u_0) = \dot{i}_0.
\] (3.3)
The homoclinic orbit which may be thought of as a right-swimming fish surrounds the center equilibrium and is symmetric about the \( v \)-axis with a maximum point at \( (v_{\max} = \frac{3b}{2u}, q = 0) \). We shall frequently use the fact that \( v_0 \) is even as function of \( t \).

The complete phase portrait of (2.12) when \( \varepsilon = 0 \) follows immediately by putting together the above geometrical information from the fast subsystem together with the simple observation that both variables \( u \) and \( p \) are constant in time when \( \varepsilon = 0 \) in (2.12). First if the plane \( \mathcal{M} \equiv \{(u, p, v = 0, q = 0)\} \) is a normally hyperbolic manifold trivially invariant since it is a plane of equilibria. Second if we let \( U \) denote a large open set on \( \mathcal{M} \) that contains the saddle equilibrium \( S \) but not points from the set \( \{u = 0\} \) then the manifold \( \mathcal{M}|_U \) has three-dimensional local stable and unstable manifolds. These three-dimensional manifolds are the unions of the one-dimensional local stable and unstable manifolds of the saddle equilibria of (3.1) and they are \( C^r \) smooth for every \( r > 0 \). Finally each point \( (u, p, v = 0, q = 0) \) on \( \mathcal{M} \) is connected to itself by a homoclinic orbit. Therefore the manifold \( \mathcal{M}|_U \) is connected to itself by a three-dimensional homoclinic manifold \( W(\mathcal{M}) \).

## 3.1 Dynamics on \( \mathcal{M} \)

The detailed geometrical information about the \( \varepsilon = 0 \) limit of (2.12) discussed above helps to determine the geometry of the full system (2.12). When \( \varepsilon > 0 \) the plane \( \mathcal{M} \) is still invariant under the flow of the full system (2.12). The flow on \( \mathcal{M} \) is slow and most orbits on \( \mathcal{M} \) leak out of \( U \) on the boundary in both forward and backward time. Before we can study the effect of taking \( \varepsilon > 0 \) on the above described unperturbed flow we need to consider the dynamics on \( \mathcal{M} \).

When \( \varepsilon > 0 \) the slow subsystem
\[
\begin{align*}
\dot{u} &= p \\
\dot{p} &= -\varepsilon \frac{(3 + 1)}{2} u - \varepsilon (2 + \sigma + \gamma) p + \varepsilon (3 + 1) a u
\end{align*}
\] (3.4)
is linear and has precisely one saddle equilibrium at the restriction \( S(u = 1/\varepsilon^{2/(3 + 1)}, p = 0) \) of \( S \) to \( \mathcal{M} \). The linearization of (3.4) has eigenvalues given by
\[
\lambda_{\pm} = \frac{1}{2} \varepsilon \frac{2}{3} (3 + 1) \left[ \pm \sqrt{4a + \varepsilon (3 + 2 + \sigma) (3 + 1)^2} - \varepsilon (3 + 2 + \sigma) (3 + 1)^2 \right]
\] (3.5)
Therefore the stable and unstable manifolds of $S$ restricted to $\mathcal{M}$ are known explicitly as graphs:

$$W^{U,S}(S)|_\mathcal{M} \overset{\text{def}}{=} \ell^{U,S} : \quad p = \lambda_{\pm} \left( u - \frac{1}{\varepsilon^\frac{3}{2} (\rho - 1)} \right),$$  \hspace{1cm} (3.6)

where $\ell^U$ and $\ell^S$ are rescaled versions of (2.1). See figure 2.b. Asymptotically we have:

$$\ell^{U,S} : \quad p = \mp \varepsilon \sqrt{a} + \text{h.o.t} \hspace{1cm} (3.7)$$

for $\alpha > 0$ (equivalently $\rho > 1$) $\Gamma u = \mathcal{O}(1)$ independent of $\gamma$ by (3.5). By contrast when $\alpha = 0$ (i.e. $\Gamma\rho = 1$) $\Gamma \ell^{U,S}$ cannot be approximated by a vertical line ‘+ h.o.t.’ and one must use (3.6).

### 3.2 Persistent fast connections

When $0 < \varepsilon \ll 1$ the stable and unstable manifolds of $\mathcal{M}|_U$ in the $\varepsilon = 0$ system persist as three-dimensional $C^r$ smooth stable and unstable manifolds of $W^U(\mathcal{M})$ and $W^S(\mathcal{M})$. This persistence result for the local manifolds follows from a straightforward application of the Fenichel theory of [6] to (2.12). See also Theorem 3 of [11]. The branches of these manifolds that coincided when $\varepsilon = 0$ no longer do so and in general will intersect each other in two-dimensional surfaces and in these intersections lie the only orbits bi-asymptotic to $\mathcal{M}$.

We will employ a Melnikov method to detect these intersections. In particular, system (2.12) is of the type to which Robinson’s extension of the Melnikov method applies see [18Γ22Γ30]. Let $t = \eta$ so that the independent variable of (2.12) is now denoted by $t$. Let $(u(t), p(t), v(t), q(t))$ represent a solution of (2.12) that passes through the point $(u_0, p_0, v(0), 0)$ at time $t = 0$. Note that we have suppressed the $\varepsilon$ dependence in this notation.

The splitting distance between the manifolds $W^U(\mathcal{M})$ and $W^S(\mathcal{M})$ can be measured in the hyperplane $\{q = 0\}$ which is the hyperplane transverse to $W(\mathcal{M})$ and is spanned by the three vectors $(1, 0, 0, 0)\Gamma(0, 1, 0, 0)$ and the unit normal

$$\hat{n} \equiv \frac{(0, 0, \frac{\partial K}{\partial v}(3b/2u, 0; u), \frac{\partial K}{\partial u}(3b/2u, 0; u))}{\| (0, 0, \frac{\partial K}{\partial v}(3b/2u, 0; u), \frac{\partial K}{\partial u}(3b/2u, 0; u)) \|} = (0, 0, 1, 0). \hspace{1cm} (3.8)$$

The distance measurement is given by

$$\Delta K(u_0, p_0; a, b, \gamma) \equiv \int_{-\infty}^{\infty} \dot{K}(v(t), q(t); u(t), p(t))dt, \hspace{1cm} (3.9)$$

as $\varepsilon \to 0^+$ where a straightforward computation yields

$$\dot{K} = -\varepsilon^{2+\sigma} \gamma q^2 + \frac{1}{3} \varepsilon \rho u^3. \hspace{1cm} (3.10)$$

Since we look for solutions on these perturbed stable and unstable manifolds $W^S(\mathcal{M})$ and $W^U(\mathcal{M})$ we need to expand the solutions $(u(t), p(t), v(t), q(t))$ of (2.12) in powers of the small parameter $\varepsilon$. The structure of this expansion will depend on the values of $\sigma$ and $\rho$. However we note that the expansion remains standard at least up to terms smaller than $\mathcal{O}(\varepsilon^2)$:

$$u(t) = u_0 + \varepsilon u_1(t) + \varepsilon^2 u_2(t) + \text{h.o.t}$$
\[ p(t) = p_0 + \varepsilon p_1(t) + \varepsilon^2 p_2(t) + \text{h.o.t.} \]
\[ v(t) = v_0(t; u_0) + \varepsilon v_1(t) + \varepsilon^2 v_2(t) + \text{h.o.t.} \]
\[ q(t) = q_0(t; u_0) + \varepsilon q_1(t) + \varepsilon^2 q_2(t) + \text{h.o.t.} \]  \hspace{1cm} (3.11)

as \( \varepsilon \to 0 \) where \( v_0(t; u_0) \) and \( q_0(t; u_0) \) are the unperturbed homoclinic solutions given in (3.3). Note that it depends on \( \sigma \) whether the next term in the expansion of \( v(t) \) is of \( O(\varepsilon^{2+\sigma}) \) or \( O(\varepsilon^3) \). This distinction will become important in section 5. Solutions on the local unstable manifold of \( M \) are represented by expansions valid on the semi-infinite time interval \([0, \infty)\) and solutions on the local stable manifold of \( M \) are represented by expansions valid on the semi-infinite time interval \((-\infty, 0)\). The higher order terms will be determined perturbatively.

We choose the initial conditions on the curve \( W^S(M) \cap W^U(M) \cap \{ q = 0 \} \) whose existence we establish below. We assume that \( u(0) = u_0 \) and \( u_j(0) = 0 \) for \( j \geq 1 \): the initial conditions \( p_0 \Gamma p_j(0) \) and \( v_j(0) \) \( (j \geq 1) \) are then determined as function of \( u_0 \) by the condition that \( \Gamma(t) = (u(t), p(t), v(t), q(t)) \in W^S(M) \cap W^U(M) \).

**Remark 3.1.** In this type of Melnikov calculation it is usually sufficient to use only the unperturbed solution \( (u_0, p_0, v_0(t; u_0), q_0(t; u_0)) \). However, there we need higher-order corrections since the magnitude of the perturbation in the fast field \( O(\varepsilon^{2+\sigma}) \) is smaller than the evolution of the slow field \( O(\varepsilon) \).

By substituting (3.11) into (2.12) we find for the first-order corrections of \( u \) and \( p \):
\[ u_1(t) = 0 \]
\[ p_1(t) = \int_0^t u_0 u_0^2(\tau) d\tau + p_1(0). \]  \hspace{1cm} (3.12)

Note that \( p_1(t) \) is an odd function of time if \( p_1(0) = 0 \). Determining \( v_1(t) \) and all other higher order terms depends on the type of solutions one is looking for and requires further analysis. Plugging these expansions into (3.10) and (3.9) yields:
\[ \Delta K = \varepsilon \int_{-\infty}^{\infty} \left[ \frac{1}{3} p_0 v_0^3(t) + \varepsilon \left( \frac{1}{3} p_1(t) v_0^3(t) + p_0 v_0^3(t) v_1(t) - \varepsilon^2 q_0^2(t) \right) \right] dt, \]  \hspace{1cm} (3.13)

where \( \Delta K \) is a function of \( u_0, p_0; \) and the parameters \( a, b, \) and \( \gamma \).

We consider solutions that are biasymptotic to \( M; \) thus \( \Delta K \) must have zeroes and there must be a balance between some of the terms in the integrand. Moreover, these solutions must be homoclinic to \( S; \) and hence they take off (respectively touch down) from (on) \( M \) near \( t^U(t^S) \). Thus, by (3.7) and the fact that the perturbations can at most have an \( O(\varepsilon) \) influence on \( p(t) \) during half a circuit through the fast field \( \Gamma \), we have to set \( p_0 = \varepsilon \tilde{p}_0 \). As a consequence, we note that we can set \( p_1(0) = 0 \) since \( \tilde{p}_0 \) determines the initial condition of \( p(t) \) at the \( O(\varepsilon) \)-level. Moreover, we observe that \( \Delta K = O(\varepsilon^2) \) and hence \( |v(t) - v_0(0)| = O(\varepsilon^2) \). Thus, the first-order correction \( v_1 \) of \( v \) is a solution of a homogeneous second-order linear equation with initial conditions \( v_1(0) = v_1(0) = 0 \) namely: \( v_1(t) \equiv 0 \). Now we recall from (3.12) that \( p_1(t) \) is odd since \( p_1(0) = 0 \) and also that \( v_0(t) \) is even, so that the second term in the integrand of (3.13) is odd. Hence, it does not contribute to the integral and we conclude that (3.13) reduces to:
\[ \Delta K(u_0, p_0; a, b, \gamma) = \varepsilon^2 \int_{-\infty}^{\infty} \left( \frac{1}{3} \tilde{p}_0 v_0^3(t) - \varepsilon^2 q_0^2(t) \right) dt + \text{h.o.t.} \]
Using (3.3) a straightforward integration yields:

\[ \Delta K(u_0, p_0; a, b, \gamma) = \varepsilon^2 \left( \frac{6b^2 \sqrt{b}}{5a_0} \right) \left( \frac{2\hat{p}_0}{u_0} - \varepsilon^\sigma \gamma \right) + \text{h.o.t.} \quad (3.14) \]

Therefore to leading order \( \Gamma \Delta K \) has simple zeroes along the line

\[ p = \frac{1}{2} \varepsilon^{(1+\sigma)} \gamma u. \quad (3.15) \]

This result should be interpreted as follows: the orbits \( \Gamma(t; x_0) \) through the points \( x_0 = (u, p, v_0(0; u), 0) \) are biasymptotic to \( M \) if \( u \) and \( p \) are related to leading order as in (3.15). Note that it has now become clear that \( \sigma \) cannot become negative for \( \Gamma \) in the terminology of (2.8) that \( \beta - \frac{1}{5} \alpha \) cannot be smaller than \( 2(1 - \frac{2}{5} \alpha) \) (the scalings in (2.3) imply that both \( u = \hat{u} \) and \( \gamma = \hat{\gamma} \) are exactly \( O(1) \) with respect to \( \varepsilon \) while \( p \) cannot be larger than \( O(\varepsilon) \) by (3.7)).

