General introduction

Preface

The results of the research described in this thesis provide new insights in antigen processing, both in novel ways of CD8⁺ T cell epitope generation as well as in strategies to modulate this process, in order to navigate the immune system towards a desired outcome in a vaccine setting. Currently, most vaccines rely on the protective effect of the humoral response. In case of intracellular- or rapidly mutating pathogens, humoral responses are less protective and instead the cellular response, mainly CD8⁺ T cells, can convey protection. However, vaccine efficacy is hampered by insufficient knowledge of vaccine-antigen processing and subsequent activation of the cellular compartment¹. Additionally, and most importantly, vaccine design in the future cannot be empirical; it needs to be rational, based on scientific knowledge of underlying mechanisms of immune responses targeted to vaccine-antigens. Therefore, the overall aim was to have a better understanding of antigen processing and subsequent initiation of a CD8⁺ T cell response. In this introduction, the various components or influencing factors of antigen processing leading to a CD8⁺ T cell response are first introduced. Thereafter, a short summary of the objectives of the different chapters is provided.

Antigen processing by the proteasome

Endogenous proteins, either self-derived or of microbial origin, are continuously degraded and replaced with newly synthesized proteins. A major role in the degradation of such proteins is played by the 26S proteasome, which is the central proteolytic enzyme complex of the ubiquitin–proteasome system (UPS). The UPS is present in every cell of an organism. In this system, a series of ubiquitin moieties is activated and transferred to protein substrates (Fig. 1). These poly-ubiquitylated proteins are thereby ‘marked’ for degradation and are channeled to the proteasome²⁻⁴. The 26S proteasome consists of two 19S regulatory caps and one 20S catalytic core. The 19S cap, also called PA700, is a proteasome activator and is responsible for substrate recognition and protein unfolding, thereby allowing entry to the channel of the barrel-shaped 20S core⁵. The 20S catalytic core is composed of two outer rings with seven α -subunits and two inner rings with seven β -subunits. Most mammalian tissues express constitutive proteasomes, which carry the proteolytic subunits β_1 , β_2 , and β_5 in their core². These β -subunits differ in their proteolytic activity; β_5 preferably hydrolyses hydrophobic residues, β_2 basic residues and β_1 acidic residues. The activities are therefore referred to as chymotrypsin-like, trypsin-like, or caspase-like, respectively^{6,7}. Once the cell is in a pro-inflammatory milieu, these three constitutive subunits are replaced by alternative catalytically active subunits

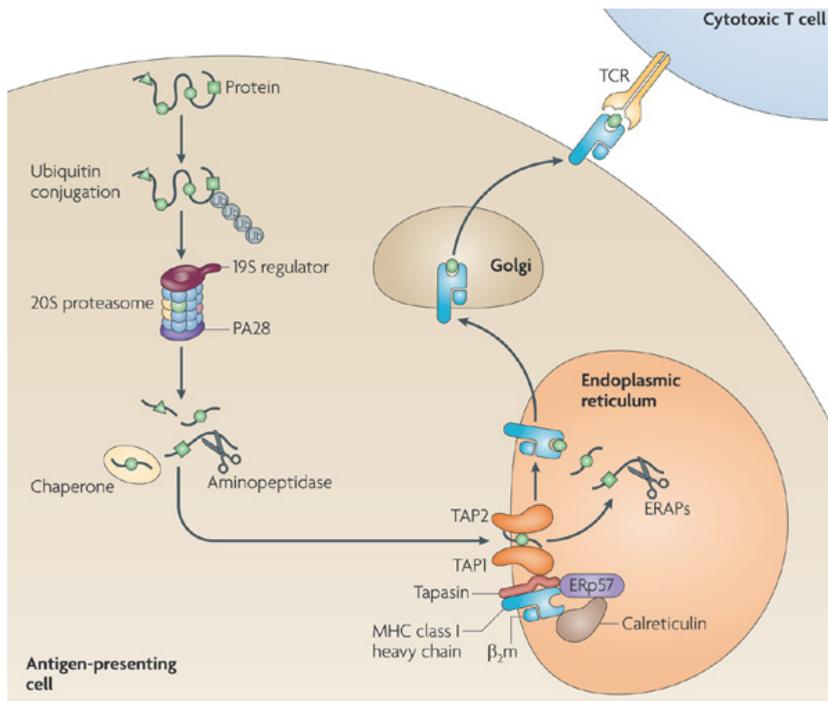

Figure 1. MHC class I antigen processing pathway. Adapted with permission from Groettrup et al., 2010 ⁴. Endogenously present self- or microbial derived proteins are degraded in various steps into peptides that can be presented on the cell surface in the context of MHC class I to TCRs of CD8⁺ T cells.

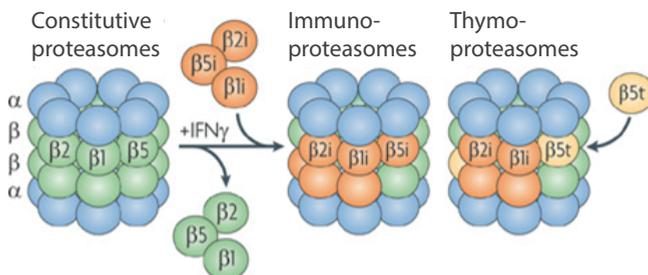

Figure 2. Constitutive, immuno- and thymic proteasomes. Adapted with permission from Klein et al., 2009 ⁸⁶. Constitutive proteasomes are present in every cell of an organism. If the cell resides in an inflammatory milieu, the immunosubunits are incorporated which has consequences for the peptides produced. In the thymus, thymoproteasomes are expressed, which have one of the immunosubunits replaced by $\beta 5t$. Thymoproteasomes are important in positive and negative selection of T cells.

called β_{1i} /LMP2, β_{2i} /MECL1, and β_{5i} /LMP7 to form immunoproteasomes⁸ (Fig. 2). The incorporation of the immunosubunits is accompanied by expression of the alternative capping subunit PA28. PA28, also called 11S, attaches to the 20S core like the 19S complex, but has been shown to stimulate hydrolysis by the proteasome. There are even certain epitopes that are known to be dependent on PA28, suggesting a role of PA28 in antigen processing that is not fully understood yet^{9,10}.

The changes in the catalytic subunit composition of β_1 , β_2 , and β_5 in constitutive proteasomes or of the β_{1i} , β_{2i} and β_{5i} subunits in immunoproteasomes were initially thought to result in qualitative differences of the peptide pool produced^{11, 12}. Due to more sensitive detection methods, it has become clear that incorporation of the immunosubunits induce subtle modifications in the conformation in the active sites, which affect proteasome proteolytic dynamics, but with consequences for only the quantities of peptides produced¹³⁻²². The cause for this difference in peptide quantity was recently shown using an integrated experimental and modelling approach. It was proven that the transport of substrates into the proteasome is the rate-limiting step of hydrolysis. The transport efficiency varies between constitutive- and immuno-proteasomes, which results in differences in amounts of peptides produced¹⁷. Although the pool of peptides produced is only quantitatively different, there are qualitative differences in the immune responses specific for these peptides. This phenomenon has been intensively studied in mouse models lacking different combinations of the immunosubunits²³⁻²⁵. In infection, there is an almost 100% replacement of constitutive proteasomes for immunoproteasomes^{26, 27}. In infected mice lacking immunoproteasomes, the need for this replacement is clear since the mice are not able to clear the pathogen²⁸ or they can even succumb to infection²⁹.

Proteasome-mediated cleavage and splicing

The generation of peptides by the proteasome can occur by simple peptide-bond cleavage as well as by proteasome-catalyzed peptide splicing (PCPS), which involves the linkage of fragments originally distant in the parental protein (Fig. 3)^{30,31}. Cleavage by the proteasome is the result of an attack on peptide bonds by the catalytic threonines of the β -subunits. This attack results in the formation of an acyl-enzyme intermediate. Rapid hydrolysis usually takes place, which gives rise to linear proteasome-generated products³². These products are stable and can leave the proteasome. However, when the acyl-enzyme intermediate is stabilized at the active site for an extended time span, the N-termini of released peptide fragments may outcompete hydrolysis and make a second attack on

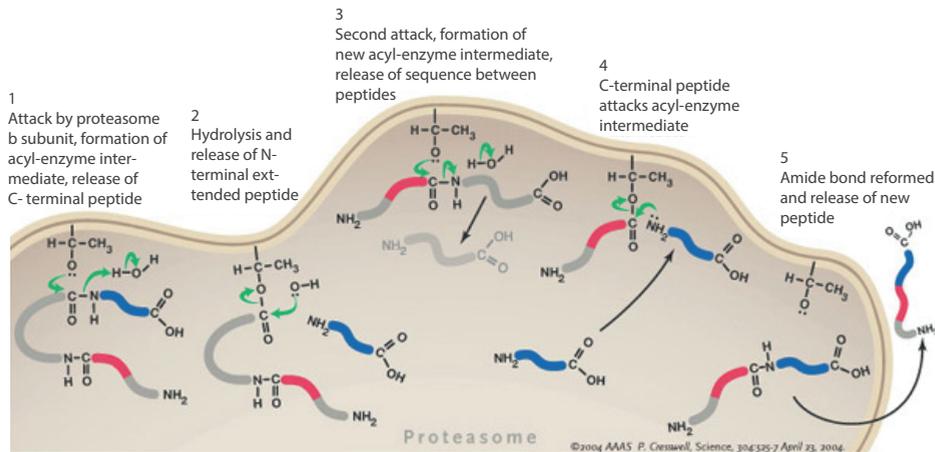

Figure 3. Proteasome catalyzed peptide splicing. Adapted with permission from Cresswell et al., 2004³². Protein catalyzed peptide splicing (PCPS) involves linkage of two segments, originally distant in the parental protein, to be pasted together in several steps.

the ester bond of the acyl-enzyme intermediate, forming a new peptide bond and producing a proteasome-catalyzed spliced product⁶. The amount of specific spliced epitopes presented by human MHC class I molecules at the cell surface can be comparable to that of linear epitopes, as shown for gp100^{mel}³³. The proteasome-generated spliced epitopes that have been described until now are all derived of tumor-associated or other self-antigens³³⁻³⁸.

In order to gain more knowledge on PCPS, accurate tools to predict spliced peptides are necessary. Some pioneering work has been done to set up 'splicing rules'³⁹ which are based on characteristics of the N- or C-terminal ligation partner. By combining such data with mathematical modelling, a reverse immunology approach can be set up for the prediction of potential spliced epitopes.

Transport to cell surface

Proteasomes usually generate the C-terminus of a peptide, while the N-terminus may need additional trimming. After generation by the proteasome, N-terminally elongated peptides enter the cytosol (Fig.1). Here, a substantial amount of proteasome-generated peptides is completely degraded by aminopeptidases^{40, 41}, but only N-terminal trimming can also take place. The peptides will be transported by TAP into the ER, where further N-terminal trimming can be carried out by aminopeptidase ERAP⁴². In the ER, peptides that contain a binding motive

will bind to the appropriate MHC class I molecule. To accomplish this, a chaperone protein called calreticulin maintains the MHC class I molecule in a partly unfolded state and tapasin links the MHC class I chains to TAP. The oxidoreductase ERp57 helps stabilizing the correctly sized peptide while it binds to this newly assembled MHC class I molecule. The binding induces a final folding and stabilization of the MHC class I-peptide complex, which then leaves the ER. Using Golgi vesicles, the complex is transported to the cell surface to be presented to the T cell receptor (TCR) of CD8⁺ T cells.

T cell selection and repertoire

Since besides pathogen-derived peptides, also self-derived peptides are presented on MHC class I molecules, the CD8⁺ T cells recognizing the self-peptides should be filtered out of the naive population to prevent auto-immunity. All progenitor T cells originate in the bone marrow but the major events in their development occur in the thymus. In the thymus, naive T cells are positively selected for their ability to recognize self-MHC, and then negatively selected to eliminate naive T cells bearing TCRs that recognize self-antigens. In this way, all T cells are able to recognize self MHC class I, but T cells recognizing self-derived peptides presented on MHC class I with high affinity are filtered out. The peptides used for positive- and negative selection are of major importance and are mainly generated by immunoproteasomes. It is therefore not surprising that immunoproteasomes have been associated with shaping the repertoire of CD8⁺ T cells. Recently, a thymic proteasome subunit was identified, $\beta 5t$ ⁴³⁻⁴⁵, which was found to be expressed only in cortical thymical epithelial cells (cTEC), and to incorporate preferentially into proteasome precursor complexes containing $\beta 2i$ /MECL1, and $\beta 5i$ /LMP7⁴⁶. This incorporation selectively reduced the proteasomal chymotrypsin-like activity⁴⁶ and altered the cleavage site usage by the proteasome. The resulting altered pool of peptides available for MHC class I binding influences positive and negative selection⁴⁷ and thereby the naive T cell repertoire. This can have tremendous consequences, as illustrated in an influenza model, showing an enhanced susceptibility to infection in $\beta 5t$ deficient mice⁴⁸.

Dynamics of a T cell responses

Naive CD8⁺ T cells can become activated if they recognize the right MHC class I-peptide complex and additional co-stimulatory molecules and cytokines are provided. All cells of an organism contain MHC class I, but only antigen presenting cells (APC), *i.e.* dendritic cells, B cells and macrophages, are able to give sufficient co-stimulation and activate naive CD8⁺ T cells. After successful recognition, the CD8⁺ T cell begins to divide, initiating the expansion phase,

during which the naive CD8⁺ T cell differentiates into a heterogeneous population of effector CD8⁺ T cells (T_{EFF}). When infected- or tumorigenic cells display the right MHC class I-peptide complex to these CD8⁺ T_{EFF} cells, they will be killed ⁴⁹, which in infection will generally lead to the eradication of the pathogen. After successful clearance of the pathogen, the CD8⁺ T_{EFF} population starts to contract because not all cells are required for memory. In this contraction phase, the far majority of the activated CD8⁺ T_{EFF} cells go into apoptosis, leaving 5–10% to go on to differentiate into different types of memory T cells ⁵⁰. The memory T cell population can be divided into three subsets depending on their surface markers ^{51, 52}; effector memory (T_{EM}), central memory (T_{CM}) and tissue-resident memory (T_{RM}). The first two subsets can be distinguished by their localization, as T_{CM} home to secondary lymphoid organs and T_{EM} circulate through non-lymphoid tissues. T_{RM} have migratory properties and are found in peripheral tissues that require expression of specific homing receptors for T cell recruitment and retention, such as the skin. It is known that particularly memory CD8⁺ T cells are able to recognize epitopes presented on MHC class I molecules that share sequence similarity with the epitope that initiated their activation, a phenomenon called cross-reactivity ⁵³. The ability of a given TCR to recognize multiple epitopes has even been described as strictly necessary ⁵³ because if every CD8⁺ T cell would solely recognize one epitope, the breadth of the CD8⁺ T cell response needed to eradicate the pathogen would not be achieved ⁵⁴.

Immunodominance hierarchy

From the pool of pathogen-derived proteasome-generated peptides, the majority will not succeed in eliciting a CD8⁺ response with subsequent memory formation. Even if a sufficient amount of antigen is present, the peptide survives proteases, is transported by TAP, binds to a MHC class I molecule with sufficient strength and is compatible with enough naive CD8⁺ T cell precursors ⁵⁵, the chances to be immunogenic are small ⁵⁶. Additionally, recognition of one peptide-MHC by the corresponding TCR, does not result in the same magnitude of the CD8⁺ T cell expansion as recognition of another peptide-MHC class I by its corresponding TCR. There appears to be a hierarchy of specific CD8⁺ T cells, whereby immunodominant peptides elicit the most vigorous CD8⁺ T cell expansion, and subdominant peptides induce less abundant CD8⁺ T cell expansion ⁵⁶. How the immunodominance hierarchy is accomplished is not fully understood yet, but as shown in viral infections, several factors play a role such as relative protein abundance; differential antigen processing; efficiency of peptide binding to MHC class I molecules; affinity of TCR to peptide-MHC class I complex and differences in CD8⁺ T cell precursor frequencies ^{55, 57-62}.

CD8⁺ T cells in infection with intracellular (myco)bacteria

While studying CD8⁺ T cell responses, multiple tumor- or pathogen models can be chosen. For this thesis, pathogens *Listeria monocytogenes* and *Mycobacterium tuberculosis* were used.

Listeria monocytogenes is a gram-positive, facultative intracellular bacterium with a wide host range. It is a food-borne pathogen and therefore infections usually occur in the gastrointestinal tract, where *L. monocytogenes* attaches to intestinal epithelial cells through interaction of its surface protein Internalin A (InIA) with E-cadherin⁶³. Bacteria enter the blood stream, after they have successfully crossed the epithelium, and infect cells in multiple other organs. *L. monocytogenes* specifically resides in hepatocytes^{64, 65} but can also replicate in splenocytes²⁸. Uptake by hepatocytes is elicited through the bacterial surface protein Internalin B (InIB), which binds to the hepatocyte growth factor receptor 66. Using this mechanism, the bacteria can not only be phagocytosed by professional phagocytes, but they can also induce their phagocytosis into cells that do not usually perform this process. After successful phagocytosis, the bacteria start to secrete virulence factors like listeriolysin O (LLO) and phospholipases (PlcA and PlcB), in order to disrupt the phagosomal membrane and subsequently escape the phagosome⁶⁷⁻⁶⁹. The metalloprotease Mpl is responsible for activation of PlcB and for the transport of this protein across the bacterial cell wall⁷⁰. *L. monocytogenes* is able to infect neighboring cells without being in the extracellular compartment. This is facilitated by expression of actin-assembly-inducing-protein (ActA) which causes polymerization of cellular actin monomers of the cytoskeleton of the host, and subsequent propelling of the bacteria from one cell to the next⁷¹. For replication, the bacteria secrete cell wall hydrolyzing proteins, such as p60⁷². Most known epitopes are derived of LLO and p60⁷³. In *L. monocytogenes* infection, CD8⁺ T cells are known to eradicate the bacteria and generate long-term protective immunity⁷⁴, which makes it an ideal pathogen to study CD8⁺ T cell responses.

Mycobacterium tuberculosis is the causative agent for Tuberculosis (TB). The bacterium has an unusual cell wall, rich in lipids, which makes it neither gram positive nor negative. *M. tuberculosis* is an air-borne pathogen, generally infecting the mammalian respiratory system. Within the lungs the bacteria primarily infect and persist in mononuclear phagocytes, although in the infected lung, bacilli interact with various cells in a multidisciplinary way⁷⁵. Upon phagocytosis, the bacteria need to go to the interstitium of the lung to establish an infection. This

process is supported by deliverance of virulence factors like ESAT-6 into the host⁷⁶. Once in the interstitium, the bacteria can be taken up by migrating cells like monocytes and dendritic cells, which are the prime events in triggering the adaptive immune response⁷⁷⁻⁷⁹. Immune responses to *M. tuberculosis* are complex since the infection manifests as a set of lesions, such as destruction of the alveolar and endothelial wall; perivascular and -bronchial infiltration; lipid and necrotic pneumonia; fibrosis; encapsulation; cavitation and granuloma formation, that coexist in the same lung. Mice are frequently used as a model to study *M. tuberculosis* infection. In this murine model, while innate immune responses are crucial as well⁷⁵, the cellular response, in particular the CD4⁺T_{CM} cells, can control infection in the lungs⁸⁰. In humans, CD4⁺T cells play a critical role in orchestrating the host immunity, but CD8⁺T cells are required as well for an optimal and protective host response against the pathogen⁸¹⁻⁸³. It is therefore that current vaccine design against *Mycobacterium tuberculosis* aims at inducing cellular responses. *Mycobacterium bovis* bacillus Calmette-Guérin (BCG) was introduced as a vaccine in 1924⁸⁴ and is still the only approved vaccine against tuberculosis. It helped to reduce TB associated childhood mortality, however, the vaccine fails to prevent pulmonary TB and disease transmission. Additionally, it is associated with adverse events in HIV positive or otherwise immunocompromised people⁸⁵. Research is conducted in order to develop vaccines that could replace or boost BCG, of which several are in clinical trials.

