Energy transfer from  $Gd^{3+}$  to  $Tb^{3+}$  and  $Eu^{3+}$  in gadolinium zirconates occurs not only from the  $^6P$  but also from the levels of  $Gd^{3+}$  to the  $4f^{75d}$  levels of  $Tb^{3+}$  and the charge transfer levels of  $Eu^{3+}$ .

### 1. Introduction

Energy transfer in gadolinium compounds from the  $Gd^{3+}$  ions to  $Tb^{3+}$  and  $Eu^{3+}$  dopants is well known [1-3]. It is generally assumed that the excitation energy migrates through the gadolinium system until it is trapped at the dopant ion. During a study of the fluorite-pyrochlore transition by analysing the  $Eu^{3+}$  luminescence [4] we accidentally observed some additional features of the transfer process from  $Gd^{3+}$  to  $Tb^{3+}$  and  $Eu^{3+}$ . These are discussed in this letter.

### 2. Experimental

We investigated compositions  $Gd_xZr_{1-x}O_{2-x/2}$  with  $x = 0.427$  (fluorite),  $x = 0.473$  (defect pyrochlore) and  $x = 0.500$  (stoichiometric pyrochlore). The luminescence of the  $x = 0.500$  sample was too weak to be measured. Samples were prepared wetchemically by means of the citrate synthesis [5]. They were heated at  $1550^\circ C$  for 70 h and were annealed after grinding at  $1000^\circ C$  for 100 h. From X-ray diffraction the samples proved to be homogeneous, whereas the samples with 47.3 and 50.0 at % Gd showed the characteristic pyrochlore superstructure reflections. Europium and terbium were not added intentionally. The  $Eu^{3+}$  concentration

amounts to some 600 ppm, that of  $Tb^{3+}$  could not be found accurately but should be considerably lower. These analyses were performed by emission spectrographical analysis. The sample composition was determined by X-ray fluorescence. The optical measurements were performed at room temperature on a MPF-2, Perkin-Elmer spectrofluorimeter.

### 3. Results

Fig. 1 shows the excitation spectrum of the  $Eu^{3+}$  and the  $Tb^{3+}$  luminescence in the gadolinium zirconate. The spectra consist of a broad band on which are superimposed a number of strong and sharp lines. The broad bands correspond to transitions to the charge-transfer level of  $Eu^{3+}$  in the case of  $Eu^{3+}$  luminescence [6] and to the  $4f^{75d}$  levels of  $Tb^{3+}$  in the case of  $Tb^{3+}$  luminescence. The sharp lines correspond to transitions in  $Gd^{3+}$  ion. Those around 310 nm are the  $^8S \rightarrow ^6P$  transitions, those around 280 nm are the  $^8S \rightarrow ^6I$  transitions. The interesting feature is that the intensity ratio between these two groups of lines is strikingly different in the two excitation spectra: whereas the  $Eu^{3+}$  emission is preferentially excited into the  $^8S \rightarrow ^6I$  transitions,  $Tb^{3+}$  emission does not show such a preference.

Diffuse reflection spectra of the samples learned

Fig. 1. Relative excitation spectrum of the 630 nm emission (mainly  $\text{Eu}^{3+}$ , lower part) and of the 490 nm emission ( $\text{Tb}^{3+}$ , upper part) of the sample  $\text{Gd}_x\text{Zr}_{1-x}\text{O}_{2-x/2}$  ( $x = 0.427$ ). The relative quantum output is plotted in arbitrary units ( $\text{Eu}^{3+}$ : left hand side;  $\text{Tb}^{3+}$ : right hand side). Upon excitation into the  $\text{Gd}^{3+} 6\text{P}$  levels the quantum output of the total  $\text{Eu}^{3+}$  and total  $\text{Tb}^{3+}$  emission is about equal (after correction of simultaneous excitation into the  $\text{Tb}^{3+} 4\text{f}-5\text{d}$  absorption band).

that the absorption strength of the group of  $8\text{S} \rightarrow 6\text{I}$  transitions is about twice as high as that of the  $8\text{S} \rightarrow 6\text{P}$  group. Because the quantum output of the  $\text{Eu}^{3+}$  and  $\text{Tb}^{3+}$  emission under excitation into the  $8\text{S} \rightarrow 6\text{P}$  transitions of  $\text{Gd}^{3+}$  is about equal and the  $\text{Eu}^{3+}$  concentration much higher than the  $\text{Tb}^{3+}$  concentration, our results point to a considerably higher probability of transfer from  $\text{Gd}^{3+}$  concentration, our results point to a considerably higher probability of transfer from  $\text{Gd}^{3+}$  to  $\text{Tb}^{3+}$  than to  $\text{Eu}^{3+}$  under  $8\text{S} \rightarrow 6\text{P}$  excitation.