In order to quantify the influence of the fast field on the \( u \) - and \( p \)-coordinates of a solution in \( W^U(M) \cap W^S(M) \) during its excursion through the fast field \( \Gamma \) we define

\[ \Delta p(u_0, p_0; a, b, \gamma) \equiv \int_{-\infty}^{\infty} \dot{p} \, dt, \quad (3.16) \]

\[ \Delta u(u_0, p_0; a, b, \gamma) \equiv \int_{-\infty}^{\infty} \dot{u} \, dt. \quad (3.17) \]

Straightforward computations give (by (2.12) where \( \rho \geq 1 \)):

\[
\begin{align*}
\Delta p &= \varepsilon \int_{-\infty}^{\infty} \left( u(t) v^2(t) + O(\varepsilon^2) \right) \, dt \\
&= \varepsilon \int_{-\infty}^{\infty} \left[ u_0 v_0^2(t) + \varepsilon \left( a_1(t) v_0^2(t) + 2 a_0 v_0(t) v_1(t) \right) + O(\varepsilon^2) \right] \, dt \\
&= \varepsilon \frac{6b \sqrt{b}}{u_0} + O(\varepsilon^3), \quad (3.18)
\end{align*}
\]

where we have again used \( a_1(t) = 0 \) and \( v_1(t) = 0 \). Finally we use the fact that we will only study \( \Delta u(u_0, p_0) \) for values of \( (u_0, p_0) \) in the neighborhood of the \( \Delta K = 0 \) line (3.15). Thus \( \Gamma p_0 = O(\varepsilon) \) which yields by (2.12) that the change in \( u \) is of higher order:

\[ \Delta u = O(\varepsilon^2), \quad (3.19) \]

There are two other curves on \( M \) that play a crucial role in the analysis of the next sections and that are obtained as follows. See figure 2b. The first intersection of \( W^S(M) \) and \( W^U(M) \) in the hyperplane \( \{ q = 0 \} \) is given by (3.15) to leading order. This intersection is a one-dimensional curve in a two-dimensional manifold. Through any point \( x_0 \) on this curve \( W^S(M) \cap W^U(M) \cap \{ q = 0 \} \) there is an orbit \( \Gamma(t; x_0) \) which approaches \( M \) for 'large' \( t \). More precisely the Fenichel theory [6] already cited above implies that for any \( \Gamma(t; x_0) \) there are two orbits \( \Gamma^+_M = \Gamma^+_M(t; x_0^+) \subset M \) and \( \Gamma^-_{\mathcal{M}}(t; x_0^-) \subset \mathcal{M} \Gamma \) respectively (where \( \Gamma^+(0, x_0^+) = x_0^+ \in M) \Gamma \) such that \( \| \Gamma(t; x_0) - \Gamma^+_M(t; x_0^+) \| \) is exponentially small for \( t > 0 \) where \( t \geq O(\varepsilon) \) and \( \| \Gamma(t; x_0) - \Gamma^-_{\mathcal{M}}(t; x_0^-) \| \) is exponentially small for \( t < 0 \) with \( -t \geq O(\varepsilon) \). As a consequence

\[ d(\Gamma(t; x_0), \mathcal{M}) = O\left( \varepsilon^{-\frac{1}{2}} \right) \quad \text{for} \quad |t| \geq O\left( \frac{1}{\varepsilon} \right) \quad \text{or larger} \]
for some $k > 0\Gamma$ and $\Gamma^\pm_{\mathcal{M}}(t; x_0^\pm)$ determine the behavior of $\Gamma(t; x_0)$ near $\mathcal{M}$. Therefore we define the curves $T_o \subset \mathcal{M}$ (take off) and $T_d \subset \mathcal{M}$ (touch down) as

$$T_o = \cup_{x_0} \{ x_0^- = \Gamma^-_{\mathcal{M}}(0; x_0^-) \}, \quad \text{and} \quad T_d = \cup_{x_0} \{ x_0^+ = \Gamma^+_{\mathcal{M}}(0; x_0^+) \},$$

(3.20)

where the unions are over all $x_0$ in $W^S(\mathcal{M}) \cap W^U(\mathcal{M}) \cap \{q = 0\}$. $T_o$ respectively $T_d$ is the collection of base points of all of the fibers in $W^U(\mathcal{M})$ (respectively $W^S(\mathcal{M})$) that lie in the transverse intersection of $W^U(\mathcal{M})$ and $W^S(\mathcal{M})$. See figure 2.b.

The locations of $T_o$ and $T_d$ can be obtained explicitly by determining the relations between $x_0 = (u_0, p_0, v_0, 0)$ and $x_0^\pm = (u_0^\pm, p_0^\pm, 0, 0)$. The accumulated change in $p$ of $\Gamma(t)$ during the (half-circuit) excursion through the fast field is measured by

$$\int_{-\infty}^{0} \dot{p} dt \quad \text{and} \quad \int_{0}^{\infty} \dot{p} dt,$$

when $t < 0$ and $t > 0\Gamma$ respectively. The change in $p$ of $\Gamma^\pm(t)$ during the same period of time can be neglected in highest orders since $\dot{p} = O(\varepsilon^3)$ on $\mathcal{M}$ by (2.12). By (2.12) and (3.19) we also conclude that $u_0 = u_0^\pm$ to leading order. Since $x_0$ is given by (3.15) we find (by a calculation similar to (3.18)) to leading order:

$$T_o : \quad p = \frac{1}{2} \varepsilon \left( \varepsilon \gamma u - \frac{6b\sqrt{b}}{u} \right),$$

$$T_d : \quad p = \frac{1}{2} \varepsilon \left( \varepsilon \gamma u + \frac{6b\sqrt{b}}{u} \right).$$

(3.21)

Having identified in this section the geometric features of (2.12) both in the invariant plane $\mathcal{M}$ and in the directions transverse to it, we are now ready to construct the stationary waves of (1.1). However we will see in section 5 that a more subtle analysis is necessary in order to study the (non-)existence of traveling waves.

4 Stationary solutions

In this section we focus on the stationary ($c = 0$) solutions of (1.1). These are given by solutions of (2.12) with $\gamma = 0$. In particular for $\alpha \in (0, 3/2)$ we construct single-pulse and multiple-pulse orbits homoclinic to $S$ in section 4.1 as well as a variety of multiple-pulse periodic solutions including the steady states reported in the simulations of [21] in section 4.2. The special case of $\alpha = 0$ is treated in section 4.3. Finally we refer the reader to section 6 for the results of numerical simulations in which many of these homoclinic and periodic stationary waves are observed as stable patterns.

4.1 Single-pulse and multiple-pulse homoclinic orbits

When $\gamma = 0$ the equations (2.12) possess the symmetry:

$$t \to -t, p \to -p, \quad \text{and} \quad q \to -q.$$ 

(4.1)
One-pulse homoclinic orbits of the type described in section 2 are constructed as follows. See figure 1.a. Let $\Gamma^{-}(t) = (u^{-}(t), p^{-}(t), v^{-}(t), q^{-}(t))$ denote an orbit of (2.12) on $W^{U}(S)$ with $v^{-}(t) > 0$. Its existence guarantees the existence of a symmetric solution on $W^{S}(S)$ which we denote: $\Gamma^{+}(t) = (u^{+}(t), p^{+}(t), v^{+}(t), q^{+}(t)) = (u^{-}(-t), -p^{-}(-t), v^{-}(-t), -q^{-}(-t))$. For large negative $t$, $\Gamma^{-}$ lies close to $M$ and moves along $\ell^{U}$ as $t$ increases. $\Gamma^{-}$ leaves the neighborhood of $M$ in an $O(\varepsilon)$ ball about a take off point $(u^{-}_{0}, p^{-}_{0})$ on $\ell^{U} \cap T_{0}\Gamma$ where $u^{-}_{0}$ is $O(1)$ and will be determined below. Then $\Gamma^{-}$ makes an excursion through the fast vector field and transversely intersects the $\{q = 0\}$ hyperplane for the first time in a point which we shall denote $(u_{1}, p_{1}, v_{1})$. By the symmetry (4.1) $\Gamma^{+}$ executes a symmetric trajectory in backward time: it departs $\ell^{S}$ in an $O(\varepsilon)$ ball about the touch down point $(u^{+}_{0}, p^{+}_{0}) = (u^{-}_{0}, -p^{-}_{0}) \in M$ and transversely intersects the $\{q = 0\}$ hyperplane for the first time in the point $(u_{1}, -p_{1}, v_{1})$.

One-pulse solutions therefore exist when $p_{1} = 0$ so that the two intersection points coincide. In that case $\Gamma^{-}(t) = \Gamma^{+}(t) \in W^{U}(S) \cap W^{S}(S)$ is the one-pulse homoclinic orbit.

We proceed to compute $p_{1}$. From section 3 we know that $p_{1} = p^{-}_{0} + (1/2)\Delta p$ where $\Delta p$ is the increment in $p$ during half an excursion in the fast field and is given by (3.18): $\Delta p = \varepsilon \sqrt{\frac{b}{a}} + \text{h.o.t.}$ Note that $\Delta p$ has been computed in section 3 for orbits $\Gamma(t)$ with $\Gamma(0) \in \{q = 0, v > 0\}$ and that we replaced $u^{-}_{0}$ the $u$-coordinate of $\Gamma(0)$ in (3.18) by $u^{-}_{0}$. However we observe by (3.19) that $u^{-}_{0} = u^{+}_{0} = u_{0} + O(\varepsilon^{2})$. We infer from (3.7) that $p^{-}_{0} = -\varepsilon \sqrt{a} + \text{h.o.t.}$ for $(u^{-}_{0}, p^{-}_{0}) \in \ell^{U}$. Hence $\Gamma^{-}$ is a function of $u^{-}_{0}$; and by setting $p_{1} = 0$ to leading order yields:

$$u^{-}_{0} = 3b \sqrt{\frac{b}{a}}. \tag{4.2}$$

Thus we have proved the following Theorem for the case $N = 1$:

**Theorem 4.1** There exists an $\varepsilon_{0}(\alpha) > 0$ such that for every $0 < \varepsilon < \varepsilon_{0}(\alpha)$, for $\alpha \in (0, \frac{3}{2})$, for every $a$ and $b > 0$, and for every positive integer $N$, the system (2.12) with $\gamma = 0$ possesses a unique $N$-pulse orbit homoclinic to $S$. Moreover, for each $N$, the homoclinic orbit consists of two slow segments interspersed with $N$ successive excursions in the fast field during which $u$ is near $3N\sqrt{b/a}$. Finally, for each $N$, the homoclinic orbit lies in the transverse intersection of $W^{U}(S)$ and $W^{S}(S)$.

**Remark 4.1.** Note that the above calculation with (3.7) is only possible for $\alpha > 0$ or equivalently $\rho > 1$. In fact $\Gamma_{0}(\alpha) \rightarrow 0$ as $\alpha \rightarrow 0$. The case $\alpha = 0$ is special. In this case (2.12) reduces to the unscaled (1.4) with $A = \delta^{2}a$ (use (2.7)). Moreover one has to use (3.6) instead of (3.7). In section 4.3 we will establish (Theorem 4.3) that when $\alpha = 0$ there can be either two or zero homoclinic orbits (with a saddle node bifurcation of homoclinic orbits in between) depending on the values of $a$ and $b$. See also the discussion after Theorem 4.3 as well as that in Remark 2.1.

**Proof of Theorem 4.1.** Note that the last statement of the theorem follows directly from the dependence of $\Delta p$ on $u^{-}_{0}$. Since $\Delta p$ depends inversely on $u^{-}_{0}$ (4.2) is a simple zero of $p_{1}$. Hence the symmetry (4.1) implies that $W^{U}(S)$ and $W^{S}(S)$ intersect transversely in this homoclinic orbit. We remark that these same results for $\gamma = 0$ can be obtained (Sec. 5) by considering the general case $\gamma \geq 0$ and examining the intersection of $T_{0}$ and $\ell^{U}$ as given by (3.21) and (3.7) respectively.

We proceed to prove the Theorem for $N \geq 2$ again relying heavily on the symmetry (4.1). See figure 3 for an illustration of an $N$-pulse orbit with $N = 2$. First we construct the 2-pulse orbit. Consider a solution $\Gamma^{-}(t)$ on $W^{U}(S)$ that intersects the hyperplane $\{q = 0\}$ a second time at
the point \((u_2, p_2, v_2)\). Such a solution exists as long as \(\varepsilon\) is sufficiently small and the take off point 
\((u_0^-, p_0^-)\) can be chosen such that \(\Delta K < 0\) so that \(\Gamma^- (t)\) neither is in the local stable manifold of \(\mathcal{M}\) nor winds up on the other side of \(W^S(\mathcal{M})\) (that is \(u^- (t)\) does not become negative immediately after the (first) return of \(\Gamma^-\) to an \(O(\sqrt{\varepsilon})\) neighborhood of \(\mathcal{M}\)). We show at the end of this construction that this choice is possible.

Due to the symmetry (4.1)|\(\Gamma^+ (t)\) also has a second transverse intersection with the hyperplane 
\(\{q = 0\}\) at the point \((-u_2, -p_2, v_2)\). The semi-orbits \(\Gamma^- (t)\) and \(\Gamma^+ (t)\) hook up if \(p_2 = 0\). Hence\(\Gamma\) remains to calculate \(p_2 = p_0^- + \Delta p\) where \(\Delta p\) is change in \(p\) during one complete circuit in the fast field (3.18). Recalling (2.12) and the fact that \(p \leq O(\varepsilon)\) over the time interval of interest \(\Gamma\) or equivalently \(\Gamma\) by using (3.19) we see that \(u\) remains constant to sufficiently high order during both of the near-separatrix excursions that this two-pulse orbit makes. Hence\(\Gamma\) this two-pulse orbit departs from \(\mathcal{M}\) in an \(O(\varepsilon)\) ball centered at the point \((u_0^-, p_0^-)\) with

\[
u_0^- = 6b\sqrt{\frac{b}{a}},
\]

(4.3) exactly as stated in the theorem. The fact that this two-pulse homoclinic orbit lies in the transverse intersection of \(W^U (S)\) and \(W^S (S)\) follows directly from the symmetry (4.1) and the fact that \(p_2\) has a simple zero at \(u_0^- = 6b\sqrt{b/a}\). For the sake of completion\(\Gamma\) we observe that \(v_2 = O(\sqrt{\varepsilon})\) since \(\Delta K = O(\varepsilon)\).

Inductively\(\Gamma\) one uses the same procedure to construct \(N\)-pulse homoclinic orbits for any finite \(N > 2\). Of course\(\Gamma\) one must ascertain\(\Gamma\) as we do below\(\Gamma\) that \(\Delta K < 0\) after \(\Gamma^- (t)\) has made its \((N - 1)\)th near-separatrix excursion\(\Gamma\) so that this orbit always stays on the correct side of \(W^S (\mathcal{M})\). We find that these \(N\)-pulse orbits leave \(\mathcal{M}\) near \((u_0^-, p_0^-)\) where:

\[
u_0^- = 3Nb\sqrt{\frac{b}{a}},
\]

(4.4) and that \(p_N\) has a simple zero at \(u_0^-\).