Scope of this thesis

The research described in this thesis explores how modulation of antigen processing affects CD8⁺T cell responses.

In the first chapters of the thesis we aim at proving the importance of the newly discovered antigen processing route PCPS in infection. In [Chapter 2](#) we report a newly developed multi-level *in silico* based prediction tool that we used to identify spliced epitopes targeted by CD8⁺T cells in infection. The CD8⁺T cells found, failed to recognize the non-spliced epitope parts in context of their natural flanking sequences. This proves that spliced epitope generation creates novel epitopes and expands the peptide pool produced in infection. We continue with proteasome-mediated splicing in [Chapter 3](#) in which we set out to illustrate the potential of the enhancement of the peptide pool by PCPS. We show an example of CD8⁺T cells that are primed by the linear epitope that can be cross-reactive to spliced epitopes that share sequence similarity. This cross-reactivity may reduce the chances of successful immune evasion by pathogens.

By discovering new immunological targets, possibilities for vaccine design are generated. The described method to identify spliced epitopes generated by PCPS could provide these new immunological targets. Next to this, vaccine efficacy can be increased by immunogenicity-enhancement of weakly immunogenic vaccine-derived epitopes. We aim at illustrating strategies to identify epitopes in model vaccine-antigens, and additionally increase their immunogenicity in [Chapter 4](#). By using dermal DNA tattoo immunization with a model antigen of *Mycobacterium tuberculosis*, we provide a full strategy to modulate antigen processing and thereby enhance the CD8⁺ T cell response. In the research described in [Chapter 5](#) the optimized antigen is tested as a potential booster vaccine for BCG using DNA tattoo immunization in combination with BCG in a heterologous prime-boost regimen. We aim at providing a full immunological profile in order to contribute to rational vaccine design against *Mycobacterium tuberculosis*. These studies were done at the Max Planck Institute of Infection Biology in Berlin.

The results reported in this thesis about several aspects of the MHC class I antigen processing pathway, important in successful navigation of CD8⁺ T cells for vaccine design, are discussed in [Chapter 6](#).

Abstract

Proteasome-catalyzed peptide splicing (PCPS) generates peptides that are presented by MHC I molecules but, as their identification is challenging, the immunological relevance of spliced peptides remains unclear. Here we developed a novel reverse immunology-based multi-level approach to identify proteasome-generated spliced epitopes. Applying this strategy to a murine *Listeria monocytogenes* infection model, we identified two novel spliced epitopes within the secreted bacterial phospholipase PlcB that were recognized by CD8⁺ T cells of *L. monocytogenes*-infected mice. While reacting to the spliced epitopes, these CD8⁺ T cells failed to recognize the non-spliced epitope parts in context of their natural flanking sequences. This is the first evidence that PCPS expands the CD8⁺ T cell response against pathogens by exposing yet undiscovered spliced epitopes on the cell surface. Moreover, the developed multi-level strategy opens new opportunities to systematically investigate proteins for spliced epitope candidates and, therewith, new possibilities for immunotherapies or vaccine design.

Introduction

CD8⁺ T cell responses play an important role in the clearance of intracellular pathogens and in protection to subsequent infections. CD8⁺ T cells react to epitopes presented by major histocompatibility complex class I (MHC I) molecules at the cell surface. Epitope generation usually starts by processing of pathogen-derived intracellular proteins by proteasomes. Peptides released by the proteasome are translocated by the transporter associated with antigen processing (TAP) into the ER, where they may undergo N-terminal trimming by ERAP¹⁻³ and are loaded onto MHC I molecules for presentation at the cell surface⁴.

Given the central role of proteasomes in MHC I antigen processing, their catalytic activity plays a fundamental role in shaping of the pathogen-derived peptide repertoire towards which CD8⁺ T cells may react. The catalytic activity of proteasomes is displayed by three subunits, β_1 , β_2 and β_5 , which are replaced by the induced catalytic subunits β_{1i} /LMP2, β_{2i} /MECL1 and β_{5i} /LMP7 when cells are exposed to an inflammatory milieu⁵. The changes in the catalytic subunit composition induce subtle modifications in the conformation in the active sites, that affect proteasome proteolytic dynamics, with consequences for the quantities of peptides produced⁶⁻¹⁰. Proteasomes can simply hydrolyze the peptide-bonds of the antigen, thereby releasing canonical non-spliced peptides, or splice two distal fragments of the antigen, thereby generating peptides with a novel sequence¹¹. The latter mechanism is called proteasome-catalyzed peptide splicing (PCPS)^{12,13}.

Despite the well-established crucial role of proteasomes in MHC I antigen processing, the immunological relevance of PCPS is still a matter of debate, in part because only few proteasome-generated spliced epitopes, mainly derived from tumor-associated antigens^{11,14-18}, have been described so far. Few recent studies however hint at a strong relevance of PCPS in the MHC I antigen presentation. It was reported that proteasome-generated spliced peptides represent one third of the self-antigenic peptides presented by MHC I molecules, as shown for different cell types, and one third of the MHC I-presented self-antigens are represented only by spliced peptides¹⁹. Such a significant increase in the variety of peptides potentially recognized by CD8⁺ T cells due to PCPS is also strengthened by their amount, which has been calculated in the order of one fourth of the MHC I-restricted self-peptides¹⁹. This is in agreement with the amount of tumor-associated spliced epitopes presented by human MHC I molecules at the cell

surface, that can be comparable to that of non-spliced epitopes as shown for the gp100^{mel} antigen¹⁸.

The relevance of PCPS in the cell-mediated immune response during infections is still unknown. We recently described cross-reactivity of CD8⁺T cells, primed during *L. monocytogenes* by the dominant listeriolysin O (LLO)-derived epitope LLO₂₉₆₋₃₀₄ towards the spliced epitope LLO_{294/297-304}²⁰. Nevertheless, so far, no clear evidence that PCPS triggers a specific CD8⁺T cell response during infection has been found. The sparsity of knowledge on the role of PCPS in immune recognition mostly illustrates the main difficulty in the identification of immunologically relevant spliced epitopes, lying in adopting a reverse immunology approach, which would need a complex *in silico* – *in vitro* workflow. To propel further investigation into the role of PCPS in antigen processing, we here developed a novel multi-level spliced epitope identification strategy, which we tested in the murine *L. monocytogenes* infection model. *L. monocytogenes* is a gram positive bacterium that primarily infects phagocytes and then mobilizes the host cell cytoskeleton to spread to neighboring cells. To enter the cytosol of infected cells, the bacteria secrete LLO and the phospholipases PlcA/phosphatidylinositol-specific phospholipase C (PI-PLC) and PlcB/phosphatidylcholine-preferring phospholipase C (PC-PLC)²¹⁻²³. Bacterial clearance during *L. monocytogenes* infection is mediated by CD8⁺T cells specific for the secreted bacterial proteins. Therefore, to test and validate our novel spliced epitope identification approach, we decided to use the secreted PlcA and PlcB proteins as model antigens.

Material and methods

In silico generation of spliced peptide target list

Given the PlcA (AEO05212.1) or PlcB (AEO05216.1) sequences, we first computed all potential non-spliced and spliced peptides of length L=8 and L=9, resulting in N peptides, denoted as [n-p1]-[p2-c], where N can be obtained via equation 1 derived from³⁷.

$$N = \sum_{L=8}^9 \sum_{n=1}^S \sum_{p1=n}^{n+L-2} \sum_{p2}^{S-L+p1-n+1} 1 \quad , \quad (\text{equation 1})$$

where S is the length of the parental antigen (PlcA and PlcB, respectively). This list was then reduced by excluding all spliced peptides generated through *trans* PCPS. This means that for a given spliced peptide denoted as [n-p1]-[p2-c] all peptides with p1 < p2 (for PCPS in same order as in parental antigen) or c > n

(for PCPS in reverse order compared to the parental antigen) are maintained in the reduced database). We next removed all peptides with intervening sequence length l larger than 40 amino acids, where l is defined as $l = p2 - p1 - 1$ for splicing in normal order, and $l = c - n - 1$ for splicing in reverse order. For all remaining 8 and 6mer spliced peptides we computed *in silico* the IC_{50} as a measure for binding strength to the murine H-2K^b or the human HLA-A*01:01, -A*02:01, -A*03:01, -B*07:02, -B*44:02, and -B*44:03 haplotypes using the offline version of the SMM algorithm ²⁶. We considered all spliced peptides with predicted $IC_{50} < 100$ nM and a further IC_{50} cut-off of 16 nM.

Peptide synthesis and 20S proteasome purification

The PlcB_{159-171/185-196} (KFDTAFYKLGLAINFTAISYPPGYH) polypeptide substrate and all non-spliced and spliced peptides derive from PlcA (AEO05212.1) or PlcB (AEO05216.1) from *L. monocytogenes*. They were synthesized using Fmoc solid phase chemistry. 20S proteasomes were purified from 5 pooled spleens of C57BL/6 mice infected or uninfected by *L. monocytogenes* ²⁰. The purity of the proteasome preparation is shown in Fig. S7. The differences in proteasome subunit composition were disclosed elsewhere ²⁰.

Identification and quantification of peptide products from *in vitro* digestions by proteasomes

The synthetic polypeptide PlcB_{159-171/185-196} (20 μ M) was digested by 2 μ g 20S proteasomes in 100 μ l TEAD buffer (Tris 20 mM, EDTA 1 mM, NaN₃ 1 mM, DTT 1 mM, pH 7.2) over time at 37°C. The identification of the polypeptide digestion products was performed by liquid-chromatography mass spectrometry (LC-MS) analyses as following: 15 μ l digested samples were analysed directly by nanoscale LC-MS/MS using an Ultimate 3000 and LTQ Orbitrap XL mass spectrometer (Thermo Fisher Scientific). The system comprises a 5 mm \times 300 μ m, 100 \AA trapping column (PepMap C18, 5 μ m; Dionex) and a PicoChip analytical column (Reprosil-pur; 3 μ m; New Objective). The mobile phase (A) was 0.1% (v/v) formic acid in water, and (B) was 80:20 (v/v) acetonitrile/water containing 0.1% (v/v) formic acid. The elution was carried out using a gradient 15-50% B in 35' with a flow rate of 300 nl / min. Full MS spectra (m/z 300–2,000) were acquired in an Orbitrap instrument at a resolution of 60,000 (FWHM). At first, the most abundant precursor ion was selected for either data-dependent CID fragmentation with parent list (1⁺, 2⁺ charge state included). Fragment ions were detected in an Ion Trap instrument. Dynamic exclusion was enabled with a repeat count of 2- and 60-s exclusion duration. Additionally, the theoretically calculated precursor ions of the expected spliced peptides were pre-elected for two Orbitrap CID- (m/z 350-2,000) and

HCD- (m/z 100-1500) fragmentation scans. The maximum ion accumulation time for MS scans was set to 200 ms and for MS/MS scans to 500 ms. Background ions at m/z 391.2843 and 445.1200 act as lock mass. Peptides were identified by PD1.4 software (Thermo Fisher Scientific) based on their merged tandem mass spectra (MS/MS) of CID and HCD. In addition for spliced peptides we compared the retention time and the merged MS/MS of CID and HCD with the fragmentation pattern of their synthetic counterparts. The database used for the LC-MS/MS analyses was generated by applying the SpliceMet's ProteaJ algorithm thereby allowing the identification of non-spliced and spliced peptides ³⁷.

The polypeptide digestion kinetics were analysed with the ESI-ion trap instrument DECA XP MAX (ThermoFisher Scientific, USA) as previously described ³⁷. The quantification of peptides produced in the *in vitro* digestion kinetics was carried out by applying QME (Quantification with Minimal Effort) method to the LC-MS analyses ³³. QME estimates the absolute content of spliced and non-spliced peptide products based on their MS peak area measured in the digestion probe. The QME algorithm parameters were empirically computed in our previous study ³³, and here applied.

Cell culture

RMA-S cells were cultured in IMDM (Invitrogen Life Technologies), supplemented with 10% FCS-HI (LONZA), 2 mM L-glutamine, 30 μ M 2-mercaptoethanol, and penicillin/streptomycin.

MHC I - peptide stability assays

RMA-S off rate assays were performed as described ³⁸. In short, TAP-deficient RMA-S cells were incubated overnight in the presence or absence of 100 μ M synthetic peptide, at 37 °C. Cells are harvested, washed 3 times with phosphate-buffered saline (PBS), and chased in the absence of peptide, at 37 °C for 8 hours, stained for H-2K^b class I expression with a conformation-sensitive, biotin-conjugated mouse Ab (AF6-88.5; BD Bioscience) and PE-conjugated SA (eBioscience) and analysed using FACS Canto II (BD Bioscience) and FlowJo software (Tree Star). The $t_{1/2}$ of the H-2K^b – peptide complex at the cell surface was computed as described elsewhere ³⁹, based on the mean fluorescence levels of peptide-pulsed cells corrected for background levels from cells that were not incubated with peptide.

Mice and infection

L. monocytogenes strain 10403S was grown in brain-heart infusion medium (Sigma-Aldrich) and harvested while in log phase. Six to eight weeks old female C57BL/6 mice were purchased from Charles River. For infection, mice were inoculated intravenously in the tail vein with 2000 bacteria (0.1 LD₅₀) in 200 µl PBS. All animal experiments were approved by the Animal Ethics Committee from Utrecht University (DEC 2014.II.11.081 and DEC 2014.II.01.003).

Intracellular IFN γ staining of CD8⁺ T cells

Erythrocyte depleted single cell suspensions were made from the spleens and 0.5×10^6 of these splenocytes were incubated with or without 1 µg/ml synthetic peptide for 6 h in 1 ml RPMI 1640 medium supplemented with 10% FCS (Lonza), 2 mM L-glutamine, 30 µM 2-mercaptoethanol, and penicillin/streptomycin containing 50 µg/ml gentamycin (GIBCO) and 10 µM monensin (eBioscience), at 37 °C. Subsequently, cells were stained with an APC-conjugated anti-mouse CD8 antibody (53-6.7; eBioscience) in the presence of anti-mouse CD16/CD32 antibody (clone 2.4G2; made in house). Cells were fixed with 2% paraformaldehyde and then stained with PE-conjugated anti-mouse IFN γ antibody (XMG1.2; eBioscience) in the presence of 0.5% saponin and analysed on a FACS Canto II (BD Biosciences) using FlowJo software (Tree Star). Percentages of specific IFN γ ⁺ CD8⁺ splenocytes were calculated by subtracting the background IFN γ ⁺ CD8⁺ level of splenocytes incubated without peptide per individual mouse.

Statistical Analysis

Data were tested for normality distribution and homoscedasticity by Kolmogorov-Smirnov, Shapiro-Wilk and Levene tests and the following tests were applied accordingly. To identify significant differences between splenocytes stimulated with the synthetic peptides we applied an unpaired ANOVA test with Bonferroni Post Hoc correction for multiple comparisons and Welch's correction. To compare the frequency of CD8⁺ T cells specific for the synthetic peptides in infected vs uninfected mice we applied an unpaired t-test with Welch's correction. For the correlations we applied a Spearman test. $P < 0.05$ was considered to be significant.

Results

Identification of *L. monocytogenes* derived spliced epitope candidates

LLO₂₉₆₋₃₀₄ and its spliced variant LLO_{294/297-304} are the main, known, targets of CD8⁺T cells responding to *L. monocytogenes* infection in C57BL/6 mice^{20, 24}. The PlcA and PlcB antigens used in this study to develop a reverse immunology-based spliced epitope prediction method lack known H-2K^b presented epitopes. These proteins possess 317 residues and 292 residues, respectively. In commonly used reverse immunology approaches to identify non-spliced epitopes, the antigen sequence is first screened *in silico* for peptides predicted to bind to the MHC molecule of interest, and subsequently the predicted epitopes are investigated *in vivo*. This approach cannot be directly applied to identify spliced epitopes because all available tools/algorithms for MHC I - peptide binding predictions only test non-spliced sub-sequences of a given length for binding. To be able to identify the potential spliced epitopes, we first computed all possible 8mer and 9mer non-spliced and spliced peptides from the two antigens (Fig. 1). Here, the peptide length was restricted to reduce the number of potential epitopes since 8mer and 9mer peptides represent the large majority of the mouse MHC I ligandome. The resulting database contained in total 1.56×10^6 sequences (Fig. 2A, B). We then reduced the number of sequences by introducing further restrictions, which were based on previous studies. In particular, among the peptide candidates we: (i) set a maximal distance of 40 residues between the two splice reactants – *i.e.* the intervening sequence and (ii) excluded spliced peptides that were generated by binding of splice-reactants derived from two distinct antigens or from two molecules of the same antigen (*i.e. trans* PCPS), as suggested by the study of Dalet and colleagues²⁵. Thus, from this point onwards only *cis* spliced peptides, *i.e.* peptides generated from fragments of the same molecule, were included. This reduced database contained 4.67×10^5 entries for potential 8-9mer spliced peptides and 1188 entries for the potential 8-9mer non-spliced peptides (Fig. 2A, B). Because we were interested in antigenic peptides efficiently presented in the H-2K^b cleft we further reduced the database by selecting only those peptides that were predicted to bind H-2K^b molecules with an $IC_{50} < 100$ nM using the algorithm SMM²⁶ (Fig. 1, Fig. 2C, Fig. 2D). This selection step reduced the PlcA and PlcB candidate list to 989 spliced peptides and 5 non-spliced peptides. From these we selected the 22 peptides with the lowest predicted IC_{50} , *i.e.* lower than 16 nM, which were all spliced peptides (Table 1, Fig. S1, Fig. S2), for further testing in *ex vivo* CD8⁺T cell recognition assays (Fig. 1).

In summary, we applied several reduction steps *in silico* based on previously collected experimental evidence in order to obtain a candidate list of 22 predicted PlcA and PlcB spliced epitopes, starting from 1.56×10^6 potential spliced peptides. This led to a progressive emergence of a peptide sequence pattern in the reduced databases, which included the known H-2K^b anchor sites ²⁷ (Fig. 2E,F).

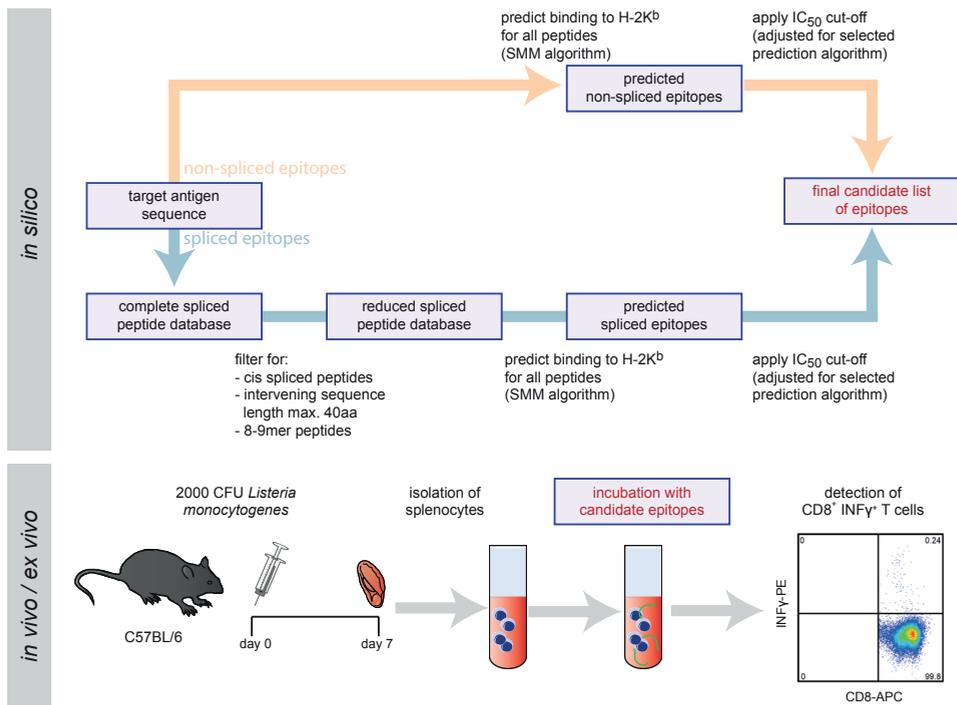

Figure 1. Reverse immunology approach to identify immunogenic spliced peptides *in vivo*. The systematic identification of immunogenic peptides requires a combined *in silico* – *in vitro* approach. Illustrated is the identification of non-spliced peptides (pink arrows) and identification of spliced peptides (blue arrows). For the latter, we first computed the complete list of theoretically possible spliced peptides from a given antigen and reduced this step-by-step to a number of spliced peptides predicted to bind to the H-2K^b molecule. The final candidate list of epitopes then was tested *ex vivo*. C57BL/6 mice were infected with *L. monocytogenes*. After 7 days the splenocytes were isolated and incubated with the spliced peptides from the final candidate list. Peptides that triggered IFN γ production in CD8⁺ T cells *ex vivo* (*i.e.*, CD8⁺ IFN γ ⁺ T cells) were targeted by the *L. monocytogenes*-induced CD8⁺ T cell response *in vivo*.