#### 4. Discussion

##### 4.1. Excitation into the $6\text{P}$ levels of $\text{Gd}^{3+}$

Under  $6\text{P}$  excitation the total amount of energy transferred from  $\text{Gd}^{3+}$  to  $\text{Tb}^{3+}$  is about equal to that transferred from  $\text{Gd}^{3+}$  to  $\text{Eu}^{3+}$ . Since the  $\text{Eu}^{3+}$  concentration is much higher than the  $\text{Tb}^{3+}$  concentration, this means that the transfer probability for the  $\text{Gd}^{3+} \rightarrow \text{Tb}^{3+}$  couple must be much higher than for the  $\text{Gd}^{3+} \rightarrow \text{Eu}^{3+}$  couple. There is an obvious explanation for this.

The  $\text{Gd}^{3+} 6\text{P}$  levels coincide approximately with energy levels of the  $4\text{f}^8 \text{Tb}^{3+}$  and the  $4\text{f}^6 \text{Eu}^{3+}$  configuration. The optical transitions involved are strongly forbidden. The  $6\text{P}$  levels overlap also with the  $4\text{f} \rightarrow 5\text{d}$  absorption band of the  $\text{Tb}^{3+}$  ion (see fig. 1; the low intensity of this band is due to the low  $\text{Tb}^{3+}$  concentration), but not with the  $\text{Eu}^{3+}$  charge transfer band. The  $4\text{f}-5\text{d}$  transition is an allowed optical transition. As a consequence the  $\text{Gd} \rightarrow \text{Tb}$  transfer has a much higher probability than the  $\text{Gd} \rightarrow \text{Eu}$  transfer, if the energy transfer originates at the  $\text{Gd}^{3+} 6\text{P}$  levels. These levels overlap with an allowed transition in the  $\text{Tb}^{3+}$  ion, but only with forbidden transitions in the  $\text{Eu}^{3+}$  ion.

##### 4.2. Excitation into the $6\text{I}$ levels of $\text{Gd}^{3+}$

If the  $\text{Gd}^{3+}$  ion after excitation into the  $6\text{I}$  levels would relax to the  $6\text{P}$  levels before transferring its energy, it is hard to understand why the ratio of the  $6\text{I}$  and  $6\text{P}$  excitation peaks is so different for the  $\text{Eu}^{3+}$  and the  $\text{Tb}^{3+}$  luminescence. The only way to explain the present results is to assume that transfer from  $\text{Gd}^{3+}$  to  $\text{Eu}^{3+}$  can also occur from the  $6\text{I}$  levels with a probability which is considerably higher than for transfer from the  $6\text{P}$  levels. The reason for such a higher probability immediately becomes clear from fig. 1. The  $6\text{I}$  levels overlap with the allowed charge-transfer band of  $\text{Eu}^{3+}$ , whereas the  $6\text{P}$  levels overlap only with the forbidden transitions within the  $4\text{f}^6$  configuration of  $\text{Eu}^{3+}$ . For transfer from the  $6\text{I}$  levels of  $\text{Gd}^{3+}$  to either  $\text{Eu}^{3+}$  or  $\text{Tb}^{3+}$  there should not be a very different transfer probability, because in both cases there is overlap with an allowed transition. In fact excitation into the  $6\text{I}$  levels yields about 8 times more  $\text{Eu}^{3+}$  than  $\text{Tb}^{3+}$  luminescence which is well in line with their concentration difference.

The reason for the slow  $6\text{I} \rightarrow 6\text{P}$  relaxation in the  $\text{Gd}^{3+}$  ion in the gadolinium zirconates is probably due to the fact that the energy difference between these levels (at least  $2500 \text{ cm}^{-1}$  [7]) must be taken up by a 4 to 5 phonon process, the highest infrared band being observed between 400 and  $600 \text{ cm}^{-1}$  [8].

In conclusion we have shown that energy transfer from  $\text{Gd}^{3+}$  to  $\text{Tb}^{3+}$  and  $\text{Eu}^{3+}$  may occur also from the  $6\text{I}$  levels and that the transfer probability depends strongly on the fact whether the  $\text{Gd}^{3+}$  levels overlap an allowed or forbidden transition of the acceptor ion.