Finally\(\Gamma\) we establish that the orbits \(\Gamma^-\) which return to the hyperplane \(\{q = 0\}\) finitely many times\(\Gamma\) whose existence we assumed in the above constructions for \(N \geq 2\) do indeed exist. Recalling (3.14)\(\Gamma\) we see that \(\Delta K < 0\) for orbits with \(p_0 < 0\) and \(\gamma = 0\) where \(p_0\) is the \(p\)-coordinate of the intersection of \(\Gamma\) with the hyperplane \(\{q = 0, v > 0\}\). Hence\(\Gamma\) each time \(\Gamma^- (t)\) departs from a neighborhood of \(\mathcal{M}\) to the left of the take off curve \(T_o\)\(\Gamma\) it always intersects the hyperplane \(\{q = 0\}\) another time with \(v = O(1)\). See figure 2b. For values of \(u_0^-\) greater than \(u_0^- = 3b\sqrt{b/a} \in \ell^U \cap T_o\) corresponding to the one-pulse homoclinic\(\Gamma\) we know that \(\ell^U\) is to the left of \(T_o\)\(\Gamma\) thus \(\Gamma^- (t)\) will at least intersect \(\{q = 0\}\) three times: twice for \(v = O(1)\) in between for \(0 < v \ll 1\). A straightforward calculation shows that a second intersection of \(\Gamma^- (t)\) with \(\{q = 0\}\) \(O(\sqrt{\varepsilon})\) near \(\mathcal{M}\) is only possible for \(u_0^- \geq 9b\sqrt{b/a} + O(\varepsilon)\). Thus\(\Gamma\) the 3-pulse homoclinic orbit constructed above plays the role of separatrix solution. Inductively\(\Gamma\) one can show along the same lines that each of the \(N = (2n - 1)\)-pulse solutions is a separatrix solution and that it is only possible for \(\Gamma^- (t)\) to have an \(n\)-th intersection with the hyperplane \(\{q = 0\}\) \(O(\sqrt{\varepsilon})\) near \(\mathcal{M}\) if \(u_0^- \geq 3(2n - 1)b\sqrt{b/a} + O(\varepsilon)\). This completes the proof of Theorem 4.1. \(\square\)

Remark 4.2. The result of Theorem 4.1 can be generalized to obtain homoclinic orbits with \(N\) pulses where \(N = o(1/\varepsilon)\). To show this\(\Gamma\) we consider an \(N\) of \(O(\varepsilon^{-s})\) for a certain \(s > 0\). Errors in
\[ \Delta u \text { and } \Delta p \text { have become } O(\varepsilon^{2-\epsilon}) \text { after } O(\varepsilon^{-\epsilon}) \text { circuits through the fast field. This expression has to remain smaller than the leading order term of } O(\varepsilon). \text { However during each excursion in the fast field the increment in } p \text { is } O(\varepsilon) \Gamma \text { so we conclude that the above analysis is valid for } N = O(\varepsilon^{-\epsilon}) \text { with } s < 1. \]

4.2. Periodic steady states

In this section we construct a variety of periodic steady states \((c = 0)\) including those observed in the numerical simulations \(\text{(see figure 1 of [21]) and section 6 of this work. The simulations of [21] were performed on an interval with periodic boundary conditions. An initially solitary pulse replicated until it filled the interval with 8 identical stationary pulses}. \text { In section 6 we will show that such a periodic pattern also occurs on unbounded domains at the core of the self-replicating pulse pattern. The } M \text {-pulse periodic orbits observed in the simulations consist of } M \text { copies of the same fundamental periodic orbit in the } (u, p, v, q) \text { phase space. This fundamental orbit consists of one fast excursion from the slow manifold } \mathcal{M} \text { and one (long) segment during which the orbit is near } \mathcal{M}. \text { Thus } v \text { and } q \text { are exponentially small during the largest part of the period which yields that the solution } V \text { of the PDE (1.1) must have the same behavior (see section 6). We prove the existence of various families of such fundamental periodic orbits. Moreover we are able to calculate the period and other key features of these orbits so that we can explicitly determine the fundamental orbit corresponding to a numerically-observed stationary periodic pattern.}

In order to carry out the construction we focus on the special case of \(\alpha = 1\) in (2.12) which corresponds to the numerically-observed steady states. The same analysis can be done however for all \(\alpha \in (0, 3/2)\) and in the proof below we show how to extend the \(\alpha = 1\) results to all these \(\alpha\). For \(\alpha = 1\) the slow vector field on \(\mathcal{M}\) is

\[
\begin{align*}
\dot{u} &= \varepsilon p, \\
\dot{p} &= \varepsilon^9 a u - \varepsilon^6 a,
\end{align*}
\]

which is simply (2.12) with \(\gamma = 0\) and \((v, q) = (0, 0)\). This slow system is linear with a saddle fixed point at \(S = (1/\varepsilon^3, 0)\) and all orbits \(\Gamma_C\) are branches of hyperbolas given by

\[
\left(\frac{1}{\varepsilon^3} - u\right)^2 - \frac{p^2}{\varepsilon^8 a} = C,
\]

parametrized by \(C\). \text { See figure 2.b. Here we are interested in the orbits } \Gamma_C \text { in the sector below } S \text { with } C > 0 \text { that is the area enclosed by } \ell^U \text { and } \ell^S \text { as defined in section 3.1. These orbits are symmetric about the } u \text {-axis and for each such orbit segment there exists a maximum value } u_{\text{max}} \text { of } u \text { such that } (u, p) = (u_{\text{max}}, 0) \text { is the symmetry point. Instead of } C \Gamma u_{\text{max}} \text { can also be used to parametrize the orbits } \Gamma_C \text { (4.6):}

\[
p^2 = \varepsilon^2 a[(1 - \varepsilon^3 u)^2 - (1 - \varepsilon^3 u_{\text{max}})^2] \text { with } C = \left(\frac{1}{\varepsilon^3} - u_{\text{max}}\right)^2.
\]

Note that the lines \(\ell^U, S\) correspond to \(C = 0\) or \(u_{\text{max}} = 1/\varepsilon^3\) the \(u\)-coordinate of the saddle \(S\); also \(C > 0\) corresponds to \(u_{\text{max}} < 1/\varepsilon^3\).

The orbits \(\Gamma_C\) can intersect the take off and touch down curves \(T_o\) and \(T_d \subset \mathcal{M}\) (see figure 2.b). Below we will show that there exist periodic solutions to (2.12) which ‘start’ at \(t = 0\) exponentially
close to \((u_{\text{max}}, 0, 0, 0) \in \mathcal{M}\) and follow \(\Gamma_C\) downwards to an intersection \(\Gamma_C \cap T_0\), then take off for a circuit through the fast field after which they again touch down on \(\mathcal{M}\) near \(\Gamma_C \cap T_0\) and follow \(\Gamma_C\) upwards to ‘end’ on its initial point near \((u_{\text{max}}, 0, 0, 0)\). However first we need to pay some attention to the intersections \(\Gamma_C \cap T_0\). For symmetrically \(\Gamma_C\) and \(T_0\), a priori one would guess that \(T_0\) might intersect \(\Gamma_C\) more than once. Using expressions (3.21) and (4.7) it is easy to determine values for \(u_{\text{max}}\) such that \(T_0\) intersects \(\Gamma_C\) twice but the \(u\)-coordinates of these intersections can never both be \(O(1)\) (unless \(\alpha = 0\); see section 4.3). This is a crucial point: if the \(u\)-coordinate of a take off point is not \(O(1)\) then the analysis of section 3 is not valid since all coefficients of the \(\varepsilon\)-expansions in that section are (implicitly) assumed to be \(O(1)\). Moreover, \(\Gamma_C\) system (2.12) is determined such that the excursions through the fast field take place for \(u = O(1)\) by construction. Thus \(\Gamma_C\) the expression (3.21) is only valid when \(u = O(1)\); and thus the intersections \(\Gamma_C \cap T_0\) with \(u > O(1)\) must be treated as \(O(1)\) intersections for a different scaling of \(u\). For better \(\alpha\). In other words: the \(u > O(1)\) intersections of (3.21) and (4.7) are described by (2.12) with \(\alpha < 1\) since we chose \(\alpha = 1\) above.

It is clear from the combination of (3.21) and (2.12) that an intersection with \(u = O(1)\) is only possible for \(u_{\text{max}} = O(1/\varepsilon^3)\). Thus we introduce the new \(O(1)\) parameter \(U_{\text{max}}\) by

\[
U_{\text{max}} = \frac{U_{\text{max}}}{\varepsilon^3}, \quad U_{\text{max}} \leq 1.
\]

(4.8)

It follows from (4.7) and (3.21) that \(\Gamma_C \cap T_0\) (with \(\gamma = 0\)) is given to leading order by

\[
(u_P, p_P) = (u_P(U_{\text{max}}), p_P(U_{\text{max}})) = \left(\frac{3b\sqrt{b}}{a(2U_{\text{max}}^2 - U_{\text{max}}^2)}, -\varepsilon \sqrt{a(2U_{\text{max}}^2 - U_{\text{max}}^2)}\right),
\]

(4.9)

which we simply denote \((u_P, p_P)\). Note that (4.9) coincides with (4.2) and (3.7) as \(U_{\text{max}} \Downarrow 1\) this is necessary since \(\Gamma_C\) merges with \(t^U \cup t^S\) in this limit. See figure 1b. We can formulate the main result of this subsection:

**Theorem 4.2** For every \(\varepsilon\) sufficiently small, \(\alpha \in (0, \frac{3}{2})\) and for any \(U_{\text{max}} < 1\) of \(O(1)\), the system (2.12) with \(\gamma = 0\) possesses a periodic orbit which consists of two distinguished parts: a slow part near \(\Gamma_C \in \mathcal{M}\) for \(u > u_P\) (4.9) and an excursion through the fast field near the \(\{u = u_P\}\) hyperplane.

**Remark 4.3.** So far we only considered the case \(\alpha = 1\). All of the above is also valid for any \(\alpha \in (0, \frac{3}{2})\) (with \(u_P\) exactly as in (4.9)). In section 4.3 we will discuss the special case \(\alpha = 0\).

**Proof of Theorem 4.2.** We fix an arbitrary value of \(U_{\text{max}} < 1\) which automatically determines a value of \(CT\) see (4.7). We recall from section 3 that \(\Gamma\) for every orbit \(\Gamma_h(t, x_0)\) of (2.12) that is homoclinic to \(\mathcal{M}\) and that passes through the point \(x_0\) in the first intersection of \(W^U(\mathcal{M})\) and \(W^S(\mathcal{M})\) in the hyperplane \(\{q = 0\}\) there exist orbits on \(\mathcal{M}\) denoted by \(\Gamma_{h, \mathcal{M}}(t; x_0^\pm)\) such that \(\|\Gamma_h(t; x_0) - \Gamma_{h, \mathcal{M}}(t; x_0^\pm)\| = O(e^{-k/\varepsilon})\) for \(|t| = O(1/\varepsilon)\). Among this family of homoclinic orbits there exists a unique one \(\Gamma_h, C(t; x_0)\) whose associated take off and touch down points \(x_0^- = \Gamma_{h, \mathcal{M}}(0; x_0^-)\) and \(x_0^+ = \Gamma_{h, \mathcal{M}}(0; x_0^+)\) lie precisely on \(\Gamma_C \cap T_0\) and \(\Gamma_C \cap T_0\) respectively for \(x_0^+ = (u_P, p_P, 0, 0)\) due to the symmetry (4.1). Also \(\Gamma x_0^-\) is the forward image of \(x_0^+\) under the flow of (4.5); since both points lie on \(\Gamma_C\). In other words the orbits \(\Gamma_C \Gamma_{h, \mathcal{M}}^-\Gamma_C\) and \(\Gamma_{h, \mathcal{M}}^+\Gamma_C\) are ‘time’ translates of each other. For completeness we note that the complete orbit \(h, C\) homoclinic to \(\mathcal{M}\) (not \(S\)) passes through an exponential neighborhood of \(\Gamma_C \cap \{u > u_P\}\) twice and its \(u\) and \(p\) coordinates are unbounded for \(t \to \pm \infty\).
We now show that there exists a periodic orbit \( \Gamma_P(t) \) of the type described in the theorem whose slow segments are exponentially close to \( \Gamma_{h,C} \cap \{ u > u_P \} \). Consider the line segment \( \ell \) of points \((u_{\text{max}}, 0, 0, 0)\) such that the \( v \) coordinate satisfies \( K_1 \exp[-(k/v^5)] \leq v \leq K_2 \exp[-(k/v^5)] \) for sufficiently small \( K_1 \) sufficiently large \( K_2 \) and for some \( k > 0 \) and all three constants are \( O(1) \). Note that the time of flight from \( u = u_{\text{max}} \) to \( u = O(1) \) along \( \Gamma_C \) is \( O(\varepsilon^5) \). Flowing the initial conditions on \( \ell \) forward generates a two-dimensional manifold \( \mathcal{L} \). Furthermore, if we choose \( u_0, v_0, w_0, q_0 \) close to \( (u_{\text{max}}, 0, 0, 0) \), then \( (u, v, w, q) \) lies on \( \mathcal{L} \) if \( u < u_P \) and some exit with \( u < u_P \). Finally, if these exit points \( \mathcal{L} \) is \( C^1 - O(\exp[-(c/v^5)]) \) close to the invariant foliation on \( W^U(\mathcal{K}) \) with base points restricted to \( \Gamma_C \). This closeness estimate follows from the modified version (see [25]) of the Exchange Lemma with Exponentially Small Error of [12]. The first application of the theory of the exchange lemma to find periodic orbits in singularly-perturbed systems is given in [25]. Of course, by the symmetry (4.1) these same arguments show that \( \mathcal{L} \) also lies \( C^1 - O(\exp[-(c/v^5)]) \) close to \( W^S(\mathcal{K}^{\Gamma_C}) \) at points at which orbits on \( \mathcal{L} \) exit an \( O(\varepsilon) \) neighborhood of \( T_\delta \cap \ell_5 \subset \mathcal{K} \) in backward time. Therefore since \( W^U(\mathcal{K}) \) and \( W^S(\mathcal{K}) \) intersect transversely, so must \( \mathcal{L} \) intersect itself transversely exponentially close to the above constructed orbit \( \Gamma_{h,C} \). Moreover, due to the transversality of the intersections \( T_\delta \cap \Gamma_C \) and \( T_\delta \cap \Gamma_C \Gamma \), this intersection of \( \mathcal{L} \) with itself is locally unique and therefore so is the periodic orbit \( \Gamma_P \) that lies inside it.