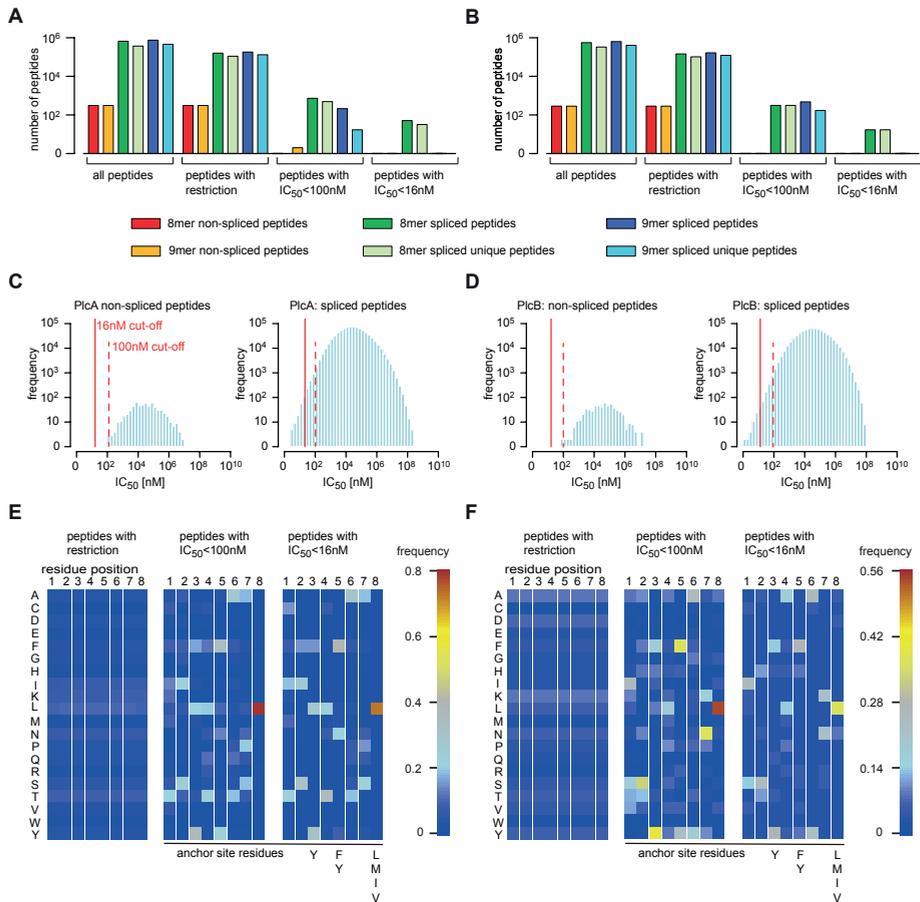

Figure 2. *In silico* identification of a spliced peptide candidate list. (A-B) All possible 8mer and 9mer non-spliced and spliced peptides were computed for (A) PlcA and (B) PlcB. Shown is the reduction of the number of potential peptides based on the spliced peptide characteristics. It is often possible to produce the same sequence through different PCPS events from the same antigen, resulting in duplicate sequences. We therefore report both, the total number of sequences and the number of unique sequences. (C-D) For all 8mer and 9mer non-spliced peptides and for all 8mer and 9mer *cis*-spliced peptides with a maximum intervening sequence length of 40 amino acids the IC_{50} of binding to the H-2K^b molecule was predicted, shown as histograms in (C) PlcA and (D) PlcB. The IC_{50} cut-offs are indicated as red lines. (E-F) The sequence profiles of 8mer spliced peptides after each reduction step are shown in (E) PlcA and (F) PlcB. The frequencies represent the marginal probability distributions for each amino acid residue in the 8mer spliced sequence. Below, the known anchor sites of the H-2K^b variants are denoted ²⁷.

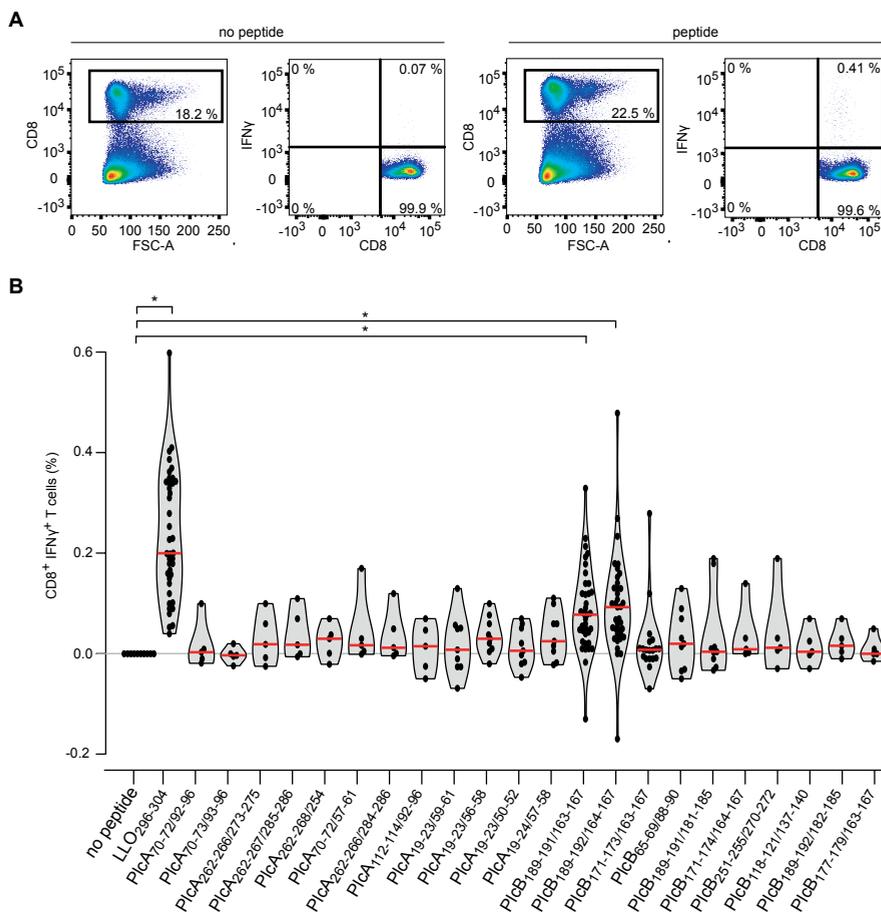

Figure 3. CD8⁺ T cells from infected mice specifically recognize PlcB spliced epitopes. **(A, B)** C57BL/6 mice were infected with *L. monocytogenes* and 7 days later the frequency of CD8⁺ T cells specific for synthetic peptides among the splenocytes of infected mice was measured *ex vivo* by intracellular staining of IFN α in CD8⁺ T cells. **(A)** Representative FACS plots of the staining in presence or absence of the target peptide LLO₂₉₆₋₃₀₄ is here depicted. **(B)** Frequency of IFN γ ⁺ CD8⁺ T cells, upon *ex vivo* stimulation with the PlcA or PlcB spliced peptides and the non-spliced LLO₂₉₆₋₃₀₄ epitope, among splenocytes derived from infected mice (n = 5 - 43). Accumulated data of five independent experiments are shown, corrected for IFN γ background measured in control samples incubated without peptide. The violin plots indicate the density of the measurements on each side, with all single mice indicated as dots. Red lines indicate the median of the measurements. Significant differences between the splenocytes incubated with or without the peptides are marked as * (ANOVA with Bonferroni and Welch's corrections; LLO₂₉₆₋₃₀₄, PlcB_{189-191/163-167} and PlcB_{189-192/164-167} p < 0.001).

PlcB derived proteasome-generated spliced epitope specific CD8⁺ T cells are activated in *L. monocytogenes* infection

To test the immunogenicity of the selected antigenic spliced peptide candidates, C57BL/6 mice were infected *i.v.* with 2000 CFU *L. monocytogenes*. At the peak of the response²⁸, their splenocytes were isolated and the frequency of CD8⁺ T cells producing IFN γ upon recognition of the spliced peptides was measured *ex vivo* (Fig. 3A). A significant expansion of specific CD8⁺ T cells in infected mice was observed for two PlcB spliced epitopes - *i.e.* PlcB_{189-191/163-167} and PlcB_{189-192/164-167} - as well as for the known control epitope LLO₂₉₆₋₃₀₄ (Fig. 3B).

The CD8⁺ T cell response in *L. monocytogenes* infected mice specific for spliced epitopes could result from cross-reactivity of CD8⁺ T cells primed by non-spliced epitope variants, as we have recently demonstrated for the LLO antigen²⁰. To address this possibility, we compared the frequency of CD8⁺ T cells in *L. monocytogenes* infected mouse spleen that were specific for the spliced epitopes PlcB_{189-191/163-167} and PlcB_{189-192/164-167} to the response elicited by the two non-spliced peptides PlcB₁₆₀₋₁₆₇ and PlcB₁₈₉₋₁₉₆, which shared part of the N- or C-terminus with the spliced epitopes. Only the spliced epitopes were specifically recognized by CD8⁺ T cells primed during the *L. monocytogenes* infection (Fig. 4A), thereby ruling out a possible cross-reaction of the CD8⁺ T cells towards non-spliced peptides derived from that antigen.

To confirm that the specific CD8⁺ T cell-mediated response towards the spliced epitopes in infected mice was the outcome of the infection, we compared the frequencies of spliced epitope-specific IFN γ ⁺ CD8⁺ T cells amongst splenocytes of infected mice to those of uninfected mice. For both the spliced (PlcB_{189-191/163-167} and PlcB_{189-192/164-167}) and non-spliced (LLO₂₉₆₋₃₀₄) epitopes we observed a significantly larger prevalence of IFN γ ⁺ CD8⁺ T cells in samples from infected mice compared to those from uninfected mice (Fig. 4B). Additionally, when performing a blast search to check for non-spliced peptides with full sequence similarity with PlcB_{189-191/163-167} or PlcB_{189-192/164-167} in any proteome of prokaryotes or eukaryotes, no hits were found (data not shown). From these data we conclude that proteasome-generated spliced PlcB-derived epitopes participate in the priming of CD8⁺ T cell responses upon *L. monocytogenes* infection.

PlcB derived spliced epitopes are generated by the proteasome

All spliced epitopes described so far were produced by proteasomes and PCPS did not occur in absence of this enzyme^{11, 14, 16, 18, 29}. However, as proof of principle to confirm that also the PlcB-derived spliced epitopes were generated

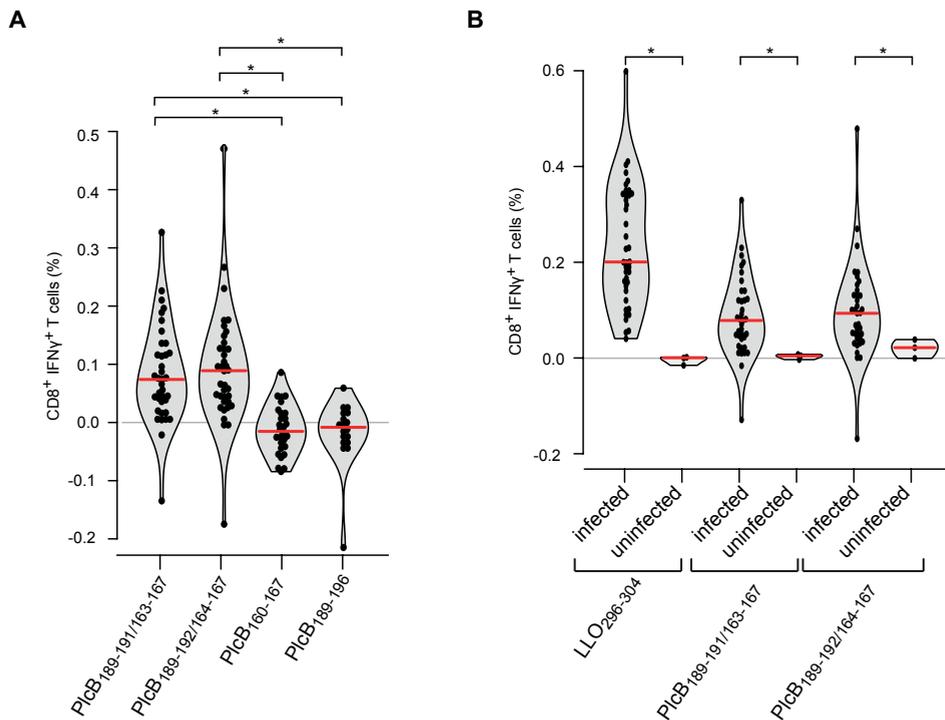

Figure 4. PlcB spliced epitope-specific CD8⁺ T cells are not cross-reactive to PlcB non-spliced peptides and are not activated in uninfected mice. **(A)** Frequency of IFN γ ⁺ CD8⁺ T cells, upon *ex vivo* stimulation with the PlcB_{189-191/163-167} and PlcB_{189-192/164-167} spliced epitopes and the PlcB₁₆₀₋₁₆₇ and PlcB₁₈₉₋₁₉₆ non-spliced peptides, among splenocytes derived from *L. monocytogenes* infected mice (n = 18 - 37) is shown. Accumulated data of five independent experiments is shown per peptide corrected for IFN γ background level as measured in control samples that were incubated without peptide. The violin plots indicate the density of the measurements on each side, with all single mice indicated as dots. Red lines indicate the median of the measurements. Significant differences between the splenocytes incubated with spliced epitopes and non-spliced peptides are marked as * (ANOVA upon Bonferroni and Welch's corrections; PlcB_{189-191/163-167} or PlcB_{189-192/164-167} vs PlcB₁₆₀₋₁₆₇ or PlcB₁₈₉₋₁₉₆, p < 0.001). **(B)** Frequency of IFN γ ⁺ CD8⁺ T cells, upon *ex vivo* stimulation with LLO₂₉₆₋₃₀₄, PlcB_{189-191/163-167} and PlcB_{189-192/164-167}, among splenocytes derived from infected (n = 37 - 40) or uninfected (n = 3) mice. Accumulated data of five independent experiments is shown. Significant differences between infected and uninfected mice are marked as * (t-student with Welch's correction; LLO₂₉₆₋₃₀₄ and PlcB_{189-191/163-167} p < 0.001; PlcB_{189-192/164-167} p = 0.001).

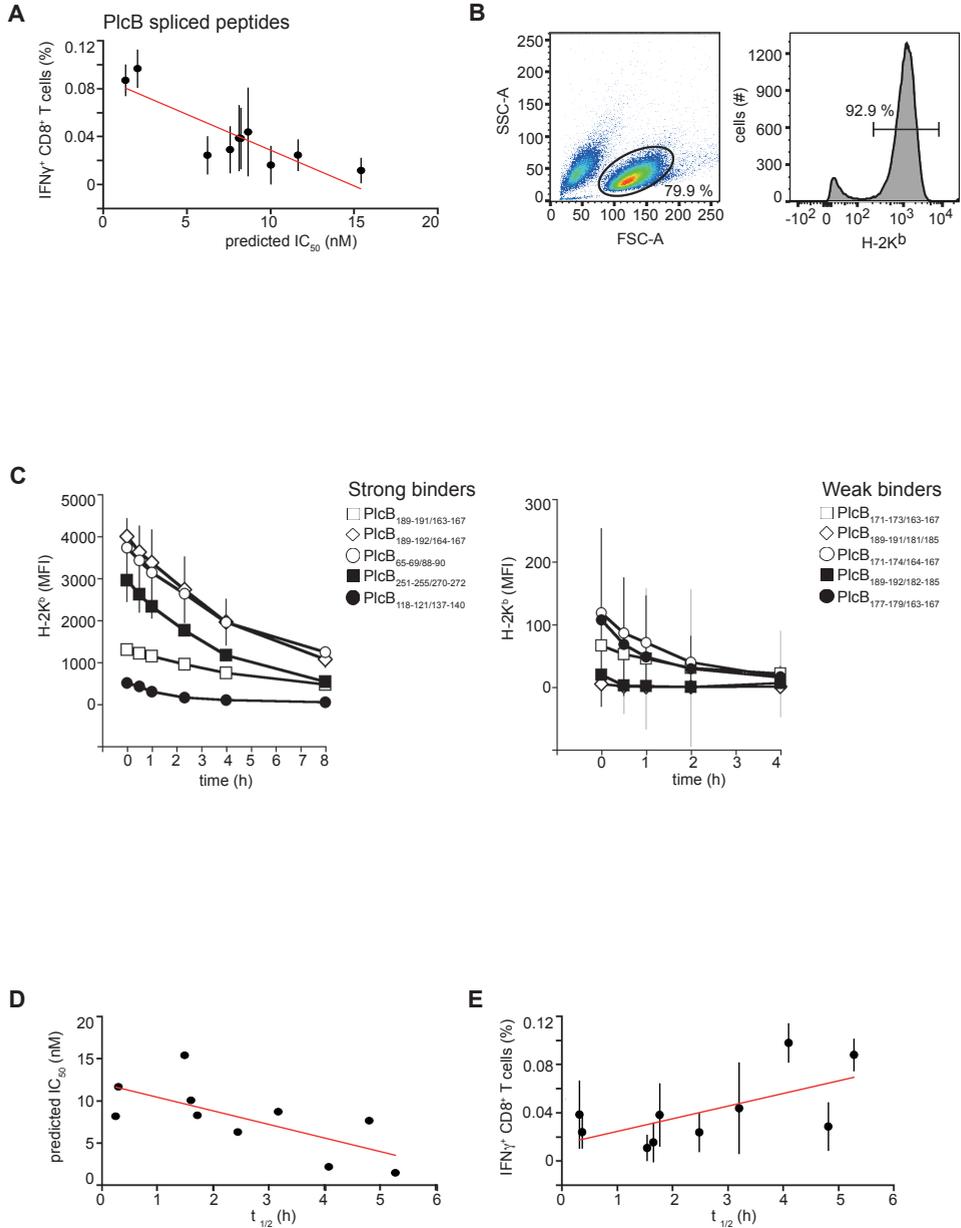

Figure 5. Correlation between predicted IC_{50} , H-2K^b – peptide stability and frequency of specific CD8⁺ T cells in infected mice. (A) Correlation between the predicted IC_{50} of PlcB spliced peptides and the frequency of IFN γ ⁺ CD8⁺ T cells specific for the peptides among splenocytes derived from *L. monocytogenes* infected mice (for all PlcB peptides tested on 5 - 37 mice). There is a significant inverse correlation (Spearman correlation test $p < 0.001$, C value = -0.559). Values are the mean and bars the SEM of tested mice for each peptide (n = 5 - 37). IC_{50} of the peptides for the H-2K^b complex was predicted by the SMM algorithm ²⁶. (B) H-2K^b – peptide stability was measured with RMA-S cells incubated with synthetic peptides and chased in the absence of peptide. At different time points the remaining H-2K^b – peptide complexes were measured using FACS and measured in MFI (mean fluorescence index). (C) The stability of the H-2K^b complexes bound to each PlcB spliced peptide is shown. Peptides were divided in strong binders (with MFI > 500 at t = 0; left panel) or weak binders (with MFI < 200 at t = 0; right panel). Incubation without peptide resulted in a background MFI level of ~ 40. Values are the mean MFI \pm SD of two independent experiments. (D) Correlation between the predicted IC_{50} of the PlcB spliced peptides (n = 10) and the H-2K^b – peptide half-life at the cells surface is shown. Values are the mean of two independent experiments. There is a significant inverse correlation (Spearman correlation test $p = 0.022$, C value = -0.709). (E) Correlation between the H-2K^b – peptide stability and the frequency of IFN γ ⁺ CD8⁺ T cells responsive against the spliced peptides among splenocytes derived from infected mice (for all peptides tested on 5 - 37 mice). There is a significant correlation (Spearman correlation test $p < 0.001$, C value = 0.498). Values are the mean and bars the SEM of mice tested for each peptide (n = 5 - 37).

by the proteasome, we performed *in vitro* digestions of the synthetic substrate PlcB_{159-171/185-196} with 20S proteasomes purified from spleens of *L. monocytogenes* infected or uninfected mice. The substrate sequences were derived from the original PlcB protein although part of the intervening sequence (PlcB₁₇₂₋₁₈₄) was removed to facilitate the *in vitro* reaction as previously demonstrated ²⁵. Mass spectrometry (MS) analysis of the digests demonstrated the proteasome-mediated generation of the spliced epitopes PlcB_{189-191/163-167} and PlcB_{189-192/164-167} (Fig. S3). By applying the quantitative method QME to samples collected at different time intervals of *in vitro* digestion of PlcB_{159-171/185-196}, we measured the generation kinetics of the spliced epitopes PlcB_{189-191/163-167} and PlcB_{189-192/164-167}. No remarkable differences in generation kinetics of the two spliced epitopes were detected between reactions carried out by proteasomes purified from uninfected or infected mouse spleens. Similar results were obtained for the non-spliced peptides PlcB₁₆₀₋₁₆₇ and PlcB₁₈₉₋₁₉₆ (Fig. S4).

^a Spliced epitope candidates PlcA and PlcB antigens were predicted by applying the *in silico* computation method shown in Fig. 1.

^b The predicted IC₅₀ for binding to the H-2K^b MHC I molecule was calculated using SMM algorithm ²⁶.

^c The H-2K^b – peptide complex stability was empirically measured; mean half-life (T_{1/2}) and SD of two independent experiments are shown.

^d The half-life of LLO₂₉₆₋₃₀₄ was in agreement with previous studies ²⁰.

^e The two non-spliced peptides listed here were used as negative controls, to exclude potential cross-reactivity of spliced epitope-specific CD8⁺ T cells.

^f -, peptides failed to stabilize H-2K^b molecules.

Thus, we confirmed that the spliced epitopes PlcB_{189-191/163-167} and PlcB_{189-192/164-167} were generated by the proteasome, both early in infection when proteasome composition has not yet been changed as result of the inflammatory milieu (see results with proteasomes of uninfected mouse spleens) and in later stages of infection. The two non-spliced peptides that share sequence similarity with the spliced epitopes are also generated by the proteasome, which suggests that other factors, *e.g.* affinity for the H-2K^b molecule (see below), are responsible for the fact that they are not targeted by the *L. monocytogenes*-induced CD8⁺ T cell response.

The measured H-2K^b-spliced peptide stability and the predicted binding affinity correlate with the relative frequency of specific CD8⁺ T cells in infected mice

During the development of our *in silico* strategy for selecting the best peptide candidates for this study we assumed, based on earlier studies³⁰⁻³², a correlation between the predicted IC₅₀ (*i.e.* H-2K^b binding affinity) and the recognition of peptides by specific CD8⁺ T cells. Therefore we restricted the list of spliced peptides that might be recognized during *L. monocytogenes* infection by their predicted IC₅₀. The validity of this approach was evaluated on the results of the *ex vivo* stimulation of splenocytes derived from infected mice with the PlcB spliced peptides. In agreement with our assumption, we observed a significant inverse correlation between the predicted IC₅₀ of the spliced peptides and the specific response (measured as frequency of IFN γ ⁺ CD8⁺ T cells *ex vivo*) in infected mice (Fig. 5A, Table 1).

As proof of principle we experimentally measured another parameter depicting the affinity between MHC I and peptide, *i.e.* the stability of H-2K^b-peptide complexes at the cell surface of RMA-S cells (Fig. 5B). Five out of ten spliced epitope candidates tested, including PlcB_{189-191/163-167} and PlcB_{189-192/164-167}, upregulated H-2K^b levels on RMA-S cells (Fig. 5C, left panel), indicating that these peptides bound to and stabilized RMA-S-expressed H-2K^b molecules. The other spliced epitope candidates tested (Fig 5C, right panel) as well as the non-spliced peptides PlcB₁₆₀₋₁₆₇ and PlcB₁₈₉₋₁₉₆ (data not shown), only weakly upregulated or failed to upregulate H-2K^b on RMA-S cells. This difference in peptide binding capacity was illustrated by the half-lives that we computed based on chase analyses of peptide-pulsed RMA-S cells (Table 1), which varied from 5,25 h for H-2K^b complexed with "strong" binders to 0,17 h for weak binders. Of note, the two identified spliced epitopes PlcB_{189-191/163-167} and PlcB_{189-192/164-167} were amongst the three highest affinity H-2K^b binders (Table 1), with computed half-lives

exceeding these of H-2K^b molecules complexed with the control epitope LLO₂₉₆₋₃₀₄. Comparing the data for all spliced peptides tested, we found a significant correlation between the predicted IC₅₀ and the measured half-lives of H-2K^b-peptide complexes at the cell surface (Fig. 5D). Accordingly, we also found a significant inverse correlation between the half-lives of H-2K^b-peptide complexes and the relative frequency of IFN γ ⁺ CD8⁺ T cells amongst infected mouse' splenocytes for the spliced peptides derived from PlcB (Fig. 5E). Thus, selection of spliced epitope candidates based on predicted IC₅₀ is a valid approach to focus *ex vivo* analyses on the most promising epitope candidates.

Discussion

We here present a novel multi-level spliced epitope identification approach which will be instrumental in uncovering the role of PCPS in immune recognition, both of pathogen-derived and self-antigens. Application of this approach enabled us to gain more insight in the contribution of PCPS to MHC I antigen processing. Focusing on two *L. monocytogenes* proteins as model antigens, we show that PCPS generates novel spliced epitopes that participate in CD8⁺ T cell priming following infection.

The method developed for this study to identify spliced epitope candidates uses an *in silico* guided-approach for the identification of spliced peptides, combined with experimental outcomes and the SMM prediction algorithm. As part of this approach, *in silico* predicted epitope candidates are selected based on their low predicted IC₅₀, which showed to be the right approach since we observed a correlation between predicted IC₅₀ (and H-2K^b – peptide complex stability) and the expansion of specific CD8⁺ T cells during infection, in agreement with earlier published works³⁰⁻³².

The demonstration that proteasome-generated spliced epitopes trigger a specific CD8⁺ T cell response during *L. monocytogenes* infection in mice could represent a mile stone in the investigation of T cell immunity against pathogens. The ability of PCPS to expand the epitope variety could be a key means of the immune system to tackle the high mutation frequency and therewith the escape mechanisms of some pathogens. The enormous number of potential combinations of spliced peptides derived from an antigen could also be a means for allowing the immune system to target antigens with few or none non-spliced antigenic peptides that could be effectively presented by the MHC I molecules of a person. Indeed, we have recently shown that one third of the self-antigens were represented only by spliced epitopes²⁹. This might also

apply to PlcB because there are no potential non-spliced antigenic peptides with strong binding affinity for the H-2K^b complex.

Thus, the so far neglected possibilities for epitopes generated by PCPS may be a tremendous asset for vaccination approaches focusing on single pathogen-derived proteins. To illustrate this, we performed a preliminary *in silico* analysis to identify PlcA and PlcB epitope candidates for the most frequent human MHC I haplotypes (Fig. S5, S6). We calculated that the number of potential spliced peptides predicted to bind with high affinity to the most frequent HLA-A or -B variants largely exceeds that of the non-spliced peptides. Thus, no non-spliced epitope candidates with a predicted IC₅₀ below 100 nM were found in PlcB or in PlcA in combination with HLA-A*01:01, -A*03:01, -B*44:02, or -B*44:03, while four and three non-spliced candidates were predicted for the PlcA antigen in combination with HLA-A*02:01 and -B*07:02, respectively. In contrast, there are hundreds of potential spliced epitopes for both antigens predicted to bind to each of the investigated MHC I haplotypes (Fig. S5, S6). Therefore, spliced peptides could be the answer to yet undiscovered immunological targets as well as a key means of the immune system to tackle pathogens.

To further facilitate studies into the contribution of PCPS to MHC I antigen processing, the here reported approach may be further optimized. Initial *in silico* selection of the spliced peptide targets could be streamlined by performing *in vitro* digestion assays with purified proteasomes. In our study the *in vitro* digestion of synthetic polypeptides confirmed to be a reliable method for the identification and characterization of immunogenic peptides in case of positive identification of the target peptides by MS/MS. However, as happened for other studies^{18, 33-35}, the assay can fail to identify samples that are produced and are immunogenic *in vivo*. Improvement of the MS devices would in the future allow for the reduction in the number of false negatives and would likely lead to the identification of a larger number of spliced peptides, thereby providing a more complete view of the PCPS occurrence both *in vitro* and *ex vivo*. Another way to optimize the initial *in silico* selection of the spliced peptide targets could be the development of an algorithm predicting the PCPS events, which would be an enormous asset, in particular in studies focusing on the contribution of proteasome-generated spliced peptides to the development of auto immune diseases. The first pioneering attempt in this direction done by Berkers et al.³⁶ was limited to a single peptide model and the HLA-A*02:01 haplotype. Other strategies should be identified and applied to expand the size and number of the datasets mandatory for the development of such a prediction algorithm.

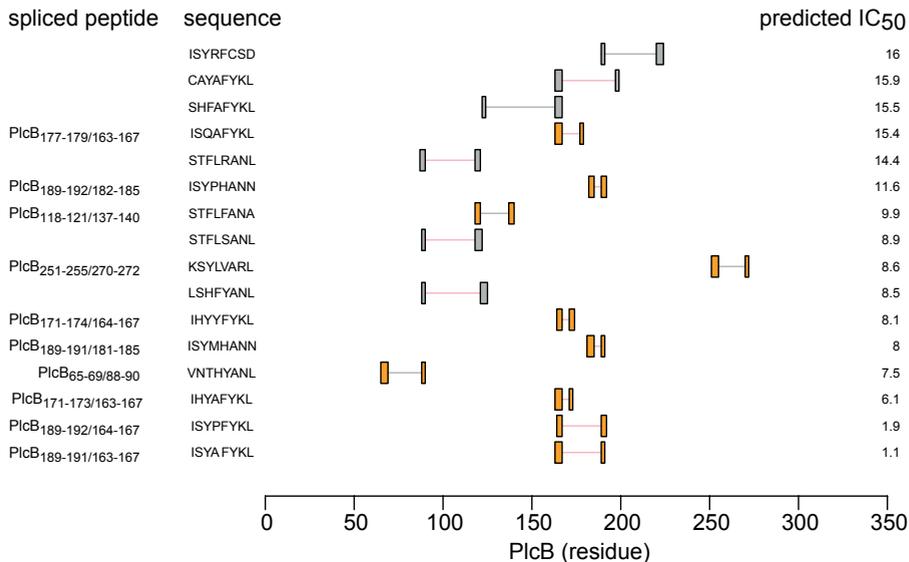

Taken together, our newly developed multi-level strategy to systematically investigate proteins for spliced epitope candidates opens novel opportunities to unravel the so far poorly understood contribution of PCPS to immune recognition of both pathogens and self-antigens. Possibilities to predict spliced epitopes may further find its application in vaccination approaches or immunotherapies.

Supplementary figure 2. List and location of predicted spliced peptide candidates for the PlcB antigen. Shown are all spliced peptides derived from PlcB that passed the described reduction steps (Fig. 1) and that have a predicted IC₅₀ of binding to H2-K^b molecules smaller than 16 nM. Rectangles depict the N- and C-terminal splice reactants. *Ex vivo* tested spliced peptides are marked with orange rectangles. Rectangles are located relative to the position in the parental antigen PlcB and are connected by a line; a grey line indicates PCPS in normal order (*i.e.* same order as the splice-reactants appear in the antigen), a pink line indicates PCPS in reverse order. The spliced peptides are ordered with increasing predicted IC₅₀ (from bottom to top). The corresponding sequences are shown on the left; the corresponding predicted IC₅₀ are shown on the right. Of note, all spliced sequences including duplicate sequences that are generated by PCPS of different splice-reactants are shown.

Asubstrate: PlcB_{159-171/185-196} KFDTAFYKLGLAINFTAISYPPGYH**B**

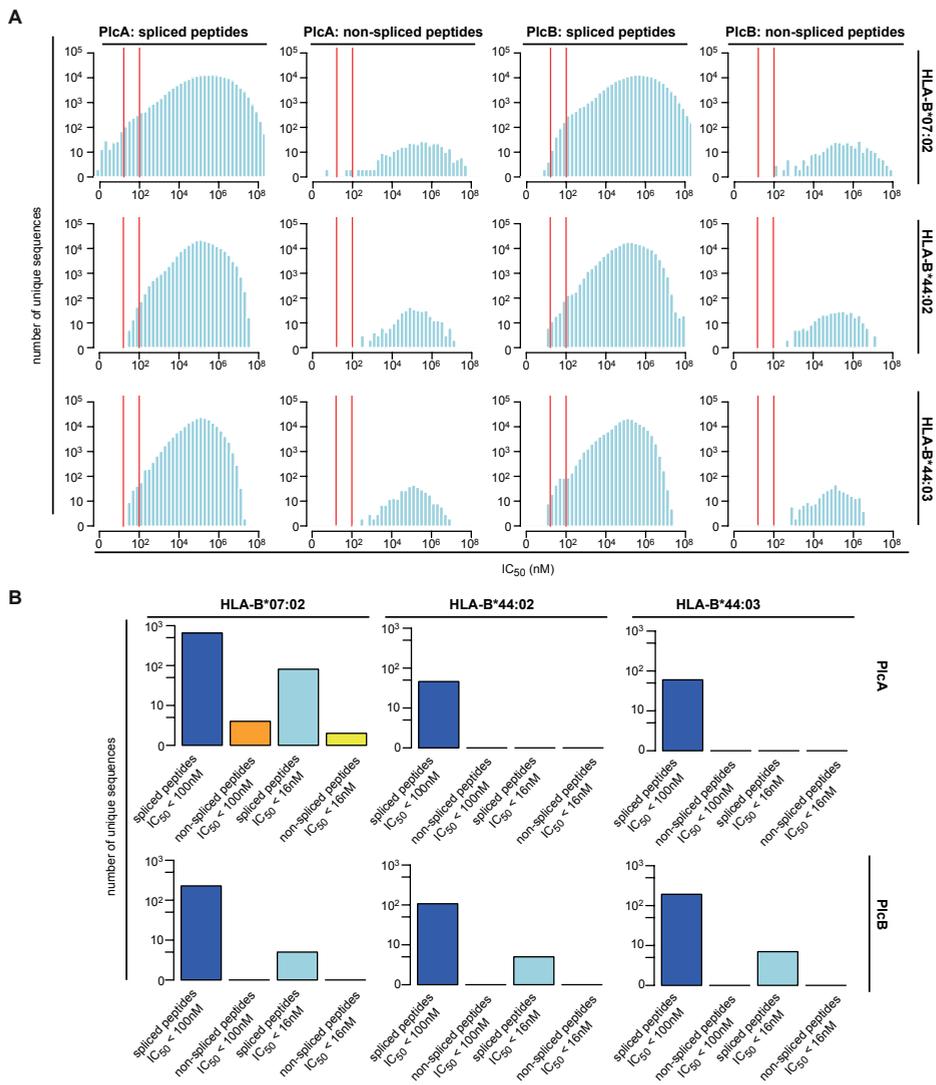

Supplementary figure 3. MS/MS of the PlcB spliced epitopes. (A, B) The MS/MS of the two spliced epitopes (A) PlcB_{189-191/163-167} (m/z 502.7576, +2) and (B) PlcB_{189-192/164-167} (m/z 515.7832, +2) are shown. In the left panel the MS/MS spectra of the peptides identified among the products of *in vitro* digestion of the synthetic substrates PlcB_{159-171/185-196} by 20S proteasome purified from spleens of mice infected by *L. monocytogenes*. In the right panel the MS/MS spectra of the corresponding synthetic peptides. Detected doubly charged $[M+2H]^{2+}-H_2O$ are enclosed in parenthesis. Single charged B-, Y-ions (related sequence is demonstrated in brackets) and the loss of water (-18Da, marked as $-H_2O$) are reported in the spectra. Spliced peptides showed similar retention times in nano-HPLC and the same fragmentation pattern in tandem mass spectra (MS/MS) of their synthetic counterparts.

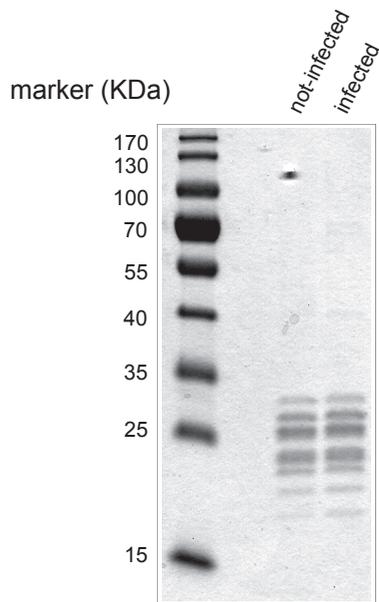

Supplementary figure 4. Quantitative kinetics of the spliced epitopes and non-spliced peptides of interest. The kinetics of (A) degradation of the synthetic substrate PlcB_{159-171/185-196} and (B) generation of the spliced epitopes PlcB_{189-191/163-167} and PlcB_{189-192/164-167} and non-spliced peptides PlcB₁₆₀₋₁₆₇ and PlcB₁₈₉₋₁₉₆ upon proteasome-mediated processing are shown. (A,B) 20S proteasomes were purified from spleens of uninfected or *L. monocytogenes*-infected mice. The values are the means, and bars the SD of two independent experiments as computed by applying QME to the MS peak area.

Supplementary figure 5. Prediction of PlcA and PlcB derived peptides for binding to human HLA-A haplotypes. (A) Shown are predicted IC_{50} distributions of spliced and non-spliced peptide candidates derived from PlcA and PlcB and selected by applying our reverse immunology approach (Fig. 1). Red lines indicate a predicted IC_{50} of 16 nM and 100 nM for some of the most frequent HLA-A haplotypes in the Caucasian population, *i.e.* HLA-A*01:01, -A*02:01, and -A*03:01. (B) Shown are the numbers of spliced and non-spliced peptide candidates with predicted IC_{50} smaller than 100 nM and 16 nM for the HLA-A*01:01, -A*02:01, and -A*03:01 variants.