To conclude the proof of the theorem, we briefly consider the case \( \alpha \neq 1 \) (\( \alpha > 0 \)). The idea of the proof in this case is in essence the same: One only has to adapt the length of the line segment \( \ell \) since the “time of flight” from \( u_{\text{max}} = O(1/\varepsilon^3/(v^{-5})) \) to \( u = O(1) \) depends on \( \alpha \) (or \( \rho \)).

Finally, we exploit the fact that the flow on \( \mathcal{K} \) is linear to explicitly calculate the leading order length of the period of a periodic orbit \( \Gamma_P(t) \). Since we want to apply the outcome to numerically observable patterns, we use the totally unscaled system (1.1) with \( c = \theta \Gamma \) where \( \theta \) denotes differentiation with respect to the spatial variable \( x \) appearing in the original PDE (1.1). The only exception is that we set \( A = \delta^2 \alpha \Gamma \) as we showed was necessary in section 2.

First, we note that the leading order of the period of \( \Gamma_P \) is determined by the time \( \Gamma_P \) spends near \( \mathcal{K} \) specifically exponentially close to a hyperbolic orbit \( \Gamma_{C} \) (4.7) on \( \mathcal{K} \). Second, we observe that the exact position of the take off and touch down points \((u_P, \pm \delta)\) has no leading order influence on the period of \( \Gamma_P \). Hence the period is determined by the time it takes \( \Gamma_C \) to travel from \( u = 0, p > 0 \) to \( u = 0, p < 0 \) via the symmetry point \((U_{\text{max}}, 0)\). Here, we have to be aware that we do not get confused by the notation: the \((u, p, v, q) = (\hat{u}, \hat{p}, \hat{v}, \hat{q}) \) in (2.12) are rescaled versions of the ‘original’ \((u, p, v, q) \) in (1.2). By (2.7) we see that \( \hat{u} = \delta^\alpha u \). Thus the jump of \( \Gamma_P \) occurs \( O(\delta^\alpha) \) close to \( \{ u = 0 \} \Gamma \) and neglecting this \( O(\delta^\alpha) \) error has no leading order influence as long as we consider \( \alpha > 0 \). Furthermore, we note by (4.8) that the introduction of \( U_{\text{max}} \) coincided with scaling the \( \hat{u} \) of (2.8) back to the original \( u \) since \( \varepsilon^3 = \delta \) if \( \alpha = 1 \) see (2.11). This is also the case for a general choice of \( \alpha \).

It is easy to check that the \( u \) coordinate of \( \Gamma_C(x) \) is given by

\[
u_{\text{C}}(x) = 1 - (1 - U_{\text{max}}) \cosh(\delta \sqrt{u x}).\]

Thus \( \Gamma_{u_{\text{C}}}(x) = 0 \) for \( x = x_C \) such that \( \cosh(\delta \sqrt{u_{\text{C}}}) = 1/(1 - U_{\text{max}}) \). This equation can be solved and by the symmetry (4.1) we conclude that the period for the length \( \Gamma_{T_P} \) of \( \Gamma_P \) is given to leading
order by:

\[ T_P = T_P(U_{\text{max}}) = \frac{2}{\delta \sqrt{a}} \log \left( \frac{1 + \sqrt{2U_{\text{max}} - U_{\text{max}}^2}}{1 - U_{\text{max}}} \right). \]  

(4.10)

Equivalently, one can express \( U_{\text{max}} \) in terms of \( T_P \). If we define the quantity \( E \) by

\[ E = e^{\frac{1}{2} T_P \delta \sqrt{a}}, \]

then we can use (4.10) to find an explicit expression for \( U_{\text{max}} \):

\[ U_{\text{max}} = \frac{(E - 1)^2}{E^2 + 1} (\text{h.o.t.}), \]

(4.11)

which is less than 1. Note that we did not need an assumption on the value of \( a \) in order to determine this \( U_{\text{max}}, \Gamma \) this is clear since the period \( T_P \) (4.10) is independent of \( a \) leading order. It is also possible to determine an approximation for the maximum value \( V_{\text{max}} \) of \( V \) the second component of equation (1.1) at the peak of the pulse: \( V_{\text{max}} \) is determined by the value of \( u_P = \hat{u}_P \) (4.9) during the jump through the fast field. In the scaled coordinates \( V_{\text{max}} \) is determined to leading order by the maximal value of \( v \) of an unperturbed homoclinic orbit (3.3) at \( u_0 = u_P \): \( u_{\text{max}} = 3b/2aP \). By scaling backwards using (2.7) we find:

\[ V_{\text{max}} = \frac{\sqrt{a(2U_{\text{max}} - U_{\text{max}}^2)}}{2 \delta \sqrt{B}} \]

to leading order. By (2.7) we see that \( \delta \alpha \beta \sqrt{b} = \sqrt{B} \Gamma \) thus we did not need to know the explicit value of \( a \) to compute \( V_{\text{max}} \); it can be avoided by scaling \( b \) back to \( B \). The same is also true for the explicit value of \( U_{\text{min}} \), the minimal value of \( u \) during a period; \( U_{\text{min}} \) is a rescaled version of \( u_P \Gamma \) (4.9) which does not depend explicitly on \( a \) if we re-introduce \( B \) by (2.7). Thus to leading order we find:

\[ V_{\text{max}} = \frac{\sqrt{a(2U_{\text{max}} - U_{\text{max}}^2)}}{2 \sqrt{B}}, \quad U_{\text{min}} = \frac{3B \sqrt{B}}{\sqrt{a(2U_{\text{max}} - U_{\text{max}}^2)}}. \]

(4.12)

Note that in the limit \( U_{\text{max}} \to 1 \) these expressions tend to the values \( V_{\text{max}} \) and \( U_{\text{min}} \) of the 1-circuit homoclinic orbit described by Theorem 4.1:

\[ V_{\text{max}} = \frac{1}{2} \sqrt{\frac{a}{B}}, \quad U_{\text{min}} = 3B \sqrt{\frac{B}{a}}. \]

(4.13)

4.3. The special case \( a = 0 \)

Here we focus on the degenerate case \( a = 0 \) (and of course still \( \gamma = c = 0 \)). When \( a = 0 \) the scalings (2.7) imply that both (2.8) and (2.12) reduce to the unscaled system (1.4) with \( A = \delta^2 a = \epsilon^2 a \). Note that the numerical simulations suggested introducing the parameter \( \alpha > 0 \); the minimum value of \( u \) and the maximum value of \( v \) during a ‘pulse excursion’ scale with some power of \( \delta \) (see section 2 and the simulations in section 6). Therefore the choice \( \alpha = 0 \) does not seem to correspond to numerically stable patterns. However from the point of view of the phase space analysis of sections 4.1 and 4.2 it is an important limit case at which interesting bifurcations occur.
Finally we make a short remark on the transition from \( a = 0 \) to \( a \neq 0 \). Theorem 4.3 seems
to contradict Theorems 4.1 and 4.2 since somewhere between $\alpha = 0$ and $\alpha \neq 0$ periodic/homoclinic orbits are either created or annihilated. Here we only consider the homoclinic orbits and show that a contradiction does not exist. The argument for the periodic orbits is essentially the same but computationally more cumbersome. We once more write down $t^U$ for $\alpha \neq 0$ (see (3.6) and (3.5) with $\gamma = 0$):

$$t^U : \quad p = -\varepsilon \sqrt{a(1 - \varepsilon^{\frac{2}{3}(\gamma - 1)}u)}.$$ 

This formula reduces to (4.14) as $\alpha \to 0$ (i.e., $\Gamma \to 1$). Using the full expression for $t^U$ the intersection $t^U \cap T_o$ is determined to leading order by

$$u(1 - \varepsilon^{\frac{2}{3}(\gamma - 1)}u) = 3b \sqrt[6]{\frac{b}{a}}.$$ 

Thus there is only one $O(1)$ solution if "$\varepsilon$ is sufficiently small". However if $\alpha \to 0$ then $\varepsilon^{\frac{2}{3}(\gamma - 1)} \to 1$ and there can be none or two solutions. Thus a possible contradiction between Theorems 4.1 and 4.3 is avoided by employing the 'traditional phrase' "$\varepsilon$ is sufficiently small". Theorem 4.1 holds for $\varepsilon < \varepsilon_0 = \varepsilon_0(\alpha)$ since $\varepsilon_0$ must become 'very small' if $\alpha$ becomes small i.e., since $\lim_{\alpha \to 0} \varepsilon_0(\alpha) = 0$. See also Remark 2.1.

5 Traveling patterns

In this section we search analytically for solutions of (1.1) that travel with a constant speed $c$ and which do not change shape in a co-moving coordinate system. Note that the self-replicating pulse solutions (numerically) found in [21] are not of this type. It was deduced in section 2 that $c$ should be at least $O(\varepsilon^{1+\beta})$ for some $\beta \geq 2 - \alpha > \frac{1}{2} \Gamma$ where $\alpha$ measures the magnitude of $a = \varepsilon^{\alpha} \hat{\Gamma}$ the $u$-coordinate of a homoclinic solution to $S \in M$ of the unscaled system (1.2) or (1.4) during an excursion through the fast field. In other words if $\alpha$ measures the magnitude of the minimal value of the solution $U(x,t)$ of the PDE (1.1) in the region where $V(x,t)$ is peaked then $\varepsilon V(x,t)$ is not exponentially close to zero.

The main result (Theorem 5.1) of this section is that for $0 \leq \alpha < 3/2$ there cannot exist orbits homoclinic to $S$ in (2.12) for $c \neq 0$. Thus Theorem 5.1 implies that the one-parameter ($c$) family of 'dissipative perturbations' of the symmetric system (1.4) with $c = 0$ destroys the entire 3-parameter family $(a,b,\alpha)$ of orbits homoclinic to $S$. There are no traveling solitary pulse solutions to the PDE (1.1).

This result is surprising in the context of the geometric singular perturbation analysis of sections 2.3 and 4. First, by simple counting arguments alone one should expect large families of orbits homoclinic to $S$. Both the stable and unstable manifolds of $S$ are two-dimensional and the phase space is four-dimensional and there are three free parameters in (1.4) for the scalings even five $a,b,\gamma,\sigma,\rho$ in (2.12). Second, homoclinic orbits are known to persist in a wide variety of systems subject to small-amplitude perturbations. For $\gamma = 0$ Theorem 4.1 states that for any $a > 0$ and $B > 0$ and $0 < \alpha < 3/2$ there is a homoclinic solution to $S$ which corresponds to a stationary pulse solution of (1.1); moreover when $\gamma = 0$ and $\alpha = 0$ Theorem 4.3 gives the existence of either two or zero orbits homoclinic to $S$ depending on the parameters $a$ and $B$. The fact that the unstable and stable manifolds of $M$ still have a 2-D intersection surface while there are no parameter combinations...
such that the stable and unstable manifolds of \( S \in M \) intersect for \( \gamma \neq 0 \) makes the behavior of system (2.12) degenerate.

The system's degeneracy stems in part from the fact that for traveling pulses with speed \( c \) smaller than \( O(\varepsilon^{(2\alpha-\alpha)}) \) (i.e., \( \varepsilon > 0 \) in (2.12)) the magnitude of the evolution of the slow field \(- O(\varepsilon) -\) is much larger than the perturbation term in the fast field which is of \( O(\varepsilon (2^{\alpha})^2) \). We performed a rather subtle and detailed perturbation analysis since there must be some kind of balance between these effects in order for homoclinic orbits to exist. Our analysis is much more delicate than that performed in Section 3.

We focus on the (non-)existence of one-pulse solutions to (2.12) that are homoclinic to \( S \). In section 3.2 we defined the take off curve \( T_0 \in M \). Orbits \( \Gamma_{\lambda_0}(t; x_0^-) \subset M \) with initial condition \( x_0^- \in T_0 \) determine the behavior of \(- t \gg 0 \) of all orbits \( \Gamma(t; x_0) \) in the first intersection of \( W^U(M) \) and \( W^S(M) \) (with \( x_0 \in W^U(M) \cap W^S(M) \cap \{q = 0, v \neq 0\} \)). Thus an intersection \( (u_0^-, p_0^-; 0, 0) \) of \( T_0 \) and \( \ell^U \) - see (3.6) - corresponds to an orbit \( \Gamma(t; x_0) \in W^U(M) \cap W^S(M) \) which "originates" on \( ST \), i.e. \( \lim_{t \to -\infty} \Gamma(t) = S \). Note that the intersection point \((u_0^-, p_0^-, 0, 0)\) determines the lower endpoint of the interval on \( \ell^U \) for which \( \Gamma(t; x_0) \) is close to \( \ell^U \); however by definition \( \|\Gamma(t; x_0) - (u_0^-, p_0^-, 0, 0)\| \geq O(\varepsilon) \) for \( t = O(1) \).

By construction \( \Gamma(t; x_0) \) touches down on \( M \) and is exponentially close (for \( t \geq O(1) \)) to an orbit \( \Gamma_{\lambda_0}^+(t; x_0^+) \) with \( x_0^+ \in T_0 \). Thus \( \Gamma_{\lambda_0}^+ \) is a (1-circuit) homoclinic solution to \( S \) if \( x_0^+ = (u_0^+, p_0^+, 0, 0) \in \ell^{2S} \cap T_0 \). Let \( x_0 = (u_0, p_0, v_0, 0) \in \{\Delta K = 0\} \) see (3.15). The corresponding

\[
\begin{align*}
-\varepsilon \sqrt{a} + \h.o.t. & = \frac{1}{2} \varepsilon \left( \varepsilon^{\sigma} u_0 - \frac{6b\sqrt{b}}{a_0^2} \right) + \h.o.t. \\
+\varepsilon \sqrt{a} + \h.o.t. & = \frac{1}{2} \varepsilon \left( \varepsilon^{\sigma} u_0 + \frac{6b\sqrt{b}}{a_0^2} \right) + \h.o.t.
\end{align*}
\]

Adding and subtracting these two equations we find

\[
\varepsilon^{\sigma} u_0 = \h.o.t. \quad \text{and} \quad 2\sqrt{a} = \frac{6b\sqrt{b}}{a_0} + \h.o.t.
\]

Thus we recover (4.2). Moreover we conclude that \( \sigma > 0 \) since neither \( \gamma \) nor \( a_0 \) can be smaller than \( O(1) \) by the scalings of section 2. It is then we assumed that \( \gamma \neq 0 \) otherwise we merely recover the stationary pulse-solutions constructed in section 4.