Supplementary figure 6. Prediction of PlcA and PlcB derived peptides for binding to human HLA-B haplotypes. (A) Shown are predicted IC_{50} distributions of spliced and non-spliced peptide candidates derived from PlcA and PlcB and selected by applying our reverse immunology approach (Fig. 1). Red lines indicate a predicted IC_{50} of 16 nM and 100 nM for some of the most frequent HLA-A haplotypes in the Caucasian population, *i.e.* HLA-B*07:02, -B*44:02, and -B*44:03. (B) Shown are the numbers of spliced and non-spliced peptide candidates with predicted IC_{50} smaller than 100 nM and 16 nM for HLA-B*07:02, B*44:02, B*44:03.

2

Supplementary figure 7. Purity of 20S proteasome preparation. 5 μ g of 20S proteasomes purified from spleens of uninfected or *L. monocytogenes*-infected mice were stained by coomassie blue. Only the characteristic bands of the proteasome are visible, confirming the high purity of the 20S proteasome preparation.

Graphical abstract

Abstract

CD8⁺ T cells responding to infection recognize pathogen-derived epitopes presented by MHC class I molecules. While most of such epitopes are generated by proteasome-mediated antigen cleavage, analysis of tumor antigen processing has revealed that epitopes may also derive from proteasome-catalyzed peptide splicing (PCPS). To determine whether PCPS contributes to epitope processing during infection, we analyzed the fragments produced by purified proteasomes from a *Listeria monocytogenes* polypeptide. Mass spectrometry identified a known H-2K^b-presented linear epitope (LLO₂₉₆₋₃₀₄) in the digests, as well as four spliced peptides that were trimmed by ERAP into peptides with *in silico* predicted H-2K^b binding affinity. These spliced peptides, which displayed sequence similarity with LLO₂₉₆₋₃₀₄, bound to H-2K^b molecules in cellular assays and one of the peptides was recognized by CD8⁺ T cells of infected mice. This spliced epitope differed by one amino acid from LLO₂₉₆₋₃₀₄ and double staining with LLO₂₉₆₋₃₀₄ - and spliced peptide-folded MHC multimers showed that LLO₂₉₆₋₃₀₄ and its spliced variant were recognized by the same CD8⁺ T cells. Thus, PCPS multiplies the variety of peptides that is processed from an antigen and leads to the production of epitope variants that can be recognized by cross-reacting pathogen-specific CD8⁺ T cells. Such mechanism may reduce the chances for pathogen immune evasion.

Introduction

CD8⁺ T cells recognize antigenic peptides that are presented by MHC class I molecules on the cell surface. These epitopes mainly derive from proteasome-mediated processing of intracellular proteins, which produces both final sized epitopes and N-terminally extended epitope precursor fragments that are trimmed to final size by cytosolic or ER-localized amino- and endopeptidases ¹. Epitopes or their precursors are translocated into the ER by TAP and there are loaded into the antigen binding cleft of MHC class I molecules ².

Although proteasomes are present in all eukaryotic cells, their subunit composition may vary. Proteasomes consist of four stacked rings, formed of seven subunits each. The two inner rings are composed of β -subunits, of which the three subunits β_1 , β_2 and β_5 are constitutively expressed and display catalytic activity. Exposure of cells to inflammatory cytokines, such as IFN γ , induces the expression of the facultative subunits β_{1i} /LMP2, β_{2i} /MECL-1 and β_{5i} /LMP7 that are preferentially incorporated by newly assembled proteasome complexes, leading to the formation of immunoproteasomes ⁴. Cells of the immune system express different combinations of the facultative subunits in a constitutive manner.

Proteasomes generate epitopes by simple peptide-bond cleavage as well as by proteasome-catalyzed peptide splicing (PCPS), which involves the linkage of fragments originally distant in the parental protein ⁵⁻⁹. Cleavage by the proteasome is the result of a nucleophilic attack on peptide bonds by the catalytic threonines of the β_1 , β_2 and β_5 subunits in constitutive proteasomes, or of the β_{1i} , β_{2i} and β_{5i} subunits in immunoproteasomes. This attack results in the formation of an acyl-enzyme intermediate. These peptides are released from the proteasome by rapid hydrolysis, giving rise to linear proteasome-generated products. However, when the acyl-enzyme intermediate is stabilized at the active site for an extended time span, the N-termini of released peptide fragments may outcompete hydrolysis and make a nucleophilic attack on the ester bond of the acyl-enzyme intermediate, forming a new peptide bond and producing a proteasome-catalysed spliced product ¹⁰. Quantitative differences in catalytic activity between proteasome isoforms have been shown to strongly affect antigen presentation of both linear- and spliced epitopes ¹⁰⁻¹⁸.

One theoretical outcome of PCPS is to enhance the variety of antigenic epitopes that is presented during infection, which would have implications for the ability

3

of our immune system to tackle pathogens^{19, 20}. While PCPS has been proven to generate MHC class I-presented tumor epitopes^{5-7, 9, 12}, its relevance in immunity is still controversial and no evidence for its involvement in pathogen-specific immune responses has been found so far. In this study, applying a SpliceMet-facilitated reverse immunology approach²¹, we identified both spliced and linear H-2K^b-presented epitopes generated by mouse proteasomes from a *Listeria monocytogenes*-derived model antigen, Listeriolysin O (LLO)₂₉₁₋₃₁₇. Our studies show that PCPS broadens the peptide repertoire derived from a single antigen.

Materials and methods

Peptides and peptide synthesis.

The *Listeria monocytogenes* Listeriolysin O polypeptide LLO₂₉₁₋₃₁₇ (AYISSVAYGROQVYLKLSNSTSHSTKVKA) and epitope candidates derived from this sequence were synthesized using Fmoc solid phase chemistry as previously described²². The purity of synthetic peptides was tested by amino acid analysis¹⁰.

20S proteasome purification

20S proteasomes were purified from spleens of: (i) control or *Listeria monocytogenes*-infected C57BL/6 mice kept in animal facilities of the Utrecht University and used at 8 weeks of age (Fig. 2C); (ii) wild type or β 1i (N2 C57BL/6x129SvJ)²³ or β 5i (N6 C57BL/6)²⁴ gene-targeted C57BL/6 mice, which had been kept in animal facilities of the Charité and were used at 8 weeks of age (Fig. 2D). To purify the 20S proteasome we modified the earlier described protocol²⁵ as follows: mouse spleens were homogenized and centrifuged, the supernatant was fractionated by ammonium sulphate precipitation, chromatography on DEAE-Sephacel, 10-40 % sucrose gradient and anion exchange chromatography on Mono Q. In each step the fractions were monitored by degradation assays of standard short fluorogenic peptides. Proteasome concentration was measured by Bradford staining and verified by coomassie staining in a SDS-Page gel as previously shown²⁶. Spleens from 5 mice were pooled prior to proteasome purification. The purity of these proteasome preparations has been shown elsewhere²¹.

In vitro digestion of synthetic polypeptide by proteasomes and peptide quantification by QME

The synthetic LLO₂₉₁₋₃₁₇ polypeptide (20 μ M) was digested with 2 μ g 20S proteasomes in 100 μ l TEAD buffer (Tris 20 mM, EDTA 1 mM, NaN₃ 1 mM, DTT 1

mM, pH 7.2) for the time intervals specified in the figure legends, at 37°C. Liquid-chromatography mass spectrometry analyses of polypeptide digestion products were performed as previously described ²¹ with the ESI-ion trap instrument DECA XP MAX (ThermoFisherScientific, USA). Database searching was performed using the SpliceMet's ProteaJ algorithm ²¹. Quantification of proteasome-generated linear and spliced peptides was carried out by applying the QME method to the liquid-chromatography-mass-spectrometry analyses as previously described ¹⁰.

ERAP1-mediated N-terminal trimming of the epitope precursors and product identification

In vitro digestion of the spliced peptides LLO_{291-298/300-304}, LLO_{291-300/302-304}, LLO_{291-294/297-304} and LLO_{291-298/291-293} by recombinant ERAP1 was carried out as described elsewhere ²⁷. Briefly, 50 μM peptide was digested *in vitro* by 3 ng recombinant ERAP 1 (R&D systems) in 20 μl buffer (25 mM Tris pH 7.5, 150 mM NaCl, 0,5 μg/ml albumin) at 37°C. Reactions were stopped by addition of 0.5% TFA after 4 hours. As a control, to test whether observed trimming was mediated by ERAP1, 3 ng ERAP1 was incubated with 30 μM leucinethiol ²⁸ at room temperature for 20 min and then used in the *in vitro* experiments as described above. No production of trimmed peptides was observed (data not shown) thereby confirming the specific trimming by recombinant ERAP1.

For identification of the trimming products, 10 μl samples of ERAP1-mediated digestion were analyzed directly by nanoscale LC-MS/MS using an Ultimate 3000 and LTQ Orbitrap XL mass spectrometer (both Thermo Fisher Scientific). The system comprises a 5 mm × 300 μm, 100 Å trapping column (PepMap C18, 5 μm; Dionex) and a PicoChip analytical column (Reprosil-pur, 3 μm; New Objective). The mobile phase (A) was 0.1% (v/v) formic acid in water, and (B) was 80:20 (v/v) acetonitrile/water containing 0.1% (v/v) formic acid. The elution was carried out using a gradient 15-50% B in 34' with a flow rate of 300 nl / min. Full MS spectra (*m/z* 200–2000) were acquired in an Orbitrap instrument at a resolution of 60000 (FWHM). The 10 most abundant precursor ions were selected for either data-dependent CID fragmentation (TOP10) with parent list (1+ charge state included). Fragment ions were detected in an ion trap instrument. Dynamic exclusion was enabled with a repeat count of 1- and 60-s exclusion duration. The maximum ion accumulation time for MS scans was set to 200 ms and for MS/MS scans to 500 ms. Background ions at *m/z* 391.2843 and 445.1200 act as lock mass. Trimmed products were identified by comparing retention time and tandem mass spectra (MS/MS) of their synthetic counterparts (Supporting Information Fig.1).

Western blot

Protein homogenates were extracted from one spleen or liver of uninfected or infected mice, three days after administration of *Listeria monocytogenes* as previously described²⁹. Proteasome subunits were revealed by Western blot assays as follows: 20 µg protein homogenates were separated in a 12.5% polyacrilamide SDS gel and transferred on a polyvinylidene difluoride filter (Immobilon-P Transfer Membrane, Millipore). Unspecific sites on the membrane were blocked for 1 h in a 5% non-fat dry milk (AppliChem) - PBS solution. Mouse proteasome subunits were detected by staining the membrane overnight at 4°C with the following primary antibodies: anti-β1 (1:10000; custom), anti-β2 (1:1000; Enzo Life Science), anti-β5 (1:1000; Abcam), anti-β1i (1:10000; Thermo Fisher Scientific), anti-β2i (1:2000; custom) and anti-β5i (1:1000; Thermo Fisher Scientific). As secondary anti-mouse or anti-rabbit HRP-conjugated Ab (1:5000; Calbiochem) was used for 2 h at room temperature followed by ECL detection (Amersham).

Cell culture

RMA-S cells were cultured in IMDM (Invitrogen Life Technologies), supplemented with 10% FBS (LONZA), 2 mM L-glutamine, 30 µM 2-mercaptoethanol, and penicillin/streptomycin.

MHC class I stability assays

RMA-S off rate assays were performed in serum-free medium as described³⁰. In short, RMA-S cells were incubated overnight in the presence or absence of 100 µM synthetic peptide, at 37 °C. The next day, cells were harvested, washed 3 times with PBS, and chased in the absence of peptide, at 37 °C. Samples of the cells were taken at t: 0, 0.5, 1 and 2 hours, stained for H-2K^b class I expression with a conformation-sensitive, biotin-conjugated mouse antibody (AF6-88.5; BD Bioscience) and PE-conjugated streptavidin (eBioscience). FACS Canto II (BD Bioscience) and FlowJo software (Tree Star) were used for the analysis.

Mice and infection

Listeria monocytogenes strain 10403S was grown in brain-heart infusion medium (Sigma-Aldrich) and harvested while in log phase. Six to eight weeks old female C57BL/6 J mice were purchased from Charles River. For primary infection, mice were inoculated intravenously in the tail vein with 2000 bacteria in 200 µl PBS. Re-infection was performed 21 days later with 2x10⁵ CFU. All *in vivo* animal experiments were approved by the Animal Ethics Committee of Utrecht University (DEC 2014.II.11.081 and DEC 2014.II.01.003).

Analysis of specific CD8⁺ T cell responses

Intracellular cytokine staining

2.5 x 10⁶ erythrocyte depleted splenocytes were incubated with or without 1 µg/ml synthetic peptide for 6 h in 1 ml RPMI Medium 1640 (Life Technologies) containing 50 µg/ml gentamycin (GIBCO) and 10 µM monensin (eBioscience), at 37 °C. Subsequently, cells were stained with an APC-conjugated anti-mouse CD8 antibody (53-6.7; eBioscience) in the presence of anti-mouse CD16/CD32 (clone 2.4G2). Cells were fixed with 2% paraformaldehyde and then stained with PE-conjugated anti-mouse IFN γ mAb (XMG1.2; eBioscience) in the presence of 0.5% saponin and analyzed on a FACS Canto II (BD Biosciences) using FlowJo software (Tree Star).

Multimer staining

PE or APC labelled MHC class I multimers were prepared by refolding H-2K^b heavy chains and murine β 2m in the presence of synthetic *Listeria monocytogenes*-derived LLO₂₉₆₋₃₀₄ or LLO_{294/297-304}. Splenocytes were incubated with either one or both tetramers simultaneously for 20 minutes at 4 °C. Cells were washed, cell surface stained with a V500 conjugated anti-mouse CD8 antibody (53 - 6.7; eBioscience) and analyzed on a FACS Canto II (BD Biosciences) using FlowJo software (Tree Star).

Statistical Analysis

Data was tested for normality by Levene's test and for homoscedasticity by Shapiro-Wilk's test. Independent *in vitro* experiments were performed with different proteasome preparations, therefore the SD also represents variability between different proteasome preparations. To compare responses to different peptides within infected mice a paired One-way ANOVA followed by Dunnet's post hoc test was used. Independent student t-test was used to compare differences between infected and non-infected mice. P values < 0.05 were considered significant.

Results

Digestion of LLO₂₉₁₋₃₁₇ by purified proteasomes produces LLO₂₉₆₋₃₀₄ and spliced epitope variants

In previous *in vitro* studies, digestion of polypeptide substrates by purified 20S proteasomes was shown to lead to the production of both linear- and spliced peptide products^{10, 21, 27}. To determine whether PCPS contributes to proteasome-

3

mediated production of MHC class I-presented antigenic peptides, we analyzed the products generated by mouse 20S proteasomes from the polypeptide LLO₂₉₁₋₃₁₇ by mass spectrometry¹⁰ and evaluated them for their MHC class I binding affinity using the online available NetMHC3.4/ANN prediction software. As expected, this approach identified LLO₂₉₆₋₃₀₄, a well-known H-2K^b-presented epitope³¹ (Table 1). By applying the mass spectrometry-based method (SpliceMet)²¹ we further identified four putative epitope precursors in the *in vitro* digests that were generated by PCPS (Table 1), hereby confirming our previous identifications obtained with 20S human and yeast proteasomes¹⁰. From these precursors, six spliced peptides (Fig. 1), with *in silico* predicted binding affinity for H-2K^b, were generated by N-terminal trimming with recombinant ERAP1 *in vitro* (Fig. 2A and Supporting Information Fig.1). The predicted IC₅₀ values showed that two of these spliced peptides might bind the MHC class I H-2K^b with similar affinity as LLO₂₉₆₋₃₀₄, while the other four spliced peptides were predicted to bind the H-2K^b complex with an IC₅₀ > 100 nM (Table 1).

LLO₂₉₁₋₃₁₇-derived spliced peptide products are produced by different proteasome types

Listeria monocytogenes infection evokes vigorous innate immune responses, leading to the release of large quantities of pro-inflammatory cytokines and, consequently, to different degrees of modification of proteasome subunit composition in the infected tissues, in favor of larger contents of immunoproteasomes. Because such differences in proteasome subunit composition may strongly affect the generation of linear epitopes^{30, 32-36}, we determined whether the increased expression of immunosubunits in spleens of mice infected by *Listeria monocytogenes* (Fig 2B) affected the *in vitro* generation kinetics of the spliced peptides / putative epitope precursors, derived from the polypeptide LLO₂₉₁₋₃₁₇. The quantitative method QME was applied, which estimates the absolute content of spliced and linear peptide products based on their mass spectrometry ion strength measured in the digestion probe, as used before^{10, 15, 27}. As shown in Fig 2C, 20S proteasomes derived from spleens of *Listeria monocytogenes* infected or from uninfected control mice produced similar amounts of the four spliced peptides, and only a marginal alteration in frequency of cleavages along the polypeptide was observed (data not shown). Thus, the increased immunosubunit content in infected mouse spleens compared to regular spleen tissue (Fig. 2B) did not lead to a change in quantities of spliced peptides generated. These observations can be explained by the fact that for example dendritic cells, macrophages and B cells in the spleen constitutively express large amounts of proteasomes

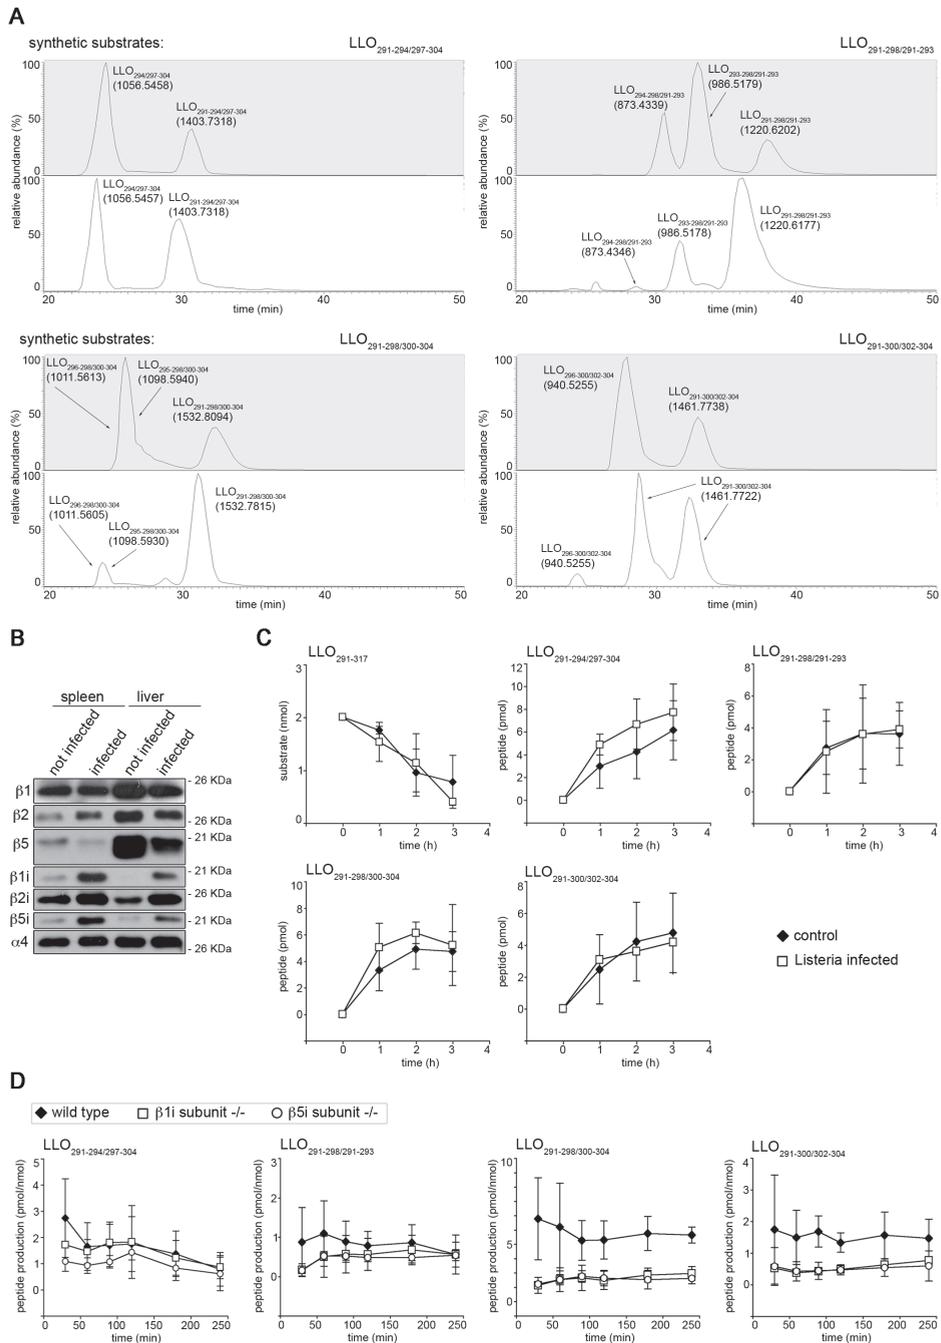

Figure 2. Generation of LLO₂₉₁₋₃₁₇-derived spliced epitopes and epitope precursors by mouse spleen 20S proteasomes and recombinant ERAP1. (A) Products of the *in vitro* degradation of the spliced peptides LLO_{291-294/297-304}, LLO_{291-298/291-293}, LLO_{291-298/300-304}, LLO_{291-300/302-304} by recombinant ERAP1. Educts and enzymatically processed products were separated by reversed phase HPLC (lower panels) and identified by MS/MS (Supporting Information Fig.1). Extracted ion chromatograms of the single and double protonated peptides versus time are displayed. The synthetic counterparts are shown in the upper panels. All peptides are detected by mass spectrometry with almost the same ionization products [M+H]⁺ and by chromatography with similar retention times of their synthetic analogous. The spliced peptides produced by recombinant ERAP1 are reported in Table 1. Data are representative of one experiment. (B) Western blot assays performed on spleen and liver of mice infected with *Listeria monocytogenes* compared to not infected mice. The three constitutive- and three immuno-subunits as well as the α_4 subunit, which is present in every proteasome isoform, were detected with proteasome subunit-specific antibodies and HRP-conjugated anti-rabbit or anti-mouse IgG secondary Ab. Blots are representative of one experiment. (C) Degradation kinetics of the synthetic substrate LLO₂₉₁₋₃₁₇ and the generation kinetics of the spliced peptides LLO_{291-294/297-304}, LLO_{291-298/291-293}, LLO_{291-298/300-304} and LLO_{291-300/302-304}. (D) The efficiency of generation of the spliced peptides LLO_{291-294/297-304}, LLO_{291-298/291-293}, LLO_{291-298/300-304} and LLO_{291-300/302-304} is here depicted as pmol peptide produced per nmol of cleaved substrate over time. Digestions of the synthetic substrate LLO₂₉₁₋₃₁₇ were carried out by wild type, β_{1i} subunit^{-/-} or β_{5i} subunit^{-/-} mouse spleen 20S proteasomes. (C-D) Quantitation of the digestion products was carried out by applying the QME method. Data are shown as mean \pm SD and are representative of two independent experiments, each performed in triplicate.

containing the immunosubunits¹⁵, thus, uninfected spleen tissue already contains considerable quantities of immunoproteasomes (Fig. 2B).

To understand the specific role of the individual immunosubunits in the generation of the spliced LLO peptide products, we further compared the digests of proteasomes purified from wildtype mouse spleens with those from spleens of gene-deficient mice that lacked either $\beta 1i$ or $\beta 5i$ ^{10, 15}. We found that both immunosubunit-deficient proteasomes generated the spliced peptides LLO_{291-298/300-304} and LLO_{291-300/302-304} less efficiently than proteasomes of wt mice (Fig. 2D). These two spliced products are the N-terminally extended precursors of the H-2K^b-restricted LLO_{295-298/300-304}, LLO_{296-298/300-304} and LLO_{296-300/302-304} epitope candidates (Fig. 2A and Table 1). The generation efficiency of the other spliced peptides LLO_{291-294/297-304} and LLO_{291-298/291-293} was not affected by the complete depletion of immunosubunits (Fig. 2D). No significant variation in the LLO₂₉₁₋₃₁₇ degradation rate was observed comparing digests of proteasomes of wildtype, $\beta 1i$ - and $\beta 5i$ -deficient mice (data not shown), as shown before¹⁵. Of note, the average amount of LLO₂₉₆₋₃₀₄ generated *in vitro* by wildtype spleen 20S proteasomes over time was higher (89.3 pmol *per* nmol of substrate processed¹⁵) than that of the spliced peptides LLO_{291-294/297-304} (1.7 pmol *per* nmol of substrate processed), LLO_{291-298/291-293} (0.8 pmol *per* nmol of substrate processed), LLO_{291-298/300-304} (4.7 pmol *per* nmol of substrate processed) and LLO_{291-300/302-304} (1.5 pmol *per* nmol of substrate processed) (Fig. 2D).

Taken together, while the absence of specific immunosubunits diminished the generation of two spliced peptide products, all proteasome types generated all four spliced, putative epitope precursors, with no significant differences observed between proteasome preparations that varied in immunosubunit contents. Furthermore, the amount of linear epitope generated over time was larger than those of spliced peptide products, for all 20S proteasomes used, independent of subunit composition (data not shown).

Six putative spliced LLO epitopes bind the H-2K^b molecule

LLO₂₉₆₋₃₀₄ is presented to CD8⁺T cells by the MHC class I H-2K^b molecule³¹. To verify that the predicted spliced epitope candidates are MHC class I H-2K^b binders, their ability to stabilize MHC class I molecules on RMA-S cells was tested. Incubation with the spliced epitope candidates LLO_{294/297-304}, LLO_{293-298/291-293}, LLO_{294-298/291-293}, LLO_{296-298/300-304} upregulated H-2K^b levels on RMA-S cells to a similar extent as incubation with LLO₂₉₆₋₃₀₄, while LLO_{295-298/300-304} and LLO_{296-300/302-304} stabilized H-2K^b to a lesser extent (Fig. 3A). During a subsequent chase in the absence of peptide,

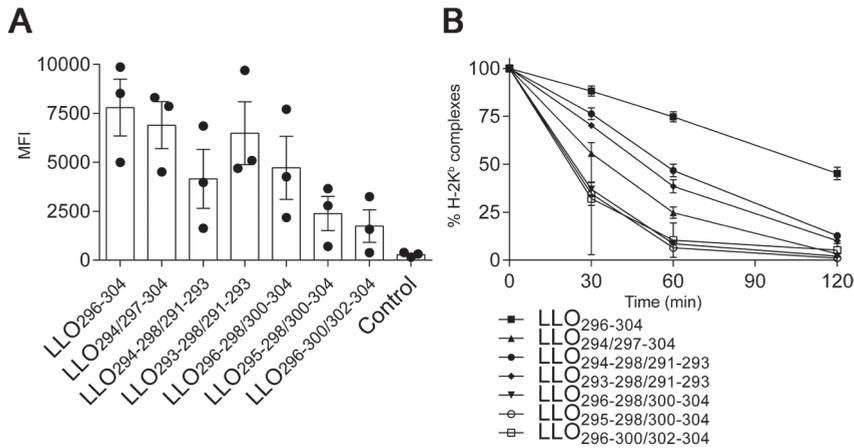

Figure 3. Binding of spliced LLO epitope candidates to H-2K^b molecules. (A and B) RMA-S cells were incubated overnight with or without synthetic peptide. (A) H-2K^b complexes (t = 0) were stained with a conformation-sensitive, biotin-conjugated anti-H-2K^b mAb and with PE-conjugated streptavidin and detected by FACS analysis. Filled circles represent stabilization of H-2K^b molecules measured in independent experiments in MFI (B) RMA-S cells loaded with peptide overnight were chased in the absence of peptide and at the indicated time points samples were stained for H-2K^b expression. Depicted are mean percentages of remaining MHC class I complexes (t=0 is 100%). (A and B) Data are shown as mean ± SEM and are representative of three independent experiments. Gating strategy is shown in Supporting Information Fig. 2.

three spliced epitope candidates LLO_{296-298/300-304}, LLO_{295-298/300-304} and LLO_{296-300/302-304} rapidly dissociated from H-2K^b molecules while the decay of the other spliced epitope candidates and LLO₂₉₆₋₃₀₄ was substantially slower (Fig. 3B, Supporting Information Fig. 2). Corresponding half-lives ranged from 14 to 120 min for the linear epitope, which displayed the highest binding affinity (Table 1). Comparing the IC₅₀ values predicted by the MHC3.4/ANN (Table 1) with the measured ability of the spliced epitope candidates to upregulate H-2K^b expression (Fig. 3A) and their dissociation rates (Fig. 3B, Table 1), we observed similar patterns, illustrating the accuracy of *in silico* prediction by NetMHC3.4/ANN.

We conclude that not only LLO₂₉₆₋₃₀₄, but also the six putative spliced antigenic peptides can bind to H-2K^b molecules and thus could be presented by infected cells *in vivo*.

CD8⁺ T cells of *Listeria monocytogenes* infected mice recognize a spliced epitope candidate

To test whether the spliced epitope candidates are targeted during infection, CD8⁺ T cell responses to the putative LLO₂₉₁₋₃₁₇-derived epitopes were measured in the spleens of *Listeria monocytogenes* infected C57BL/6 mice *ex vivo*, at the peak of the response after primary infection and secondary infection³⁷. Intracellular IFN γ staining (Supporting Information Fig.3) showed that both LLO₂₉₆₋₃₀₄ and the spliced LLO_{294/297-304} epitope candidate were recognized by CD8⁺ T cells stimulated *ex vivo* with these peptides, in both primary (Fig. 4A) and secondary infection (Fig. 4B). None of the other spliced LLO₂₉₁₋₃₁₇-derived epitope candidates induced IFN γ production in CD8⁺ T cells, exceeding the background measured upon incubation in the absence of peptide (Fig. 4A, Fig. 4B).

Because LLO₂₉₆₋₃₀₄ and LLO_{294/297-304} share 8 out of 9 residues, the detected CD8⁺ T cell response to LLO_{294/297-304} could be due to cross-reactivity of CD8⁺ T cells recognizing LLO₂₉₆₋₃₀₄. To test this possibility, we stained splenocytes of infected mice and uninfected controls *ex vivo* with PE-labelled MHC class I H-2K^b/LLO_{294/297-304} and APC-labelled MHC class I H-2K^b/LLO₂₉₆₋₃₀₄ multimers. CD8⁺ T cells specific for the linear epitope were significantly ($p = 0.007$) detected in all infected mice (Fig. 5A, Fig. 5D). In contrast, the percentages of LLO_{294/297-304}-specific CD8⁺ T cells were above the background in only 5 out of 9 infected mice (Fig. 5B, Fig. 5D). In double staining with the two MHC/peptide multimers, CD8⁺ T cells specific for both LLO_{294/297-304} and LLO₂₉₆₋₃₀₄ were significantly ($p = 0.025$) detected in all mice (Fig. 5C, Fig. 5D). While a small population of single, MHC H-2K^b/LLO₂₉₆₋₃₀₄ multimer-positive CD8⁺ T cells were detected in double stained samples (Fig. 5D, right panel), no solely LLO_{294/297-304} positive cells were detected any more (Fig. 5D, left panel).

Thus, all CD8⁺ T cells specific for the spliced epitope candidate also recognize the linear epitope LLO₂₉₆₋₃₀₄. These data suggest that LLO₂₉₆₋₃₀₄-specific CD8⁺ T cells cross-react with LLO_{294/297-304}-presented on H-2K^b molecules, demonstrating that spliced epitopes could be recognized by pathogen-specific CD8⁺ T cells during infection.

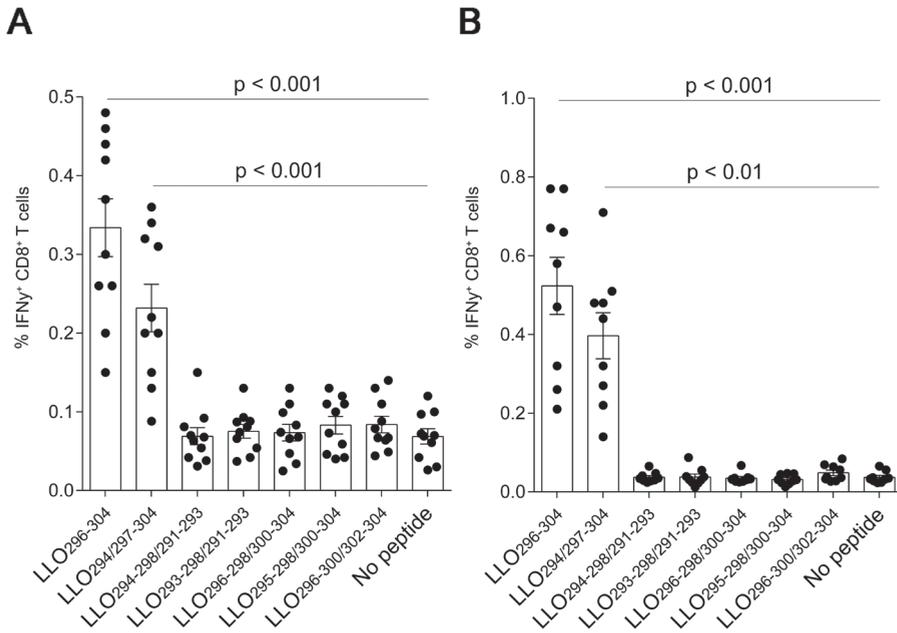

Figure 4. Recognition of LLO-derived linear and spliced peptides by CD8⁺ T cells of *Listeria monocytogenes*-infected mice. C57BL/6 mice were infected *i.v.* with (A) a primary dose of 2000 CFU *Listeria monocytogenes*, and (B) challenged 21 days later with a 100 fold higher bacterial dose. At day 7 following primary infection and day 26 following secondary infection, percentages of LLO peptide-specific CD8⁺ T cells in the spleen were measured *ex vivo* by re-stimulation of spleno-cytes with the indicated peptides, followed by staining of cell surface CD8 with APC-anti-CD8 and intracellular IFN γ staining with PE-anti-IFN γ antibodies. (A and B) Data are shown as mean \pm SEM in which every dot represents an individual mouse, representative of three independent experiments ($n > 5$ animals per experiment). Data was tested for normality using Levene's test and analyzed using a paired One-way ANOVA, comparing responses per peptide to the no peptide control per mouse, followed by Dunnet's post hoc test. At both time points, a significant difference ($p < 0.05$) was found between the CD8⁺ T cell responses specific for LLO₂₉₆₋₃₀₄ and LLO_{294/297-304} compared to background responses measured in samples stimulated without peptide. Uninfected control animals did not show any response (data not shown). Gating strategy is shown in Supplementary figure 3.

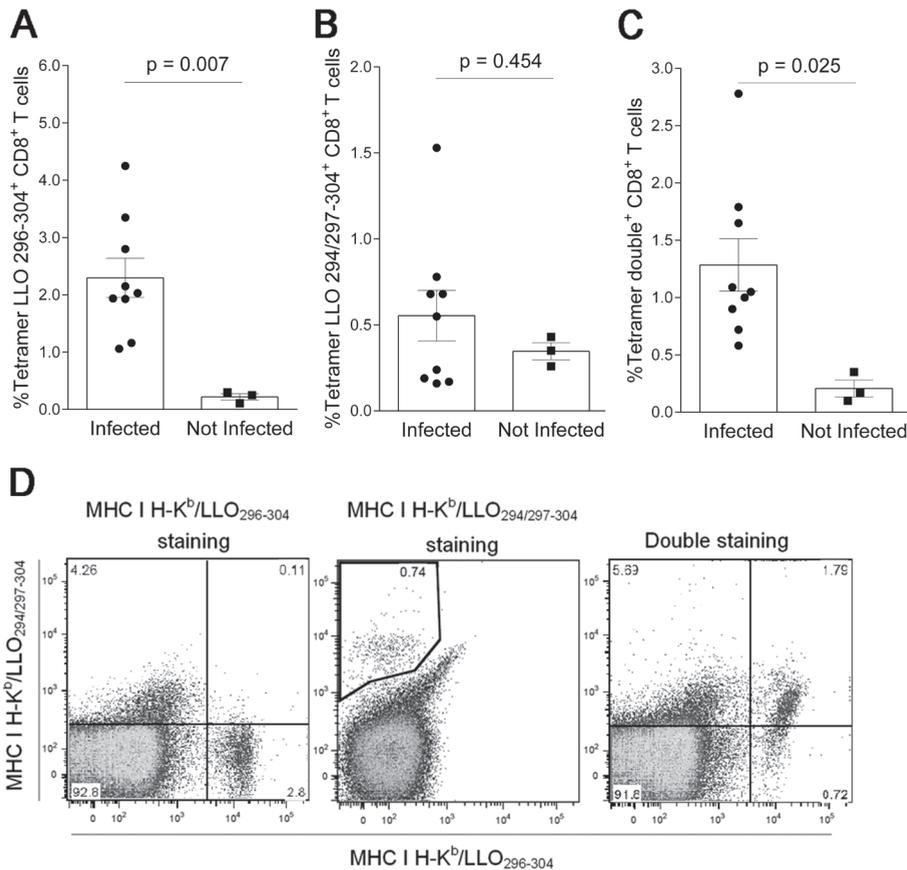

Figure 5. Recognition of LLO₂₉₆₋₃₀₄ and its spliced epitope variant by CD8⁺ T cells of *Listeria monocytogenes*-infected mice. LLO₂₉₆₋₃₀₄- and LLO_{294/297-304}- specific CD8⁺ T cell responses in the spleens of infected and control mice were measured *ex vivo* at day 7 post primary infection with 2000 CFU *Listeria monocytogenes* using V500-anti-CD8 mAb and (A) APC-labeled MHC multimers folded with LLO₂₉₆₋₃₀₄, (B) PE-labeled MHC multimers folded with LLO_{294/297-304} or (C) by double staining with the two MHC multimers. (A and B) Data are shown as mean ± SEM in which every dot represents an individual infected (circles) or uninfected (squares) mouse. The data are representative of two independent experiments (n = 15 animals in total), tested for normality using Levene's test and analyzed using an independent student's T test comparing infected with non-infected mice. A significant difference (p < 0.05) was found between percentages of LLO₂₉₆₋₃₀₄-specific CD8⁺ T cells in infected versus non-infected mice. (D) Representative FACS plots of CD8⁺ T cells from the spleens of infected mice stained with V500-anti-CD8 in combination with APC conjugated MHC class I H-2K^b/LLO₂₉₆₋₃₀₄ multimers only (left), PE conjugated MHC class I H-2K^b/LLO_{294/297-304} multimers only (middle) or both multimers (right).

Discussion

CD8⁺ T cell responses to complex pathogens often target a relatively small number of antigenic peptides only. The parameters that influence whether a pathogen-derived peptide will elicit an immune response are still not fully understood. Nevertheless, the requirements to be fulfilled by antigenic peptides to be recognized by T cells, *e.g.* successful proteolytic liberation, TAP transport, MHC class I binding and TCR recognition, are numerous ³⁸. Thus, the number of epitopes that is processed from an antigen and presented by a specific MHC class I molecule is limited. It has been hypothesized that PCPS could expand the pool of antigenic peptides ^{19, 20} and here we report first evidence that this may happen during an infection *in vivo*. We demonstrate that, from a small portion of the *Listeria monocytogenes* LLO antigen only, proteasomes generate one linear epitope along with four spliced epitope precursors from which, by ERAP-mediated N-terminal trimming, six spliced antigenic peptides that bind to H-2K^b molecules can be generated. The generation efficiency of the spliced peptides was smaller than that of the linear epitope, as described by quantitative comparison of several linear and spliced peptides produced *in vitro* by 20S proteasomes ¹⁰. These findings are in line with a publication by Berkers et al. ³⁹, showing that peptide ligation even under the most optimal conditions *in vitro* occurs with at most 30% efficiency. It is worth to note, however, that spliced epitopes can be presented in similar amounts as linear epitopes on the cell surface (Ebstein et al., *personal communication*).