However so far it is not clear at all that the term \( \varepsilon^{\sigma} u_0 \) cannot be 'balanced' by one of the higher order terms in (5.1). In fact it is possible to obtain that the computation of the higher order terms in (5.1) will lead to equations for \( \sigma \) and \( \gamma \). Given the fact that a traveling wave exists if a solution of system (5.1) can be found but does not if no solution exists we now proceed to find the higher order terms using the same method as we employed above. We find the curve on \( W^S(M) \cap W^U(M) \cap \{q = 0\} \) along which \( \Delta K = 0 \) up to and including as many higher order terms as necessary. Then we derive expressions for \( T_0 \) and \( T_0 \subset M \) and determine the intersections \( T_0 \cap \ell^U \) and \( T_0 \cap \ell^ST \) again obtaining as many higher order terms as are necessary. To achieve both of these objectives we have to extend the expansion (3.11) so that we can compute a more accurate approximation of an orbit \( \Gamma(t; x_0) = (u(t; x_0), p(t; x_0), v(t; x_0), q(t; x_0)) \) with initial condition \( x_0 \in W^S(M) \cap W^U(M) \cap \{q = 0\} \). Only then can we determine with sufficient precision the initial conditions of the orbits \( \Gamma_{\lambda_0}^+(t; x_0^+) \) which determine \( T_0 \) and \( T_0 \) as defined by (3.20).
As we already did in section 3 we will frequently exploit the fact that many terms especially those of lower order in the expansion of the solutions $\Gamma(t) = (u(t), p(t), v(t), q(t))$ are either odd or even. This simple observation forms the foundation of the non-existence proof below. This special character of the lower order terms in the expansion of $\Gamma(t)$ can be interpreted as the remains of the symmetry (4.1) which exists in the case $\gamma = 0$: all solutions $\Gamma(t) = (u(t), p(t), v(t), q(t)) \subset W^U(M) \cap W^S(M)$ with $\Gamma(0) \in \{q = 0\}$ must have $p(0) = 0$ which yields $\Gamma$ by the symmetry (4.1): $u(t)$ and $v(t)$ are even $\Gamma p(t)$ and $q(t)$ are odd. Since the non-symmetric dissipative effects are of order $O(\varepsilon^{2+\sigma})$ or higher it is clear that the lower order terms in the expansions of $u(t)$ and $v(t)$ must be even as function of $t \Gamma$ while those of $p(t)$ and $q(t)$ must be odd. Before we present the details of the analysis we state the main result:

**Theorem 5.1.** For $\gamma \neq 0$, $0 \leq \alpha < 3/2$, and $0 < \delta \ll 1$, there are no one-pulse solutions homoclinic to $S$ in equation (1.4) (equivalently (2.8) or (2.12)).

**Remark 5.1.** For $\sigma = 0$ the result of this theorem follows immediately from the straightforward application of the ideas developed in section 3 that led to (5.2). The case of $\sigma = 0$ (i.e. $\beta = 2 - \alpha$) is the significant degeneration $\Gamma$ recall (2.8); see [5] for a discussion of what constitutes significant degeneration in singularly-perturbed systems. By contrast we shall see in the numerical simulations of section 6 that the self-replicating pulses do travel with this critical speed $\epsilon = O(\delta^{1+\beta}) = O(\delta^{3-\alpha})$.

**Proof of Theorem 5.1.** For simplicity we first consider the case $0 < \sigma < 1$ and $\rho > 1 + 2\sigma$ so that $p = \epsilon^2 v + \rho + \sigma$ terms smaller than $O(\epsilon^{3+\sigma})$ (recall $\rho = 3$ when $\alpha = 1$). These conditions will minimize the technical difficulties $\Gamma$ since we do not have to pay attention to the higher order terms in the equation for $\dot{p}$. At the end $\Gamma$ we show that the proof is readily generalized to the cases of $\sigma \geq 1$ and $0 < \rho \leq 1 + \frac{2}{3} \sigma$.

We begin by rewriting the main equations (2.12) so that we may more easily refer to them:

\[
\begin{align*}
\dot{u} &= \varepsilon p \\
\dot{p} &= \varepsilon [u v^2 - \varepsilon^{\beta+1} u - \varepsilon^{(2+\gamma)q} \gamma p + \varepsilon^{(3-\sigma)q} a u] \\
\dot{v} &= q \\
\dot{q} &= -u v^2 + b v - \varepsilon^{(2+\sigma)q} q.
\end{align*}
\]  

From (3.15) we find that an orbit $\Gamma(t) = (u(t), p(t), v(t), q(t)) \in W^S(M) \cap W^U(M)$ $\Gamma$ with $\Gamma(0) \in \{q = 0\}$ must have $p(0) = \frac{1}{2} \varepsilon^{1+\gamma} u(0)$ (to leading order). Thus we need to adapt and extend (3.11) to:

\[
\begin{align*}
u(t) &= u_0 + \varepsilon u_1(t) + \varepsilon^2 u_2(t) + \varepsilon^{2+\sigma} u_{2+\sigma}(t) + \varepsilon^3 v_3(t) + O(\varepsilon^4) \\
p(t) &= \varepsilon p_1(t) + \varepsilon^{(1+\gamma)} p_1(t) + \varepsilon^2 p_2(t) + \varepsilon^3 p_3(t) + \varepsilon^{(3+\sigma)} p_{3+\sigma}(t) + \text{h.o.t.} \\
v(t) &= \nu_0(t; u_0) + \nu_1(t) + \varepsilon^2 v_2(t) + \varepsilon^{2+\sigma} v_{2+\sigma}(t) + O(\varepsilon^3) \\
q(t) &= \nu_0(t; u_0) + \varepsilon q_1(t) + \varepsilon^2 q_2(t) + \varepsilon^{2+\sigma} q_{2+\sigma}(t) + O(\varepsilon^3).
\end{align*}
\]  

**Remark 5.2.** In writing (5.4) above we have used some foreknowledge of the equations at each order: we did not write down those terms for which it is clear without much extra analysis $\Gamma$ that they need to satisfy a trivial equation after the expansions are substituted into (2.12).

Here $p_{1+\sigma}(t) \equiv \frac{1}{\gamma} u_0$ by (3.15) since $p_{1+\sigma} = 0$. We may assume as in section 3 $\Gamma$ that $u(0) = u_0$ and all higher order terms of $u$ are 0 at $t = 0$. In this fashion $\Gamma u_0$ again parametrizes the curve
$W^S(M) \cap W^U(S) \cap \{ q = 0 \}$: $p(0)$ and $v(0)$ are determined as functions of $u_0$ up to any order in $\varepsilon$. This yields that $u_{2+\sigma}(t) = \frac{1}{2\gamma} u_0 t$. Also after inserting (5.4) into (5.3) we immediately find that

$$u_1 \equiv 0, \quad p_1 \text{ odd}, \quad u_2 \text{ even}, \quad p_{1+\sigma} = \frac{1}{2\gamma} u_0, \quad v_1 \equiv 0, \quad q_1 \equiv 0. \quad (5.5)$$

See also section 3.

The following simple result helps us to establish the parity (odd/even) properties of further terms in the expansion of $v$:

**Lemma 5.2** Let $f(t)$ and $g(t)$ be real-analytic functions. Let $z(t)$ be a solution of

$$\ddot{z} + f(t)z = g(t) \quad \text{with} \quad z(0) = z_0, \quad \dot{z}(0) = 0.$$  

Then $z(t)$ is an even function of $t$ if both $f$ and $g$ are even and $z(t)$ is odd if $g$ is odd and $z_0 = 0$.

This Lemma is proven by computing the derivatives $d^n z/dt^n$ inductively and then evaluating them at $t = 0$. Applying this lemma to

$$\ddot{v}_2 + (2u_0 v_0 - b)v_2 = -u_2 v_0^2, \quad (5.6)$$

we see that $v_2$ is also even (and $q_2$ odd). Note that it is possible to obtain an explicit expression for $v_2$. The second-order differential operator consists of a soliton potential created by the unperturbed homoclinic solution $v_0(t)$ with solutions given by associated Legendre polynomials. See for example problem 5TSec. 23 of [14]. However we will not use this.

Next we need to extract more information from the condition that $\Gamma = (u, p, v, q)$ lies in $W^S(M) \cap W^U(M)$ in order to determine the initial conditions on $v_2(t), p_2(t)$ etc... In other words we have to impose that $\Delta K = 0$ on $\Gamma$ which using (5.5) amounts to:

$$\Delta K(u_0, p_0) = \varepsilon^2 \int_{-\infty}^{\infty} \frac{1}{2} p_1 v_0^3 dt + \varepsilon^{(2+\sigma)} \int_{-\infty}^{\infty} \left( \frac{1}{2} p_{1+\sigma} v_0^3 - \gamma q_0^2 \right) dt + \varepsilon^4 \int_{-\infty}^{\infty} \frac{1}{3} p_2 v_0^3 dt + \varepsilon^4 \int_{-\infty}^{\infty} \left( \frac{1}{3} p_{2+\sigma} v_0^3 + p_1 v_0^3 v_2 + p_{1+\sigma} v_0^3 v_2 - 2\gamma q_0 q_2 \right) dt + O(\varepsilon^5). \quad (5.7)$$

The first integral vanishes since $p_1(t)$ is odd and $v_0(t)$ is even. Thus by imposing $\Delta K = 0$ we recover $p_{1+\sigma} = \frac{1}{2\gamma} u_0$. Next the initial value $v_2(0)$ is determined by the value of $K|_{\Gamma}$ at $q = 0$. We see from the first term in (5.7) that $v_2(0) \neq 0$ since $p_1(t)$ is odd and $\int_{-\infty}^{\infty} \frac{1}{3} p_1 v_0^3 dt \neq 0$. Hence $K|_{\Gamma \cap \{ q = 0 \}} = O(\varepsilon^2)$.

We now determine $v_{2+\sigma}(t)$ and its initial value. Since the terms in the integrand of the $O(\varepsilon^{(2+\sigma)})$ integral are both even we conclude that also the accumulated change at the $O(\varepsilon^{(2+\sigma)})$-level in $K$ along a solution $\Gamma$ over the time intervals $(-\infty, 0)$ and $(0, \infty)$ are the same. In fact the two semi-infinite integrals are equal and each is precisely half of the full integral. But the full integral must be identically zero along a persistent homoclinic solution $\Gamma$. So each of the half integrals is zero as well. Hence unlike $v_2 \Gamma v_{2+\sigma}$ does not have to ‘correct’ the value of $K$ at $t = 0\Gamma$ and we have $v_{2+\sigma}(0) = 0$. Also using (5.5) we get the equation for $v_{2+\sigma}$ reads

$$\ddot{v}_{2+\sigma} + (2u_0 v_0 - b)v_{2+\sigma} = -\gamma (q_0 + \frac{1}{2} u_0 v_0^2 t).$$
Therefore we conclude by Lemma 5.2 that $p_{2+\sigma}$ is an odd function of time.

Higher order terms in the expansion of $p(t)$ along $\Gamma$ are obtained as follows. By straightforward calculations similar to that for $p_1(t)$ we find that $p_2(t) = p_2(0)$ and $p_3(t) = p_3(0) + \text{an odd function.}$ But from the $O(\varepsilon^3)$ and $O(\varepsilon^4)$ levels of (5.7) we know that $p_2(0) = p_3(0) = 0$ since $\Delta K$ must be 0. Next the equation for $p_{3+\sigma}$ reads:

$$\dot{p}_{3+\sigma} = u_{2+\sigma} v_0^2 + 2u_0 v_0 v_{2+\sigma}.$$ 

Here we have used $\rho > 1 + \frac{3}{2}\sigma$. Thus $\Gamma p_{3+\sigma}(t)$ is even because $u_{2+\sigma}(t)$ and $v_{2+\sigma}(t)$ are odd.

What do the above terms tell us about $\Delta K$ and $p(0)$? They imply that all terms in the integral at the $O(\varepsilon^{[4+\sigma]})$-level of (5.7) are even. Hence the requirement $\Delta K = 0$ fixes $p_{3+\sigma}(0)$ as a function of $u_0$ and $\gamma$: $p_{3+\sigma}(0) = F(u_0; \gamma)$. Of course $F(u_0; \gamma)$ can be computed explicitly but this is not needed here. Therefore the curve $\{\Delta K\} = 0 \subset W^S(\mathcal{M}) \cap W^U(\mathcal{M}) \cap \{g = 0\}$ is given by

$$p(0) = \varepsilon^{1+\sigma} p_{1+\sigma}(0) + \varepsilon^{3+\sigma} p_{3+\sigma}(0) = \frac{1}{2} \varepsilon^{1+\sigma} \gamma u_0 + \varepsilon^{3+\sigma} F(u_0; \gamma) + O(\varepsilon^4).$$

(5.8)

This completes the first part of the proof.