Of the six spliced epitope candidates, one spliced peptide, LLO_{294/297-304}, along with the linear epitope LLO₂₉₆₋₃₀₄, was recognized by CD8⁺ T cells of mice infected with *Listeria monocytogenes*, in both primary- and secondary infection (Fig. 4). Double staining with MHC/peptide multimers folded with either LLO_{294/297-304} or LLO₂₉₆₋₃₀₄ (Fig. 5D) showed that all CD8⁺ T cells specific for the spliced epitope were detected also by the multimer folded with the linear epitope. Conversely, most but not all CD8⁺ T cells stained with LLO₂₉₆₋₃₀₄-folded multimers were stained by the multimer folded with the spliced epitope candidate. From these data we infer that most likely, CD8⁺ T cells primed by LLO₂₉₆₋₃₀₄, recognizing the C-terminal part of this peptide (residues between amino acid 297-304) cross-react to the spliced epitope candidate, while a small proportion of LLO₂₉₆₋₃₀₄-specific CD8⁺ T cells recognize the peptide N-terminal amino acid and therefore fail to detect the LLO_{204/297-304} peptide. Thus, based only on the data shown in Fig 5, it is unclear whether LLO_{204/297-304} is presented and participates in CD8⁺ T cell priming during infection.

Notwithstanding the above notion, the LLO_{204/297-304} is generated by the MHC class I antigen processing machinery of *Listeria* infected mice (Fig. 2) and the H-2K^b off rate of this peptide, although higher than that of LLO₂₉₆₋₃₀₄ (Table 1), is within the range of off rates that we detect for CD8⁺ T cell epitopes in RMA-S based assays³². In addition, *in vivo* antigen processing of *Listeria monocytogenes* derived antigens has been shown to be highly efficient⁴⁰⁻⁴². LLO₂₉₆₋₃₀₄ is the immunodominant known epitope in C57BL/6 mice³¹ and LLO₉₁₋₉₉ is immunodominant in BALB/c mice^{31, 37}, which most likely is due to the rapid degradation of LLO antigen and the very efficient liberation of these two peptides in combination with high MHC class I binding affinity⁴¹. Because the spliced antigenic peptides are derived from the LLO antigen, they are processed with similar rates as the described dominant epitopes (although with a lower efficiency) and therefore will appear early on MHC class I molecules. Thus, LLO_{294/297-304} may well be presented over the course of *Listeria monocytogenes* infection, albeit in smaller quantities than LLO₂₉₆₋₃₀₄ and be recognized by CD8⁺ T cells primed against the linear epitope, thereby facilitating bacterial clearance.

Remarkably, it has been argued that the ability of any given TCR to recognize multiple epitopes is a strict necessity, because if every T cell recognized one epitope only, the breadth of the T cell response needed to eradicate a pathogen could not be achieved⁴³. Moreover, if multiple TCR recognize multiple peptides, displaying a high degree of similarity, the chances of a diverse, broad T cell response are higher, which would make it substantially more difficult for pathogens to escape the immune system. It was shown that amino acid exchanges in the epitope- or epitope flanking residues can diminish the ability of proteasomes to efficiently liberate epitope' C-termini⁴⁴⁻⁴⁶. In case of presentation and concurrent recognition of proteasome cleavage and proteasome spliced products by (cross reactive) CD8⁺ T cells, the impact of such mutations in epitope or epitope flanking sequences of pathogens would decrease substantially.

Thus, it might be advantageous for infected cells to present linear epitopes as well as spliced epitope variants simultaneously. Such mechanism may help the host by tackling mutation-driven escape mechanisms of pathogens, which might have been one of the reasons for the preservation of PCPS along evolution.

Graphical Abstract

Vaccine H56 antigen cDNA (1), fused to TTFC (tetanus toxin fragment C) or UB (ubiquitin) cDNA (2) and modified to flank CD8⁺ T cell epitope C-termini with an glutamic acid residue (3) was administered by tattoo immunization. Linkage to either TTFC or UB enhanced CD8⁺ T cell responses to all epitopes, while replacement of C-terminal epitope flanks for a Glu residue further increased the CD8⁺ T cell response to 4 out of 6 epitopes. These strategies can be exploited for vaccine design.

4

Abstract

Most vaccines are based on protective humoral responses while for intracellular pathogens CD8⁺ T cells are regularly needed to provide protection. However, poor processing efficiency of antigens is often a limiting factor in CD8⁺ T cell priming, hampering vaccine efficacy. The multistage cDNA vaccine H56, encoding three secreted *Mycobacterium tuberculosis* antigens, was used to test a complete strategy to enhance vaccine' immunogenicity. Potential CD8⁺ T cell epitopes in H56 were predicted using the NetMHC3.4/ANN program. Mice were immunized with H56 cDNA using dermal DNA tattoo immunization and epitope candidates were tested for recognition by responding CD8⁺ T cells in ex vivo assays. Seven novel CD8⁺ T cell epitopes were identified. H56 immunogenicity could be substantially enhanced by two strategies: (i) fusion of the H56 sequence to cDNA of proteins that modify intracellular antigen processing or provide CD4⁺ T cell help, (ii) by substitution of the epitope's hydrophobic C-terminal flanking residues for polar glutamic acid, which facilitated their proteasome-mediated generation. We conclude that this whole strategy of in silico prediction of potential CD8⁺ T cell epitopes in novel antigens, followed by fusion to sequences with immunogenicity-enhancing properties or modification of epitope flanking sequences to improve proteasome-mediated processing, may be exploited to design novel vaccines against emerging or 'hard to treat' intracellular pathogens.

Introduction

CD8⁺ T cells recognize epitopes of pathogen-derived, intracellularly degraded proteins that are presented by MHC class I molecules. A major role in the generation of such epitopes is played by proteasomes. Proteasomes usually liberate the C-terminus of the epitope by cleaving after hydrophobic or basic residues¹. The N-terminus may undergo further N-terminal trimming by cytosolic or ER-localized amino- and endopeptidases. The correctly sized ligands that contain a binding motif will bind to newly assembled MHC class I molecules and presented at the cell surface^{2,3}.

Proteasomes consist of four rings composed of seven subunits each and are present in every cell of an organism. In constitutive proteasomes, the β_1 , β_2 and β_5 subunits, located in the inner rings, display catalytic activity. Upon exposure of cells to inflammatory cytokines, expression of three homologous subunits, β_{1i} /LMP2, β_{2i} /MECL1 and β_{5i} /LMP7 is induced, which leads to the formation of intermediate- or immunoproteasomes⁴. The different pocket conformations and peptide transport dynamics quantitatively alter the pool of peptides produced by the proteasomes⁵⁻⁹.

Multiple strategies can be used to influence epitope generation and processing by the proteasome which can enhance immunogenicity of CD8⁺ T cell epitopes and thus could aid in designing better vaccines against intracellular pathogens. Especially for DNA vaccines, which generally elicit cellular responses in animals but show limited immunogenicity in clinical studies¹⁰, those strategies can help to increase immunogenicity.

One strategy directly targets proteasome-mediated processing; since the proteasome usually creates the epitope' C-terminus, characteristics of the last amino acid of the epitope (positioned at P₁) and the C-terminally flanking residue (positioned at P₁') in the protein sequence have been shown to greatly influence epitope processing¹¹⁻¹⁶. Although the limited size of the datasets analyzed so far does not allow generalizations, proteasomes often favor hydrolyzing the peptide bond between hydrophobic large residues at P₁ and polar large residues at P₁', whereas hydrophobic large residues at P₁' are disfavored¹⁷. By for example introducing a residue at P₁' that is favored by the proteasome, chances of effective processing may be increased.

A second strategy to influence epitope processing is fusion of the target cDNA to cDNA that codes for proteins with immunogenicity-enhancing properties. The underlying mechanisms differ with the characteristics of the fusion protein but both self-derived (e.g. HSP-70¹⁸, invariant chain¹⁹) as well as pathogen-derived proteins (e.g. *E. coli* β -glucuronidase²⁰) have been reported to enhance immunogenicity.

We combined these strategies to study the effect of antigen processing modulation on the immunogenicity of a DNA-encoded antigen. The multistage DNA vaccine H56 was used as a model antigen, which expresses the full protein sequence of the *Mycobacterium tuberculosis* (*Mtb*) antigens Ag85B, ESAT-6 and Rv266oc²¹. This was delivered using dermal DNA tattoo immunization, which is a proven method to induce an effective CD8⁺ T cell response²². We report seven novel CD8⁺ T cell epitopes in H56, identified using *in silico* prediction²³. Immunogenicity of H56 was enhanced by fusion of the H56-encoding DNA sequences to cDNA encoding ubiquitin or TTFC, and by substitution of C-terminal flanking residues of epitopes. The two proposed approaches increased the immunogenicity and such a combined strategy may be applied in vaccine design.

Materials and methods

Peptide synthesis and 20S proteasome purification

All peptides were synthesized using Fmoc solid phase chemistry. The sequence enumeration of the synthetic peptides referred to the vaccine H56²¹. In particular, for the polypeptides H56₅₃₋₇₉ (WDINTPAFEWYYQSGLSIVMPVGGQSS) the residue V₇₁ was substituted to E, for H56₁₃₇₋₁₆₀ (LAAYHPQQFIYAGSLSALLDPSQG) L₁₅₅ to E and for H56₆₄₋₈₆ (YQSGLSIVMPVGGQSSFYSDWYS) Y₈₁ to E. 20S proteasomes were purified from 5 pooled spleens of C57BL/6 mice⁶ and purity was verified¹⁷.

In vitro digestion of synthetic polypeptide and peptide quantification

The synthetic polypeptides (20 μ M) were digested by 2 μ g 20S proteasomes in 100 μ l TEAD buffer (Tris 20 mM, EDTA 1 mM, NaN₃ 1 mM, DTT 1 mM, pH 7.2) for a period of 1-4 hours at 37°C. Liquid-chromatography mass spectrometry (LC-MS) analyses of polypeptide digestion products was performed with the ESI-trap instrument DECA XP MAX and the LTQ Orbitrap XL MS (ThermoFisher Scientific) coupled with nanoUPLC Aquity (Waters)²⁴. The database used for the LC-MS/MS analyses was generated by applying the SpliceMet algorithm to allow

the identification of linear and spliced peptides ²⁵. Quantification of peptides was carried out by applying QME to the LC-MS analyses by DECA XP MAX of the in vitro digestion kinetics ²⁴. QME estimates the absolute content of peptide products based on their MS ion peak area measured in the digestion probe. It makes use of the law of mass conservation and MS instrument features. The QME algorithm parameters were empirically computed in a previous study ²⁴. QME also estimates the site-specific cleavage strength (SCS), which describes the relative frequencies of proteasome cleavage after residues of the synthetic polypeptide ²⁴. The values showed in this study are the averages of SCS measured over time ²⁴. For the comparison of the SCS and the investigated peptides of wild type and E-substituted synthetic substrates we ran QME by including only the peptide products common to the wild type and corresponding substituted substrates ²⁶.

Mice, DNA and dermal tattoo immunization

Six week old CB6F1 mice from Charles River were immunized at day 0, 3 and 6 with 15 μ l cDNA (2 μ g/ μ l) in TE buffer with a 9-needle bar mounted on a tattoo rotary device (Cheyenne) on 100 Hz, at 1 mm depth for 1 minute ²². The full length H56 cDNA ²¹ was codon optimized and inserted 3' of tetanus toxin fragment C domain 1 (TTFC) ^{27, 28}, ubiquitin (UB) with UB₇₅ mutated to A and UB₇₆ mutated to V ²⁹, HLA-F-adjacent transcript 10 (FAT10) ²⁹ or mouse invariant chain (mLi) ³⁰ in pVAX1 vector (Invitrogen). In the H56_E construct (ThermoFisher Scientific), H56-V₇₁, H56-Y₈₁, H56-T₁₀₄, H56-L₁₅₅, H56-M₁₇₀ and H56-S₃₆₄ were changed into E (GAA). All animal experiments were approved by the Animal Ethics Committee from Utrecht University (DEC.2014.II.01.001, DEC.2014.II.08.069).

Analysis of specific CD8⁺ or CD4⁺ T cell responses

Intracellular cytokine staining

T cell responses were quantified as reported ⁶. Briefly, 2.5 x 10⁶ erythrocyte depleted splenocytes were incubated in RPMI 1640 medium supplemented with 10% FCS (Lonza), 2 mM L-glutamine, 30 μ M 2-mercaptoethanol, and penicillin/streptomycin (RPMI medium) with or without 1 (CD8) or 10 μ g/ml synthetic peptide (CD4) and 10 μ M monensin (eBioscience), for 6 h at 37 °C. Cells were stained with an APC-conjugated anti-mouse CD8 antibody (53-6.7; eBioscience) or APC-conjugated anti-mouse CD4 (L3T4; eBioscience) in the presence of anti-mouse CD16/CD32 (2.4G2; made in house), fixed and stained with PE-conjugated anti-mouse IFN γ antibody (XMG1.2; eBioscience) and analyzed on a FACS Canto II (BD Biosciences) using FlowJo software (Tree Star).

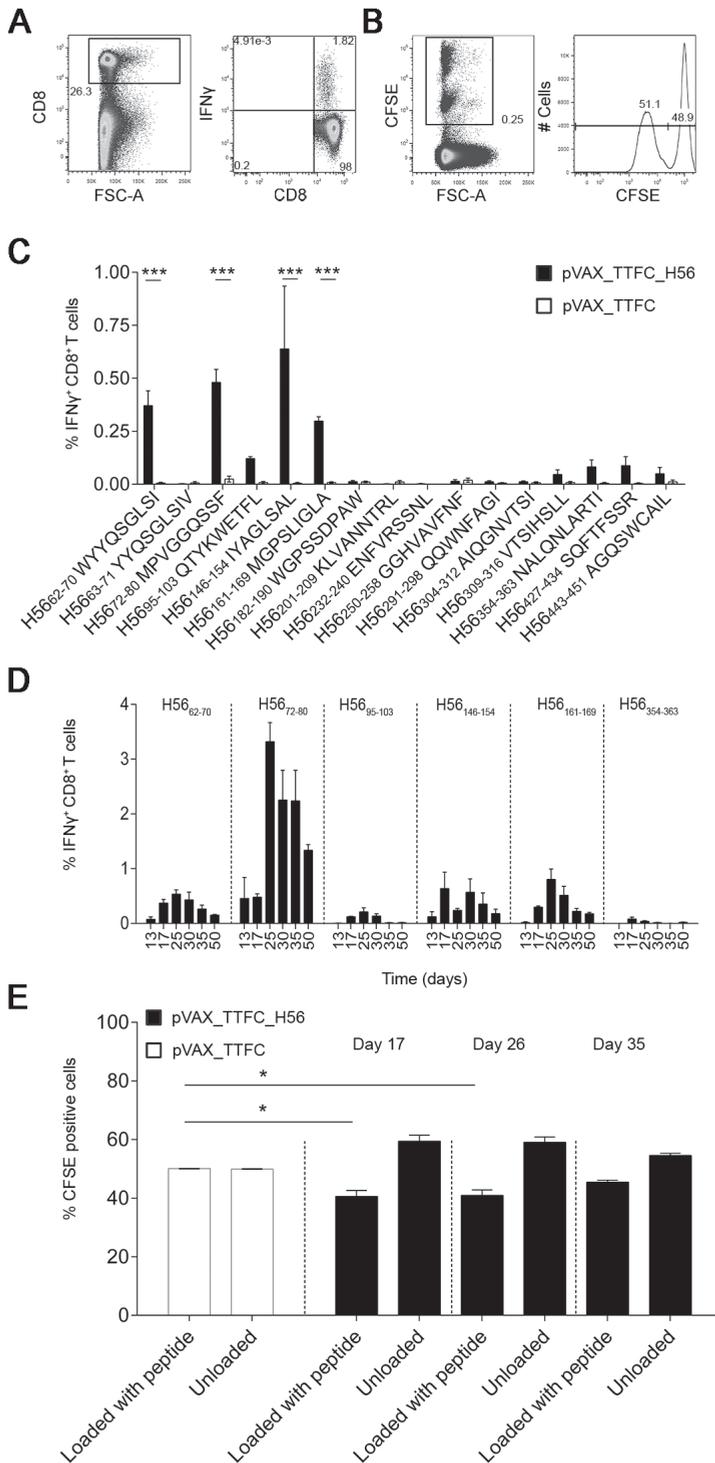

Figure 1. CD8^T cell responses specific for novel epitopes in H56 are functional and persist 50 days after immunization. (A, B) CB6F1 mice were immunized with H56 cDNA using dermal DNA tattooing and percentages or killing capacity of IFN γ -producing specific CD8^T cells were determined using (A) intracellular cytokine staining or (B) *in vivo* killing assays. (C, D) At day 17 (C) or indicated dates (D), percentages of epitope-specific CD8^T cells were measured *ex vivo* from spleen. Data are shown as mean of 5-8 mice per group \pm SEM per peptide corrected for IFN γ background level as measured in control samples that were incubated without peptide, and are representative of 2 independent experiments. (E) At indicated days, pVAX_TTFC_H56- (black bars) or pVAX_TTFC (white bars) immunized animals were injected with splenocytes labeled with CFSE and synthetic H56₆₂₋₇₀ WYYQSGLSI, H56₇₂₋₈₀ MPVGGQSSF, H56₉₅₋₁₀₃ QTYKWETFL, H56₁₄₆₋₁₅₄ IYAGLSAL, H56₁₆₁₋₁₆₉ MGPSLIGLA and H56₃₅₄₋₃₆₃ NALQNLARTI. Bars indicate percentages of CFSE labeled cells in the spleen after 2 hours of 5 mice per group \pm SEM. (C, E) All data were analyzed using a two tailed independent sample T test comparing pVAX_TTFC_H56 immunized animals with pVAX_TTFC immunized control animals per peptide, combined with a Sidak-Holm correction for multiple comparisons. P values < 0.05 are depicted with * and P < 0.001 with ***.

4

IFN γ ELISpot

MAIP ELISPOT plates (Millipore) were coated overnight with 2 μ g/ml AN18 in PBS at 4 $^{\circ}$ C. Wells were washed and blocked with RPMI medium (Life Technologies). 5×10^5 erythrocyte depleted splenocytes were plated with or without 2 μ g/ml synthetic peptide for 6 h in RPMI medium at 37 $^{\circ}$ C. Plates were washed with PBS plus 0.01% tween 20 (PBST), and IFN γ was detected with biotinylated IFN γ antibody (XMG1.2; BD), followed by alkaline phosphatase-conjugated streptavidin (Jackson Immuno Research Laboratories), in PBST supplemented with 2% BSA. The assay was developed with the Vector blue substrate kit (Vector Laboratories) and analyzed using an ELISpot plate reader and scanner (AELVIS).

In vivo killing assay

CB6F1 splenocytes were divided into two populations and labelled with either 0.4 μ M or 4 μ M CFSE (Invitrogen) in PBS at room temperature for 10 minutes and quenched with FCS HI. CFSE high cells were subsequently pulsed with 1 μ M of H56₁₄₆₋₁₅₄ IYAGLSAL, H56₁₆₁₋₁₆₉ MGPSLIGLA, H56₆₂₋₇₀ WYYQSGLSI, H56₇₂₋₈₀ MPVGGQSSF, H56₉₅₋₁₀₃ QTYKWETFL and H56₃₅₄₋₃₆₃ NALQNLARTI in PBS containing 2% FCS, for 1 h at 37 $^{\circ}$ C, and washed with PBS before *i.v.* injection.