In this second part of the proof we construct $T_o$ and $T_d$ to sufficiently high order. For a given $x_0 = (u_0, p(0), v_0(0), 0) \in W^S(\mathcal{M}) \cap W^U(\mathcal{M})$ we must find $x_0^\pm = (u_0^\pm, p_0^\pm, 0, 0) \in \mathcal{M}$ such that the orbits $\Gamma_{\mathcal{M}}(t; x_0^\pm)$ are exponentially close to $\Gamma(t; x_0)$ for $t \geq O(\frac{1}{2})$. First we write expansions for $\Gamma_{\mathcal{M}}(t; x_0^\pm)$ similar to the expansion above for $\Gamma(t; x_0)$. By (5.3) we see that $\dot{p} = o(\varepsilon^{[3+\sigma]}) \ll O(\varepsilon^{[3+\sigma]})$ on $\mathcal{M}$ (since $\rho > 1 + \frac{3}{2}\sigma$) which yields for $t = O(1)$:

$$\begin{cases}
\dot{p}^\pm(t) = p_0^\pm + o(\varepsilon^{3+\sigma}) \\
u^\pm(t) = u_0^\pm + \varepsilon p_0^\pm t + o(\varepsilon^{4+\sigma})
\end{cases}$$

(5.9)

Second we find $p_0^\pm$ and $u_0^\pm$ using the functions $p_j(t)$ computed above in the expansion of $p(t)$ along $\Gamma(t)$, and the functions $G_j(u_0)$ and $P_j(t; u_0)$ ($j = 1, 3, 3 + \sigma$) are defined by:

$$p_j(t; u_0) = G_j(u_0) + P_j(t; u_0) \quad \text{with} \quad \lim_{t \to \infty} P_j(t; u_0) = 0 \quad (j = 1, 3).$$

By construction $\Gamma$

$$G_1(u_0) = \frac{1}{2} \Delta p(u_0) = \frac{3b}{u_0},$$

(5.10)

where we recall (3.12) and (3.18). In terms of these functions we may write the expansion of $p(t)$ for $t > 0$ as:

$$p(t) = (p_1(t) + \varepsilon^{1+\sigma} p_{1+\sigma}(0) + \varepsilon^3 G_3 + \varepsilon^{3+\sigma} (p_{3+\sigma}(0) + G_{3+\sigma})) + (p_1(t) + \varepsilon^3 P_3(t) + \varepsilon^{3+\sigma} P_{3+\sigma}(t)),$$

where we have neglected higher-order terms. Also for $t > 0$ the expansion of $u(t)$ along a homoclinic orbit $u(t)$ is known from (5.7) and (5.3). Now the initial condition $p_0^\pm(u_0)$ is determined by the condition that $p^\pm(t)$ and $p(t)$ have the same asymptotic behavior. Since the $P_j(t)$'s vanish for large $t$ we conclude from (5.9) that

$$p_0^\pm(u_0) = \varepsilon G_1(u_0) + \varepsilon^{1+\sigma} p_{1+\sigma}(0) + \varepsilon^3 G_3(u_0) + \varepsilon^{3+\sigma} (p_{3+\sigma}(0) + G_{3+\sigma}(u_0)) + \text{h.o.t.}$$

(5.11)
Also by defining
\[ H_1(u_0) = \int_0^\infty P_1(t; u_0) dt, \]
we find by (5.3) and (5.9) that
\[ u_0^+(u_0) = u_0 + \varepsilon^2 H_1(u_0) + O(\varepsilon^4). \] (5.12)

The \( p_0^+ \) and \( u_0^+ \) coordinates of \( T_o \) are clearly implicitly related since both are functions of \( u_0 \) by (5.8). Taylor expanding the functions \( G_j \) in the right hand side of (5.11) about \( u_0^+ \) and using (5.12) we get:
\[ p_0^+(u_0) = \varepsilon G_1(u_0) + \varepsilon^{1+\sigma} p_{1+\sigma}(0) + \varepsilon^3 (G_3(u_0^+)-G_1'(u_0^+))H_1(u_0^+) + \varepsilon^{3+\sigma} (p_{3+\sigma}(0)+G_{3+\sigma}(u_0^+)) + \text{h.o.t}. \]

Similarly, one must Taylor expand the functions \( F \) and
\[ p_{1+\sigma}(0) = \frac{\gamma}{2} u_0 = \frac{\gamma}{2} \left( u_0^+ - \varepsilon^2 H_1(u_0^+) \right) + \text{h.o.t}. \]

Therefore, we find
\[ T_1 : \quad p - \varepsilon G_1 - \varepsilon^3 (G_3 - G'_1 H_1) - \varepsilon^{3+\sigma} G_{3+\sigma} = \frac{1}{2} \varepsilon^{1+\sigma} \gamma u + \varepsilon^{3+\sigma} (F - \frac{1}{2} \gamma H_1) + \text{h.o.t.}, \] (5.14)
where \( p = p_0^+ \Gamma u = u_0^+ \) and \( G'_1 = dG_1/du(u) \).

Using the parity (odd/even) properties of the functions \( p_j(t) \) we immediately find the analogous results for \( p_0^- \Gamma u_0^- \) and \( T_o^- : \)
\[ p_0^-(u_0) = -\varepsilon G_1(u_0) - \varepsilon^{1+\sigma} p_{1+\sigma}(0) - \varepsilon^3 G_3(u_0) + \varepsilon^{3+\sigma} (p_{3+\sigma}(0) + G_{3+\sigma}(u_0)) + \text{h.o.t}. \]
\[ u_0^-(u_0) = u_0 + \varepsilon^2 H_1(u_0) + O(\varepsilon^4). \] (5.15)

The \( u_0^- \) and \( p_0^- \) coordinates for \( T_o \) are also implicitly related since both are functions of \( u_0 \) by (5.8).

This relation can be made explicit in a straightforward manner:
\[ T_0 : \quad p + \varepsilon G_1 + \varepsilon^3 (G_3 - G'_1 H_1) - \varepsilon^{3+\sigma} G_{3+\sigma} = \frac{1}{2} \varepsilon^{1+\sigma} \gamma u + \varepsilon^{3+\sigma} (F - \frac{1}{2} \gamma H_1) + \text{h.o.t.}, \] (5.16)
where \( p = p_0^- \Gamma u = u_0^- \) and \( G'_1 = dG_1/du(u) \). Note that to leading order these expressions (5.14) and (5.16) correspond to those obtained for \( T_o \) and \( T_o^- \) in (3.21).

A traveling pulse with a speed \( c = \delta^{(1+\beta)} \gamma \Gamma \) such that \( \beta > 2 - \alpha \Gamma \) exists for \( u_0 \) such that the corresponding orbit \( \Gamma_h(t; x_0) \) with initial condition \( x_0 = (u_0, p(0; u_0), v(0; u_0), 0) \) \( \Gamma \) lies in the intersection of \( W^S(S) \) and \( W^U(S) \). In other words, the the off point \( (u_0^-(u_0), p_0^-(u_0)) \) of \( \Gamma_h \) must be on \( \ell^U = W^U(S) \cap \mathcal{M} \) and the touchdown point \( (u_0^+(u_0), p_0^+(u_0)) \) lies on \( \ell^S \). Thus we have to compute the intersections \( T_o \cap \ell^U \) and \( T_o^- \cap \ell^S \). Expanding (3.6) yields:
\[ \ell^U : \quad p = -\varepsilon \sqrt{a} + \varepsilon^{2(3\sigma-1)} \sqrt{a} u + \text{h.o.t.}, \]
where the higher order terms are smaller than \( O(\varepsilon^{3+\sigma}) \) for any \( \sigma > 0 \). A similar expression can be obtained for \( \ell^S \). The homoclinic solution \( \Gamma_h \) exists for \( u_0 \Gamma \gamma \) and \( \sigma \) which satisfy the system of equations given by \( T_o \cap \ell^U \) and \( T_o^- \cap \ell^S \) where \( u_0 \) appears only implicitly in the equations through
than or equal to /1 /+

as on the calculation of /#01

\[ u = u_0^+ (u_0) \] in the expressions (5.16) for \( T_o \) and (5.14) for \( T_2 \). However I we observe by (5.12) and (5.15) that \( u_0^- (u_0) = u_0^+ (u_0) \) up to \( O(\varepsilon) \) thus we can solve the system defined by \( T_o \cap \ell^U \) and \( T_2 \cap \ell^S \) in terms of \( u = u_0^- = u_0^+ \) and \( \gamma \) instead of \( u_0 \) and \( \gamma \). Adding these two equations and dividing by \( \varepsilon^{1+\sigma} \) yields:

\[
\gamma u + \varepsilon^2 (2G_{3+\sigma} - \gamma H_1 + 2F) = \text{h.o.t.}
\]

We now observe that it is not possible to solve this equation unless we admit dividing by \( T \).

When we observe that it is not possible to solve this equation, unless we admit dividing by \( T \).

Again, when we have to conclude that no change in these terms all cancel.

The terms also obey symmetry (4.1), thus they will not influence (5.17). This concludes the proof of Theorem 5.1.

Before we go on with the proof of the general case I we make two observations. First I we note that substituting the equations for \( T_o \cap \ell^U \) and \( T_2 \cap \ell^S \) just gives higher order corrections to the critical value of \( u_0 \) (see (5.2)). Second I we note that a priori one might think that the \( O(\varepsilon^2) \) part of (5.17) causes problems since it also must be zero. However one can check if a straightforward manner the behavior of the terms in (5.4) as function of \( \gamma \) and conclude that \( G_{3+\sigma} = G_{3+\sigma}(u_0; \gamma) = \gamma G_{3+\sigma} \) and \( F = F(u_0; \gamma) = \gamma \tilde{F}(u_0) \). Thus the \( O(\varepsilon^2) \) term also disappears when \( \gamma = 0 \).

The question is now: what happens if \( \rho \) and \( \sigma \) do not satisfy these conditions? Let’s first consider \( 0 < \sigma < 2 \). It is easy to see how expansion (5.4) should be modified: the \( \sigma \)-dependence now only occurs at the levels \( u_{2+\sigma} = u_{3+\sigma} \), \( p_{1+\sigma} = p_{2+\sigma} \), \( p_{3+\sigma} = p_{4+\sigma} \), \( v_{2+\sigma} = v_{3+\sigma} \), and \( q_{2+\sigma} = q_{3+\sigma} \). It is also easy to show that \( u_0, u_1, u_2, u_3 \) are even, \( v_0, v_1, v_2, v_3 \) are odd; and \( p_0, q_0, p_2, q_2, p_3, q_3 \) are even. exactly as above these solutions do not feel the dissipative terms yet and thus obey the symmetry (4.1). The equations for \( u_{2+\sigma}, p_{3+\sigma}, v_{2+\sigma} \) and \( q_{2+\sigma} \) are the same as those in the case \( \sigma < 1 \). Thus the only differences between \( T_o \), \( T_2 \) in the case \( 0 < \sigma < 1 \) and the case \( 1 < \sigma < 2 \) are some extra symmetrical terms of \( O(\varepsilon^4) \) in (5.16) and (5.14). These terms cancel when we add the equations for \( T_o \cap \ell^U \) and \( T_2 \cap \ell^S \). Thus: there is no change in (5.17). Again I we have to conclude that \( \gamma = 0 \) and that the theorem holds.

The same will happen for any value of \( \sigma \): all symmetrical contributions of the expansions will vanish when we add the equations for \( T_o \cap \ell^U \) and \( T_2 \cap \ell^S \) (5.17) will not change so the theorem holds. The only extra technical complications appear when \( \sigma = 1, 2, ... \) since then we have to split the solutions \( u_{2+\sigma}, p_{3+\sigma}, v_{2+\sigma} \) and \( q_{2+\sigma} \) in an even and an odd part: one part takes care of the dissipative effects and the other obeys (4.1). Only the first part appears in (5.17) so it again does not change. A similar technicality has to be taken into account in the case when \( \rho \) is less than or equal to \( 1 + \frac{2}{9} \sigma \): expansion (5.4) has to be adapted to include the higher order effects in the equation for \( \dot{\rho} \) in (5.5) which appear before the dissipative effects. However these higher order terms also obey symmetry (4.1) thus they will not influence (5.17). This concludes the proof of Theorem 5.1.

**Remark 5.3.** In section 4 we found that \( \alpha = 0 \) was a special case since the approximation (3.7) of (3.6) could not be used in this case. In the proof of Theorem 5.1 we did not pay attention to the special case \( \alpha = 0 \): this is not necessary since it again has no influence on those terms in the equations for \( T_o \cap \ell^U \) and \( T_2 \cap \ell^S \) which do not cancel after addition.

**Remark 5.4.** The proof of Theorem 5.1 also implies the non-existence of traveling patterns consisting of the periodic stationary patterns translating uniformly in time. We recall that the central argument used to establish Theorem 5.1 relies on the adiabatic Melnikov function \( \Delta K \) to find solutions in the transverse intersection of the stable and unstable manifolds of \( \mathcal{M} \Gamma \) as well as on the calculation of \( \Delta \rho \text{FtO} \) to insure that the jump in the \( p \)-coordinate during a fast excursion
precisely bridges the gap between \( \ell^U \) and \( \ell^S \). The existence of periodic patterns when \( \gamma \neq 0 \) relies on precisely these same two calculations. Moreover the details are similar: the fast excursion corresponds to an orbit of the fast subsystem that lies in the transverse intersection of the slow plane’s stable and unstable manifolds and the jump in \( p \) must coincide with the horizontal distance between two points on the same hyperbolic orbit \( \Gamma_C \) on \( M \). Since these conditions have the same form as those for the traveling one-pulse solutions \( \Gamma \) arguments similar in structure to those used above show that no such solution is possible.

**Remark 5.5.** Besides extending to the non-existence of periodic traveling solutions \( \Gamma \) Theorem 5.1 also extends to the non-existence of \( N \)-pulse homoclinic traveling waves for any \( N = O(1) \) \( \Gamma \) implying that the \( \gamma = 0 \) symmetry of (2.12) is broken and all of the orbits given by Theorem 4.1 disappear when \( \gamma > 0 \). Instead of looking for zeroes of \( \Delta K \) as we did for one-pulse orbits \( \Gamma \) one looks for zeroes of the appropriate inductively-defined \( N \)-pulse adiabatic Melnikov function \( [26] \): \( \Delta K_N(u, p, \varepsilon) \equiv \Delta K_{N-1}(u, p, \varepsilon) + \Delta K_1 \left(u, p + \varepsilon \frac{\partial^2}{4v} \sum_{i=1}^{N-1} \tau_i \right) \Gamma \) where \( \tau_i \) denotes the period of the unperturbed periodic orbit of the fast subsystem with slow-parameter \( u \) and with energy given by \( \Delta K_{i-1} \). Also \( \Delta K_1(u, p) \equiv \Delta K(u, p) \) as introduced in section 3. The same proof as given in [26] for planar Hamiltonian systems depending on a slowly-varying parameter (here \( p \)) implies here that \( \Delta K_N = \text{correct higher-order adiabatic Melnikov function for (2.12)} \) because the fact that \( \Delta u = O(\varepsilon^2) \) during each fast excursion relegates \( u \) to the status of a parameter in this calculation. Now since the periods \( \tau_i \) for \( i = 1, ..., N-1 \) only diverge logarithmically as \( \varepsilon \rightarrow 0 \) the arguments of the terms in the sum for \( \Delta K_N \) lie close to \( \rho_0 \) the \( p \)-coordinate of the zero of \( \Delta K \). Therefore the simple zeroes of \( \Delta K_N \) lie close to those of \( \Delta K \) and the asymptotic expansions for the \( N \)-pulse case are similar in structure (with extra log terms that can’t be balanced by the \( \gamma \) terms) to those of the one-pulse case. Thus \( \Gamma \) the same argument as used above also rules out the existence of \( N \)-pulse traveling waves. Note that of course one requires that \( N \Delta p \) equals the horizontal distance between \( \ell^U \) and \( \ell^S \) instead of requiring that \( \Delta p \) equal that distance.

### 6  Numerical simulations

In this section we study the numerically-observed dynamics of the PDE (1.1). In order to do numerical calculations \( \Gamma \) we have to restrict \( x \) to a bounded interval. However to obtain patterns which can be described by the analysis of the previous section we only consider intervals that are long enough so that the boundaries are ‘far away’ and do not influence the dynamics. The simulations presented in this section have been repeated several times on intervals of different lengths. We only show the outcome of simulations on intervals which are so large that enlarging the intervals did not influence the behavior. Moreover we have done the simulations with different types of boundary conditions and checked that this also did not change the dynamics inside the interval.

There are three parameters in (1.1): \( A \Gamma B \) and \( \delta \). We have rescaled \( A \) and \( B \) into \( A = \delta^2 a \) and \( B = b \delta^{2v} / 3 \) in section 2; \( \alpha \) measures the magnitude of \( B \). In this section we focus on the choice \( \alpha = 1 \) This means that \( \Gamma \) as was observed in [21] we assume that \( U = O(\delta) \) during a ‘pulse-excursion’ of \( V \). Note that this choice is not essential since we have seen in section 4.2 that the maximum and minimum values of \( U \) and \( V \) can be expressed in an unscaled form \( \Gamma \) independent of an explicit value of \( \alpha \) see (4.12) and (4.13). Reynolds \( \Gamma \) Pearson \( \Gamma \) Ponce-Dawson \( \Gamma \) and Hasslacher observed self-replicating pulse patterns for the choice \( \delta^2 = 0.01 \) \( \Gamma A = 0.02 \) and \( B = 0.079 \) in (1.1)
see figure 1 of [21] and figure 2 of [3]. These values correspond in our scaling to \( a = 2 \) and \( b \approx 0.37 \).

Below we shall frequently choose \( \delta^2 = 0.01 \Gamma a = 2 \) and \( b = 0.4 \Gamma \) so that we can compare with the results of [21].

6.1 The code.

We used a moving-grid code to integrate system (1.1). The code which is described in detail in [2] is designed to numerically solve systems of time-dependent PDE models in one space dimension having solutions with steep gradients in space and time. The moving-grid technique in the code is based on a Lagrangian description of the PDE model combined with a smoothed-equidistribution principle to define the grid positions at each time-level. The dynamically moving adaptive grid is coupled to a discretization method which automatically discretizes the spatial part of the user-defined PDE system following the method-of-lines approach. The spatial discretization and the time-integration are carried out with a nonlinear Galerkin method and an implicit (stiff) BDF method with variable order and step-size control respectively. It must be noted that application of the moving-grid code is not restricted to reaction-diffusion equations of type (1.1). The interested reader is referred to [2] and [31] where PDEs from various other application areas have been solved using this technique.

The boundary conditions are of Dirichlet type:

\[
U(\tilde{x} = 0, t) = U(\tilde{x} = 1, t) = 1, \quad V(\tilde{x} = 0, t) = V(\tilde{x} = 1, t) = 0. 
\]

Neumann conditions were also used but did not influence the inner solutions. Moreover the initial data for the results we report consists of a sharp pulse centered in the middle of the spatial domain:

\[
U(\tilde{x}, 0) = 1 - \frac{1}{2} \sin^{100}(\pi \tilde{x}) \quad \text{and} \quad V(\tilde{x}, t = 0) = \frac{1}{4} \sin(\pi \tilde{x}).
\]

The spatial variable \( \tilde{x} \) is a rescaled version of the spatial variable \( x \) in (1.1): \( \tilde{x} \) has been scaled such that the numerical simulations always take place on the \( \tilde{x} \)-interval \([0, 1]\).

Since we wanted to be able to observe patterns described by the analysis of this paper we focused in the numerical simulations on values of \( a \) and \( b \) which are \( O(1) \) with respect to \( \delta \). Our search in the \((a, b)\)-parameter space of (1.1) has not yet found patterns that differ essentially from the ones described and shown below (by contrast if larger \( a \) we have observed various different patterns; an example is shown in section 7 figure 10 of a structurally different pattern at \( a = 9 \Gamma \) \( b = 0.4 \) and \( \delta^2 = 0.01 \)). Moreover especially the dynamic splittings – the self-replications of the traveling pulses – are driven by processes which are very sensitive to the numerical accuracy: if there are not enough grid points ‘on’ a \( V \)-pulse a splitting just cannot occur or occurs much later. Thus if one does not use enough grid points (or a non-moving grid) one is tempted to conclude that the self-replicating process does not occur. This observation also means that the error made by the code can ‘explode’ in a very short amount of time. For all numerical tests we have used 400 moving grid points to take care of the sharp pulses. In one case (20 pulses out of 20,000) 600 grid points had to be used (figures 7 and 8). Note that a conventional non-moving uniform would have required several (4–5) times more grid points than used for the moving grid case.

Moreover we found that decreasing \( \delta \) increased both the (temporal) distance between successive splittings and the number of necessary grid points so drastically that one approaches very rapidly the limits of the machine one is working on for \( \delta^2 \ll 0.01 \) if one is interested in the long-time behaviour of the self-replicating patterns (see section 6.3 and figures 7 and 8).
Before we start the description of the patterns observed in the numerical simulations we remark on the magnitude of $\varepsilon$ both as small quantity in our asymptotic analysis and as part of the data in the numerical simulations. First we note that by our scalings $\varepsilon = \delta^{1/3}$ (see (2.11)$\Gamma \alpha = 1$) is the ‘true’ asymptotically small quantity of the analysis. This means that a ‘standard’ choice of $\varepsilon = 0.1$ corresponds to a value of $\delta^2 = 10^{-6}$ as input in the numerical simulations of equation (1.1). On the other hand we noted that choices of $\delta^2 = 0.003$ are already near the boundary of the capacity of the hardware and software one is using. Thus theoretically one expects only a small overlap between the numerically ‘safe’ and the analytically ‘safe’ regions. However we shall see that there is a good qualitative and quantitative agreement between the analytical predictions and the numerical observations.

### 6.2 Stationary behavior and a transition region.

In the bifurcation analysis we performed we fixed $b$ at a certain value $b \in (0.2, 1)$ and varied $a$ over a certain range $a \in (0.2, 5)$ (approximately). For each parameter pair we repeated the simulations for several values of $\delta$ but we found that the value of $\delta$ did not have an essential influence on the dynamics. Except for the time scale of the evolution. For $a > 0$ ‘too small’ we observed the following behavior:

$$\lim_{t \to \infty} U(x, t) \equiv 1, \quad \lim_{t \to \infty} V(x, t) \equiv 0.$$  

Note that this is not completely surprising since the trivial pattern $(U \equiv 1, V \equiv 0)$ is an asymptotically stable solution of (1.1) on the unbounded domain.

As we increase $a$ we enter a transition region between the trivial behavior and the self-replicating pulse regime. Moreover we find that the transition region is not a clear 1-dimensional bifurcation curve in the $(a, b)$-parameter space and the behavior in the transition region depends rather subtly on the initial conditions and small perturbations.

First we observe stable stationary solitary pulse solutions of the type constructed in section 4.1. See figure 4. These solutions of (1.1) are precisely the 1-circuit slow/fast homoclinic described by Theorem 4.1 and they seem to be stable in this transition region (see below for a quantitative check). In figure 4 we show plots of $U(x, t)$ and $V(x, t)$ for $a = 1$ and $b = 0.6$. Note that they are insensitive to the details of the initial one-pulse concentration.

Second we find parameter values at which initial solitary pulses split into two non-traveling pulses. These depend sensitively on the initial concentrations in the interval. These patterns do not correspond to the 2-circuit homoclinic solutions described by Theorem 4.1 $(N = 2)$: $V$ becomes exponentially small between the two fast excursions while the 2-circuit pulse described by Theorem 4.1 does not approach the slow manifold $M$ closer than $O(\sqrt{\varepsilon})$ during its circuits through the fast field. Using the symmetry (4.1) it is not hard to show that such a solution to the stationary problem (1.4) or (2.12) with $\gamma = 0$ does not exist: a homoclinic solution which takes off at $\ell^U \cup T_a$ can only touch down exactly on $\ell^S \cap T_a$. This is confirmed by the numerics: Although the pulses do not move the two pulse pattern is not stationary. In figure 5 we see that the heights of the two pulses ‘dance’ up and down until one of them disappears completely and only a stationary solitary pulse remains. Note that this pulse is not located exactly in the middle of the $x$-interval contrary to the initial values of $U$ and $V$. We found that the length and the outcome of this process (i.e. the answer to the question: ‘which pulse disappears after what period of time?’) depends very sensitively on
small perturbations. It also depends on the width of the initial \( V \)-pulse whether the solutions \( V \) undergoes an initial splitting\( \Gamma \)as in figure 5. For whether it does not. In the latter case\( \Gamma \)the initial solution deforms immediately into a stationary solitary peak described by Theorem 1 \( (N = 1) \) (see figure 4; the pulses are exactly at the middle of the \( x \)-interval).

We now compare the outcome of the numerical simulations with the analytical results of section 4.1. We show numerically stable stationary 1-pulses for \( a = 1\Gamma b = 0.6\Gamma \) with \( \delta^2 = 0.01 \) in figure 4.a and with \( \delta^2 = 0.003 \) in figure 4.b. Numerically\( \Gamma \)we find:

\[
\begin{align*}
\delta^2 &= 0.01: \quad V_{\text{max}} \approx 1.11, \quad U_{\text{min}} \approx 0.16 \\
\delta^2 &= 0.003: \quad V_{\text{max}} \approx 1.49, \quad U_{\text{min}} \approx 0.08.
\end{align*}
\]

Since \( B = b\delta^2/\Gamma(4.13) \) implies:

\[
\begin{align*}
\delta^2 &= 0.01: \quad V_{\text{max}} \approx 1.39, \quad U_{\text{min}} \approx 0.14 \\
\delta^2 &= 0.003: \quad V_{\text{max}} \approx 1.69, \quad U_{\text{min}} \approx 0.076,
\end{align*}
\]

to leading order. The leading order correction to \( \Gamma \) the \( \mathcal{O}(1) \) scaled version of \( V_{\text{max}} \) is \( \mathcal{O}(\varepsilon) \). By (2.7) we see that \( V_{\text{max}} \) is \( \mathcal{O}(\varepsilon^1) \) to leading order with \( \varepsilon = \delta^1/3 \) ((2.11) and \( \alpha = 1 \)). We conclude that the leading order correction in the above determined theoretical value of \( V_{\text{max}} \) is \( \mathcal{O}(1) \). The differences between the numerically-observed values of \( V_{\text{max}} \) and the theoretical predictions are clearly within this range. Furthermore\( \Gamma \)we note that the relative error\( \Gamma \)\( |V_{\text{max}}^{\text{num}} - V_{\text{max}}^{\text{theo}}|/V_{\text{max}}^{\text{num}} \) decreases as \( \delta \) is decreased (from \( \approx 0.25 \) for \( \delta^2 = 0.01 \) to \( \approx 0.13 \) for \( \delta^2 = 0.003 \)) and that these errors are again well within the theoretical bound of \( \mathcal{O}(\varepsilon) \) (\( \varepsilon \approx 0.46 \) for \( \delta^2 = 0.01 \) and \( \varepsilon \approx 0.38 \) for \( \delta^2 = 0.003 \)). A similar argument yields that the distance between the numerically observed value of \( U_{\text{min}} \) and the above theoretical prediction is within the leading order correction to the theoretical value of \( U_{\text{min}} \) of \( \mathcal{O}(\varepsilon\delta) = \mathcal{O}(\varepsilon^4) \) (\( \varepsilon^4 \approx 0.046 \) for \( \delta^2 = 0.01 \) and \( \varepsilon \approx 0.21 \) for \( \delta^2 = 0.003 \)).

One might expect that it should be possible to find a (numerically stable) 2-circuit pulse solution — as described by Theorem 4.1 for \( N = 2 \) — in this transition region by varying the initial conditions. We did not do an extensive numerical search to find these solutions; however\( \Gamma \)we did find that in the transition from initial data which splits into two solitary ‘dancing’ pulses to a non-splitting initial condition\( \Gamma \)there exist initial conditions that initiate solutions which are like the stationary 2-circuit pulse for a very long time (but\( \Gamma \)eventually\( \Gamma V \) becomes exponentially small between the peaks and the ‘dancing behavior’ starts).

### 6.3 Self-replicating pulses.

For values of \( a \) above this transition region (with \( b \) still fixed)\( \Gamma \)we observe that the two solitary pulses created from the initial condition at the first stationary splitting begin to move away from each other\( \Gamma \)both with the same\( \Gamma \)constant speed (see below for a discussion on the magnitude of this speed). We know from section 5 that these patterns cannot be interpreted as some kind of nonlinear superposition of two solitary traveling pulses with speeds \( c \) and \( -c \); these solutions do not exist. This observation is remarkable\( \Gamma \)if one only pays attention to the \( V \)-solution\( \Gamma \)since \( V \) seems to be exponentially small between the two traveling peaks (see figure 6.a where \( a = 2 \)). However\( \Gamma \)\( U \) does not ‘return’ to \( 1 \) in between the pulses\( \Gamma \)which should be the case for the solitary traveling waves studied in section 5. On the other hand\( \Gamma \)the maximum value of \( U \) between the two traveling \( V \)-pulses grows towards \( 1 \) as the distance between these pulses grows: the traveling pulses begin to
resemble the non-existing solitary pulses more and more. A conflict with the non-existence result of Theorem 5.1 would occur if these pulses go on traveling away from each other with constant speed without changing shape while the value of $U$ approaches 1 ‘in the middle’: both pulses then become identical to the solitary traveling pulses considered in section 5.

Therefore something else must happen: for $a = 2\Gamma$ we see in figures 6.b – 6.d that both $V$-pulses split into two similar traveling pulses (with distinct speed) yielding a pattern of four moving pulses. After yet more time all four of these $V$-pulses split once again and this process of replication continues for the outermost two pulses on each side until an equilibrium state is reached. In fact the number of peaks a domain can support depends on $a$ and $b$. In figure 7 we show the solutions $U$ and $V$ at time $t = 20,000$ for the choice of parameters $a = 2\Gamma b = 0.4$ and $b^2 = 0.01$. There are 20 peaks present.

For the same simulation shown in figure 7 we plot the positions of the grid points of our code as functions of time in figure 8. The position of the $V$-pulses is revealed by a local concentration of grid points. Thus due to the character of the code we can follow the pulses and their self-replicating behavior by plotting the positions of the grid points. Note that the horizontal bands in figure 8 just indicate the fact that one (or more) of the pulses ‘needs more grid points’ since it is near a self-replication: the other pulses ‘send’ some of ‘their’ grid points to the self-replicating one(s). Thus the horizontal bands suggest dynamical behavior for a large $x$-interval but the dynamics are only local near a number of self-replicating pulses for the solutions $(U, V)$ of the PDE (1.1).

From these observations as well as from those of many other initial data it seems a priori that the solutions to (1.1) with $A (a)$ and $B (b)$ in the splitting region have a strictly non-stationary behavior. However we observe in figure 8 that only the outermost pairs of pulses continue the self-replicating process: after a pulse has been created by a ‘boundary pulse’ it only splits just one more time. The two resulting pulses are then enclosed by other pulses: it is as if the pulses are repelling each other. As a consequence we observe that the core of the pattern created by the self-replicating process is a stationary, periodic pattern of the type described by Theorem 4.2: it clearly has distinguished slow and fast parts. This can also be seen in figure 7: the pattern in the middle (middle 6 peaks) is clearly periodic in $U$ and $V$. It follows from grid dynamics (figure 8) that this periodic core is also stationary. Note also that the splittings of the boundary pulses and their latest images have a tendency to occur simultaneously after sufficiently large times in this simulation. Lastly we remark that in addition to this outer–pair splitting process we have observed other sequences of pulse–splittings. However after ‘long’ times all of these patterns had periodic cores described by the stationary periodic solutions of Theorem 4.2. Moreover the $U_{\text{max}}$ and $T_P$ of these cores were accurately related by the theoretically deduced equations (4.10) and (4.11).

This statement is also readily verified quantitatively in the simulations. We make a quantitative comparison of the periodic core properties of the pattern in figure 7 with the periodic solutions constructed in section 4.2. Numerically we find that:

$$T_P \approx 20, \ U_{\text{max}} \approx 0.54, \ V_{\text{max}} \approx 1.26, \ U_{\text{min}} \approx 0.07.$$  

We know from section 4.2 that $T_P$ and $U_{\text{max}}$ are related by (4.10) or (4.11). Inserting $U_{\text{max}} = 0.54$ into (4.10) gives $T_P \approx 19.97$ (where $a = 2\Gamma b = 0.4$ and $b^2 = 0.01$). Equivalently we find that inserting $\mathcal{T} = 20$ into (4.11) yields a value of $U_{\text{max}}$ which agrees with the numerically observed one. The fact that the numerically measured values of $T_P$ and $U_{\text{max}}$ obey the relations (4.10) and
(4.11) with this accuracy is a bit surprising: both (4.10) and (4.11) are just the leading order approximations. Nevertheless this result at least indicates that the stationary periodic patterns at the core of the self-replicating patterns are described by the slow/fast periodic solutions of Theorem 4.2. Moreover we can use (4.12) to ‘predict’ the leading order values of $V_{\max}$ and $U_{\min}$ for this pattern: $V_{\max} \approx 2.14$ and $U_{\min} \approx 0.06$. Both values differ from the numerically-observed values by an amount which is of the order of the leading order corrections to (4.12) determined above.

Finally we remark on the speed $\pm c$ of the ‘boundary pulses’ of the self-replicating pattern. It is clear from figure 8 that this speed is (at least at leading order) constant for all time. We noted that this speed approaches zero as $a$ decreases towards the above described transition region. Thus $c$ clearly depends on $a$ and $b$. However $c$ also depends on $\delta$. We have seen in section 5 that the magnitude of $c$ with respect to $\delta$ does have an essential influence on the singular perturbation analysis. Therefore we performed the following experiment: we fixed $a = 2$ and $b = 0.41$ and we varied $\delta^2$. We waited until the ‘boundary pulses’ were created and moved and then we measured their speed $c$. In figure 9 we present a log-log plot of this $c$ as function of $\delta$: $c$ is clearly $\mathcal{O}(\delta^2)$. Note that this is exactly the value of the significant degeneration of the asymptotic analysis encountered in section 5.

7 Discussion

We have proven the existence of single-pulse solutions for any $a$ and $b$ (the rescaled versions (2.7) of $A$ and $B$ in (1.1)). However only those with $a$ and $b$ in the transition region described in section 6 are observed and thus probably stable. A similar selection occurs for the periodic patterns constructed in section 4.2: for any $a \neq b$ and $U_{\max} < 1$ ($U_{\max} = \mathcal{O}(1)$) there exists a stationary periodic pulse pattern but periodic patterns are only observed for parameter values $(a, b)$ in the self-replicating pulse region (section 6). Moreover $U_{\max}$ is also selected by the process. Furthermore the numerical simulations suggest that also the parameter $\alpha$ which we can choose in the interval $[0, \frac{1}{2}]$ in the analysis of section 4 is the subject of a selection process: our simulations and those in [21] suggest that $\alpha \approx 1$ (note that $\alpha$ is determined by the magnitude of $B$ with respect to $\delta$ (Remark 2.3) therefore it is not possible to determine $\alpha$ exactly for given values of $\delta$ and $B$). Determining the analytical origin of these selection mechanisms is the subject of future research.

In addition the pulse-splitting process requires considerable further analysis. While an argument based on the chemistry has been given for when the dynamic splitting should commence – indicating that the onset time coincides with time at which the flux of $\mathcal{U}$ into the tail of the moving pulse is exceeds the minimum level needed to sustain a new pulse [21] – a mathematical theory for the pulse-splitting presently does not exist. Our simulations suggest that the process occurs largely at the ‘fronts’ of the moving pulse pattern. In particular for the simulation reported in section 6.3 the outermost pair of moving pulses on each side were the ones that self-replicated and as time progressed these self-replicating edge pairs created the stationary periodic core of the self-replicating pulse pattern. This observation is consistent with the chemical explanation in the sense that only between the new outermost pulses is there enough $\mathcal{U}$ present (both from the as yet unconsumed supply available in the domain and from the reservoir) to create new pulses. By contrast in the core region all of the $\mathcal{U}$ supplied by the reservoir is needed to maintain the already-existing pulses and there is very little excess (free unconsumed) $\mathcal{U}$ in between the pulses.
Although we did not perform any detailed analysis on the system with \( A > O(\delta^2) \) we believe that an approach similar to that established here – based on a different scaling of the parameters and variables – can be used in this region of phase space. The combination of such an analysis and simulations might give another explanation of the origin of the self-replicating pulse process. In figure 10 we plot the results of a simulation with \( a = 9 \Gamma b = 0.4 \) and \( \delta^2 = 0.01 \). Thus it is not natural to assume that \( A = a \delta^2 = O(\delta^2) \). However, just as in the case \( a = O(1) \) a first stationary splitting occurs but \( IV \) does not become exponentially small between the two traveling boundary pulses (figure 10.a). Moreover we observe that \( U \) remains small in that region: it seems that the slow manifold \( M \) is much less important in this case. No pulse-splitting occurs but \( I \) after some time there is again a stationary periodic core (see figure 10.b). This core is now formed by a stationary solution which ‘lives’ entirely in the fast field. As we decrease \( a \) we observe that the pulse-splitting process starts as soon as the periodic orbit at the core of the pattern touches down on \( M \). For completeness we note that the choice of parameters for the simulation of figure 10 is a little bit outside the chemical relevant region since \( A = a \delta^2 = 0.09 > B = b \delta^2/3 \approx 0.86 \) (see Remark 2.2). However, the pattern does not change significantly if we decrease \( a \) a little such that \( A < B \).

Note that it is not hard to show that the ‘purely fast’ stationary periodic orbits do not exist in the scaled system (2.8) and (2.12); the accumulated change in \( p \) along such an orbit cannot be zero (cf. (3.18)). However such orbits can be created by a Hopf-bifurcation around critical points in the fast field of the unscaled (1.4) system which exist if \( A > 4B^2 \) (see also [10; 21]). These critical points did not appear in this paper since \( A \) cannot be larger than \( 4B^2 \) by the scalings ((2.7) \( \Gamma a < \frac{3}{2} \)) derived in this paper. Analogously one can say that the fact that the pulse patterns are not observed for value of \( A \) and \( B \) outside the region defined by our scalings justifies these scalings: they were derived as necessary conditions for the existence of the pulse-like solutions (see section 2). Thus the phenomena described above cannot be described by the main equations of this paper (2.8) and (2.12) but we believe that they can be studied by methods similar to those employed in this paper.

It is clear that all of the necessary ingredients of the analysis in this paper also exist in other systems of the general form:

\[
\begin{align*}
\frac{\partial U}{\partial t} & = \nabla^2 U + f_1(U, V) \\
\frac{\partial V}{\partial t} & = \delta^2 \nabla^2 V + f_2(U, V)
\end{align*}
\]

where \( f_1 \) and \( f_2 \) satisfy some additional conditions. In particular the nonlinearities must be such that the fast kinetics have one or more equilibria connected to themselves by homoclinic or heteroclinic orbits. In addition the slow subsystems must possess either equilibria with stable and unstable manifolds or or other orbit segments that are transverse to the appropriate take off and touch down curves defined by the fast homoclinics and/or heteroclinics. Once again one can check numerically whether the constructed patterns can be stable. Moreover whether the non-existence of traveling waves plays a role in signaling that a general system exhibits pulse-replication can also be investigated since a priory it is not clear that general systems of the form (7.1) which do have (stable) stationary pulse-like patterns share the nonexistence result of (1.1).

Acknowledgements. The authors thank Thomas Erneux for suggesting this subject to them. We also thank Wiktor Eckhaus for his very useful suggestions and for helping us pinpoint an error in the initial formulation. This research was partially supported and financed by the Netherlands
Organization for Scientific Research (NWO). T.K. thanks the Mathematical Instituut of Utrecht University for its hospitality during the Summer of 1995. Figure 1. Schematic illustrations of (a) the one-pulse homoclinic orbit $\Gamma_\delta(t) \subset W^S(S) \cap W^U(S)$ and (b) a periodic orbit $\Gamma_P(t)$ in the 4-d phase space of (2.12) with $\Gamma$ for simplicity $\Gamma \gamma = 0$. Note that these schematic illustrations show the slow segments in $(p, u)$ coordinates and the fast segments in $(v, -q)$ coordinates.

Figure 2. Schematic illustrations of (a) the $(v, q)$ phase space of the fast subsystem $\Gamma$ and (b) the slow vector field on $\mathcal{M}$ for $\gamma = 0$ showing the location of the curves $T_\delta IT_\delta IT^U IT^S$ and a hyperbolic orbit segment $\Gamma_C$. Note that the $u$-coordinates of the saddle $S$ and the upper two intersections $T_o \cap \ell^U$ and $T_d \cap \ell^S$ are only $O(1)$ if $\gamma = 0$.

Figure 3. Schematic illustration of the $N = 2$ pulse homoclinic orbit of (2.12).

Figure 4. Stationary one-pulse homoclinic orbits observed in numerical simulations of (1.1) at time $t = 1000$. In these simulations $\Gamma a = 1$ and $b = 0.6 \Gamma$ while in (a) $\delta^2 = 0.01$ and in (b) $\delta^2 = 0.003$. The concentration $U$ is given by a dashed curve and the concentration $V$ is denoted by a solid curve.

Figure 5. A pair of dancing pulses observed in numerical simulations of (1.1) with $a = 0.6 \Gamma b = 0.4 \Gamma$ and $\delta^2 = 0.01$: (a) at time $t = 250$; (b) at time $t = 350$; (c) at time $t = 450$; and (d) at time $t = 500$ showing that only the left pulse survives as a stable solitary pulse in the asymptotic state.

Figure 6. The dynamic pulse-splitting process at times: (a) $t = 2100$; (b) $t = 2150$; (c) $t = 2200$; and (d) $t = 2400$. New pulses are formed on the trailing (inner) edges of the existing two pulses (near the $x$-values corresponding to the inflection points of $U$) and are sent into the center of the domain. Here $a = 2 \Gamma b = 0.4 \Gamma$ and $\delta^2 = 0.01$.

Figure 7. The pulse-pattern observed at $t = 20,000$ for $a = 2 \Gamma b = 0.4 \Gamma$ and $\delta^2 = 0.01 \Gamma$ where 600 moving grid points were used.

Figure 8. Positions of the grid points as functions of time for the moving grid code described in section 6.1 for the same parameters as used in figure 7. Note that the first dynamic splitting occurs earlier than in figure 6 (although $a = 2 \Gamma b = 0.4$ and $\delta^2 = 0.01$ in both cases): the simulations have different initial conditions (the initial conditions are the same in the rescaled variable $\tilde{x}$).

Figure 9. The log-log plot of the speed with which the outermost pulses travel as a function of $\delta$ showing that this speed scales as $O(\delta^2)$; $a$ and $b$ are kept fixed at $a = 2 \Gamma b = 0.4$.

Figure 10. A plot of the solution to (1.1) with parameter $a \neq O(1)$: $a = 9 \Gamma b = 0.4 \Gamma \delta^2 = 0.01$: (a) at $t = 100 \Gamma$ (b) at $t = 500 \Gamma$ and (c) at $t = 1000$. As in figure 7 there is a stationary periodic core but is has not been created by a pulse-splitting process.