Statistical Analysis

To compare functionality of responses or responses to individual epitopes, both between the H56 immunized group compared to the control group, epitope

specific responses of every mouse were corrected for background IFN γ level as measured in samples incubated without peptide, in both IFN γ ELISpot and IFN γ ICS. The variance homogeneity was tested using Levene's test. A two-tailed independent sample T test was used, combined with a Holm-Sidak correction for multiple comparisons. P values < 0.05 were considered significant.

Results

Identification of novel CD8⁺ T cell epitopes in H56

Rational vaccine design aimed at inducing protective CD8⁺ T cell responses would start with predicting the pathogen derived potential epitopes. To test this approach we used the *Mtb* vaccine candidate H56 in which we predicted potential CD8⁺ T cell epitopes for H-2^b and H-2^d MHC class I molecules using the NetMHC3.4/ANN prediction algorithm²³. As expected, the known epitopes *e.g.* H56₇₂₋₈₀ MPVGGQSSF and H56₁₄₆₋₁₅₄ IYAGLSAL³¹⁻³³, as well as 14 novel epitope candidates, were predicted to bind the H-2^{b,d} MHC class I molecules with IC₅₀ < 500 nM (Table 1). To determine which of these were epitopes, peptide specific CD8⁺ T cell responses were determined *ex vivo* in spleens of mice immunized with H56 cDNA using dermal DNA tattoo immunization²². Intracellular IFN γ staining (ICS) (Fig. 1A) showed that four peptides (H56₆₂₋₇₀ WYYQSGLSI, H56₇₂₋₈₀ MPVGGQSSF, H56₁₄₆₋₁₅₄ IYAGLSAL, H56₁₆₁₋₁₆₉ MGPSLIGLA), out of 16 potential epitopes, were recognized by CD8⁺ T cells of mice immunized with a H56 containing construct when compared to mice immunized with a control construct (Fig. 1C). For five other peptides (H56₉₅₋₁₀₃ QTYKWETFL, H56₃₀₉₋₃₁₆ VTSIHSLI, H56₃₅₄₋₃₆₃ NALQNLARTI, H56₄₂₇₋₄₃₄ SQFTFSSR, H56₄₄₃₋₄₅₁ AGQSWCAIL) a trend towards recognition was visible (Fig. 1C). Of these epitopes, H56₃₀₉₋₃₁₆ VTSIHSLI and H56₃₅₄₋₃₆₃ NALQNLARTI derived from ESAT-6, H56₄₂₇₋₄₃₄ SQFTFSSR and H56₄₄₃₋₄₅₁ AGQSWCAIL from Rv266oc, and all other peptides from Ag85B. CD8⁺ T cell responses to the identified epitopes persisted until 50 days after immunization (Fig. 1D) and dominance hierarchy of responding CD8⁺ T cells was maintained over time, with the already known epitope H56₇₂₋₈₀ MPVGGQSSF³¹⁻³³ being responsible for the activation of the largest percentage of specific CD8⁺ T cells.

To check whether the H56 cDNA vaccine-induced CD8⁺ T cells displayed killing capacity, *in vivo* killing assays were performed at different days (Fig. 1B). At day 17 and 25, from the 1 : 1 ratio of cells that were labeled in high CFSE concentration and loaded with epitopes (H56₆₂₋₇₀ WYYQSGLSI, H56₇₂₋₈₀ MPVGGQSSF, H56₉₅₋₁₀₃ QTYKWETFL, H56₁₄₆₋₁₅₄ IYAGLSAL, H56₁₆₁₋₁₆₉ MGPSLIGLA and H56₃₅₄₋₃₆₃

Table 1. Predicted CD8⁺ T cell epitopes in H56.

H-2D ^d	443	451	AGQSWCAIL	392.12

^a NetMHC 3.4/ANN ²³ predicted H-2^b and H-2^d binding affinities (IC₅₀). All peptides were included in this study ⁵⁸.

NALQNLARTI) versus unloaded cells that were labeled in low CFSE concentration, we found less CFSE high cells back in the H56 immunized mice, implying specific killing of peptide loaded splenocytes by H56 specific CD8⁺ T cells (Fig. 1E). In the mice that were immunized with a control construct, this balance was still 1 : 1.

Thus, by applying the NetMHC3.4/ANN prediction algorithm, we identified 16 potential epitopes of which four (H56₆₂₋₇₀ WYYQSGLSI, H56₇₂₋₈₀ MPVGGQSSF, H56₁₄₆₋₁₅₄ IYAGLSAL, H56₁₆₁₋₁₆₉ MGPSLIGLA) were recognized by CD8⁺ T cells of H56 immunized mice. These responses could be measured up to day 50 after immunization and CD8⁺ T cells showed measurable killing capacity until day 26.

4

Fusion of H56 cDNA to cDNA of UB or TTFC in antigen construct increases immunogenicity

Fusion of antigen-encoding cDNA to cDNA, encoding specific pathogen-derived proteins or self-proteins involved in antigen processing, is known to increase immunogenicity^{18, 27-30, 34-36}. To determine whether the immunogenicity of H56 could be improved likewise, different cDNA fusion constructs encoding H56 preceded by self- and non-self-derived proteins were tested. ICS for identification of specific CD8⁺ T cells (Fig. 2A) or CD4⁺ T cells^{37, 38} (Fig. 2B) at day 17 showed that constructs with ubiquitin (UB)^{29, 36} or tetanus toxin fragment C (TTFC)^{27, 28} fused to the N-terminal end of H56, were capable of enhancing CD8⁺ T cell responses to the H56 epitopes, as compared to responses elicited by immunization with H56 alone, which is poorly immunogenic in this experimental setting (Fig. 2C). The dominance hierarchy of the responses to different epitopes seemed similar for the two H56 fusion constructs, with H56₇₂₋₈₀ MPVGGQSSF being responsible for activation of the largest percentage of CD8⁺ T cells. The control peptide OVA₂₅₇₋₂₆₄ was not recognized, illustrating specificity of the responses. Fusion of H56 to TTFC and UB also enhanced H56 specific CD4⁺ T cell responses (Fig. 2D, Fig. 2E). HLA-F-adjacent transcript 10 (FAT10)^{29, 39} and mouse invariant chain (mLi)^{19, 30} did not increase H56 specific CD8⁺ or CD4⁺ T cell responses (Supplementary Fig.1). We conclude that TTFC and UB are able to increase immunogenicity of the H56 encoding construct.

Substitution of the C-terminal flanking residues of identified H56 epitopes generally increases immunogenicity

The substitution of C-terminal flanking residues of epitopes in the parental antigen sequence can affect proteasome-mediated cleavage and therefore have major consequences for epitope generation¹¹⁻¹⁶. In 5 out of 6 epitopes used in the current study, P1 contains a hydrophobic large residue with the exception of H56₁₆₁₋₁₆₉ MGPSLIGLA (Table 2). Of those 6 epitopes, 3 have a hydrophobic large residue at P1' as well, thereby creating a peptide bond that has been shown to be infrequently hydrolyzed by proteasomes¹⁷. In order to further enhance immunogenicity of the vaccination, we adopted a second strategy in which the flanking residues of the H56 peptides H56₆₂₋₇₀ WYYQSGLSI, H56₇₂₋₈₀ MPVGGQSSF, H56₉₅₋₁₀₃ QTYKWETFL, H56₁₄₆₋₁₅₄ IYAGLSAL, H56₁₆₁₋₁₆₉ MGPSLIGLA, and H56₃₅₄₋₃₆₃ NALQNLARTI were changed to glutamic acid (E)¹⁷. As proof of principle we also included the weakly immunogenic epitopes in our experimental set up, since especially their immunogenicity may be enhanced by introduction of novel COOH-terminal flanking residues that facilitate proteasome-mediated epitope generation. Responses of mice immunized with the modified H56 construct were

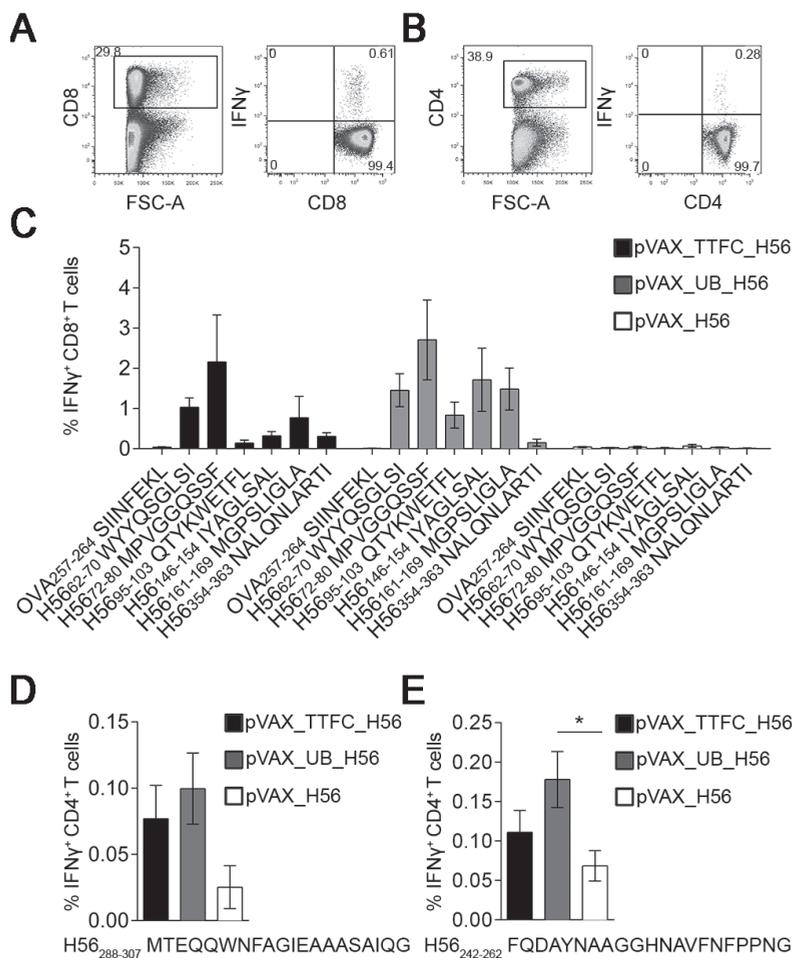

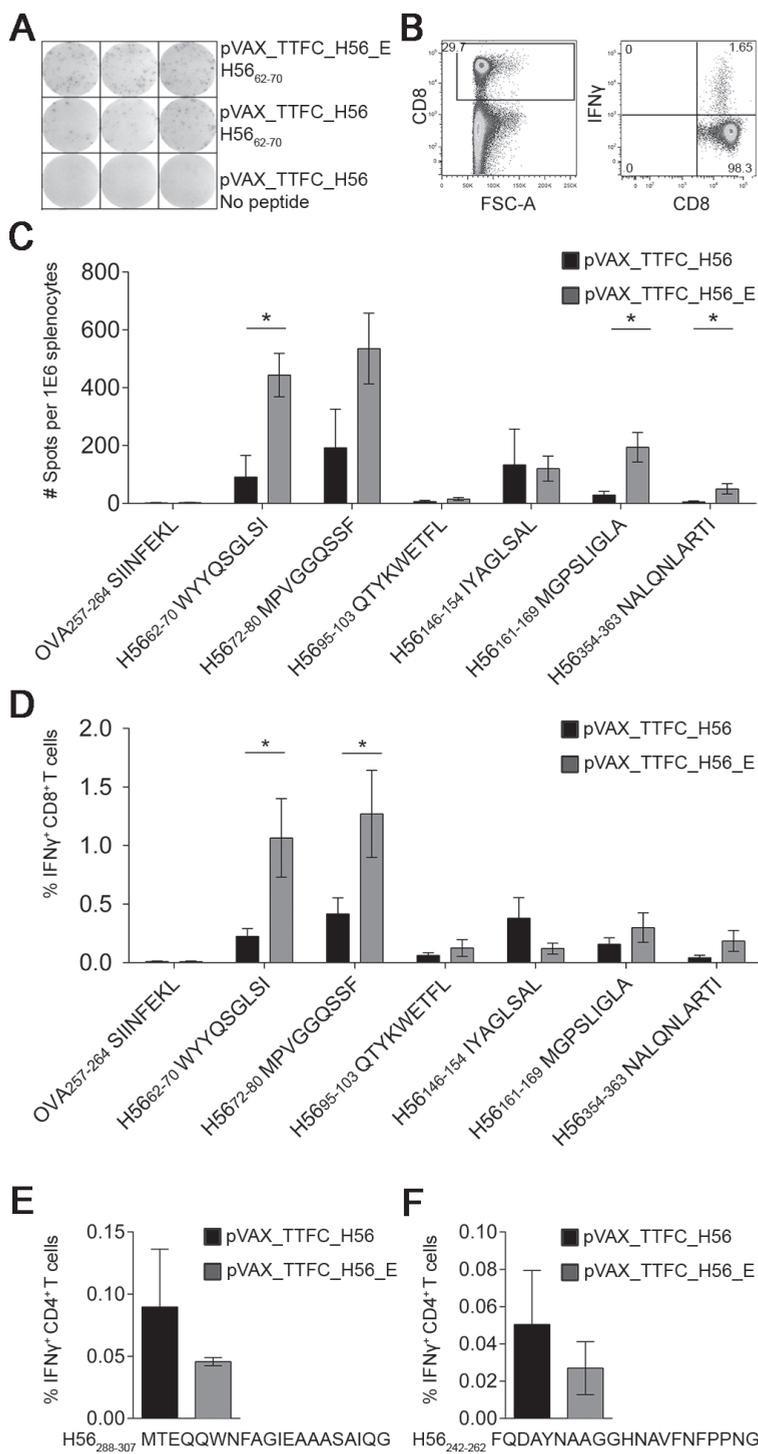

Figure 2. Fusion of H56 cDNA to cDNA of UB and TTFC enhances immunogenicity. (A, B) CB6F1 mice were immunized with H56 cDNA using dermal DNA tattooing and percentages of (A) specific CD8⁺ T cells and (B) CD4⁺ T cells were determined using intracellular cytokine staining at day 17. (C) Data of CD8⁺ T cells are shown as mean of 4-5 mice per group \pm SEM per peptide corrected for IFN γ background level as measured in control samples that were incubated without peptide. (D, E) Data of CD4⁺ T cells are shown as mean of 4-5 mice per group \pm SEM per peptide corrected for IFN γ background level as measured in control samples that were incubated without peptide. P values < 0.05 are depicted with *.

Table 2. Characteristics of last amino acid of epitope or first C-terminal flanking residue of different CD8⁺ T cell epitopes in H56

Epitope	Characteristics P1^a	Residue at P1'	Characteristics P1'^a
H56 ₆₂₋₇₀ WYYQSGLSI	HL	V	HS
H56 ₇₂₋₈₀ MPVGGQSSF	HL	Y	HL
H56 ₉₅₋₁₀₃ QTYKWETFL	HL	T	PS
H56 ₁₄₆₋₁₅₄ IYAGLSAL	HL	L	HL
H56 ₁₆₁₋₁₆₉ MGPSLIGLA	HS	M	HL
H56 ₃₅₄₋₃₆₃ NALQNLARTI	HL	S	PS

^a Amino acid characteristics of last residue of epitope (P1) and C-terminal flanking residue (P1'). Amino acid characteristic acronyms are the following: HS, hydrophobic small; HL, hydrophobic large; PS, polar small.

Figure 3. C-terminal flanking residue modulation of epitopes from hydrophobic- to polar residues enhances immunogenicity. (A-D) CB6F1 mice were immunized with H56 cDNA using dermal DNA tattooing. **(A, C)** At day 17 IFN γ ELISpot was used to measure IFN γ secreting T cells in spleen. Data are shown as mean \pm SEM of 5 mice per group per peptide corrected for IFN γ background level as measured in control samples that were incubated without peptide, and are representative of pooled data of 2 independent experiments out of 4 independent experiments. **(B, D)** Additionally at day 17 using, intracellular cytokine staining, percentages of epitope specific CD8⁺ T cells in the spleen were measured *ex vivo*. Data are shown as mean \pm SEM of 5 mice per group measured in triplicate per corrected for IFN γ background level as measured in control samples that were incubated without peptide, and are representative of 3 independent experiments. **(E,F)** Data of CD4⁺ T cells are shown as mean of 4 mice per group \pm SEM per peptide corrected for IFN γ background level as measured in control samples that were incubated without peptide. **(A-D)** All data were analyzed using a two tailed independent sample T test comparing pVAX_TTFC_H56 immunized animals with pVAX_TTFC_H56_E immunized animals per peptide, combined with a Sidak-Holm correction for multiple comparisons. P values < 0.05 were considered significant and marked by *.

4

compared to those triggered by the wildtype H56 version using IFN γ ELISpot (Fig. 3A) and IFN γ ICS (Fig. 3B). Both assays showed the same pattern of CD8 $^+$ T cell responses that were enhanced to E-flanked epitopes. IFN γ ELISpot showed 3 out of 6 E-flanked epitopes to be enhanced (Fig. 3C) and ICS 2 out of 6 (Fig. 3D). The overall results of these two assays, despite inter-experimental differences, were similar and combining these two assays, we found that 4 epitopes (H56₆₂₋₇₀ WYYQSGLSI, H56₇₂₋₈₀ MPVGGQSSF, H56₁₆₁₋₁₆₉ MGPSLIGLA, H56₃₅₄₋₃₆₃ NALQNLARTI) showed an enhanced immunogenicity following substitution of their C-terminal flanking residue for E, whereas immunogenicity of H56₁₄₆₋₁₅₄ IYAGLSAL seemed mildly diminished. The control peptide OVA₂₅₇₋₂₆₄ was not recognized, illustrating specificity of the responses. The substitutions at the P1' site were not in the regions encoding the H56 CD4 $^+$ T cell epitopes H56₂₄₂₋₂₆₂ FQDAYNAAGGHNAVFNFPPNG and H56₂₈₈₋₃₀₇ MTEQQWNFAGIEAAASAIQG_{37, 38} and they did not influence the CD4 $^+$ T cell response to these epitopes (Fig. 3E, Fig. 3F). Thus, C-terminal flanking residue substitution to E, where the hydrophobic epitope C-terminus is followed by a hydrophobic large or small residue in the wildtype sequence, can increase the CD8 $^+$ T cell response independent of the CD4 $^+$ T cell response.

The substitution of the C-terminal flanking residue of H56 derived epitopes alters their generation dynamics by the proteasome

To investigate the biochemical effects of substitution of the C-terminal flanking residues of the H56-derived epitopes into E, we performed *in vitro* digestions of the synthetic substrates H56_{137-160'}, H56_{64-86'} and H56₅₃₋₇₉ with mouse spleen 20S proteasomes. In the digestions of the first two substrates we identified the epitopes H56₁₄₆₋₁₅₄ IYAGLSAL and H56₇₂₋₈₀ MPVGGQSSF and their potential N-extended precursors, for the latter substrate we neither identified the epitope H56₆₂₋₇₀ WYYQSGLSI nor its potential precursors (data not shown). The inability of MS to identify epitopes in *in vitro* proteasome-mediated digestions, which are generated *in vivo* in a proteasome-dependent fashion, has been reported^{24, 40, 41} and is likely due to the limited sensitivity of the MS methods used.

By using the quantitative analytical approach based on QME method²⁴, for comparison of H56₁₃₇₋₁₆₀ and H56₆₄₋₈₆ wild type and mutated substrates, we observed that the H56 L₁₅₅E and the Y₈₁E substitutions did not improve the relative frequency of cleavage after the preceding residues L₁₅₄ and F₈₀', respectively (Supplementary Fig. 2). The substitutions however modified the peptide pool produced by the proteasome (data not shown) and altered the overall substrate degradation rate and the proteasome preference of hydrolysis of peptide bonds

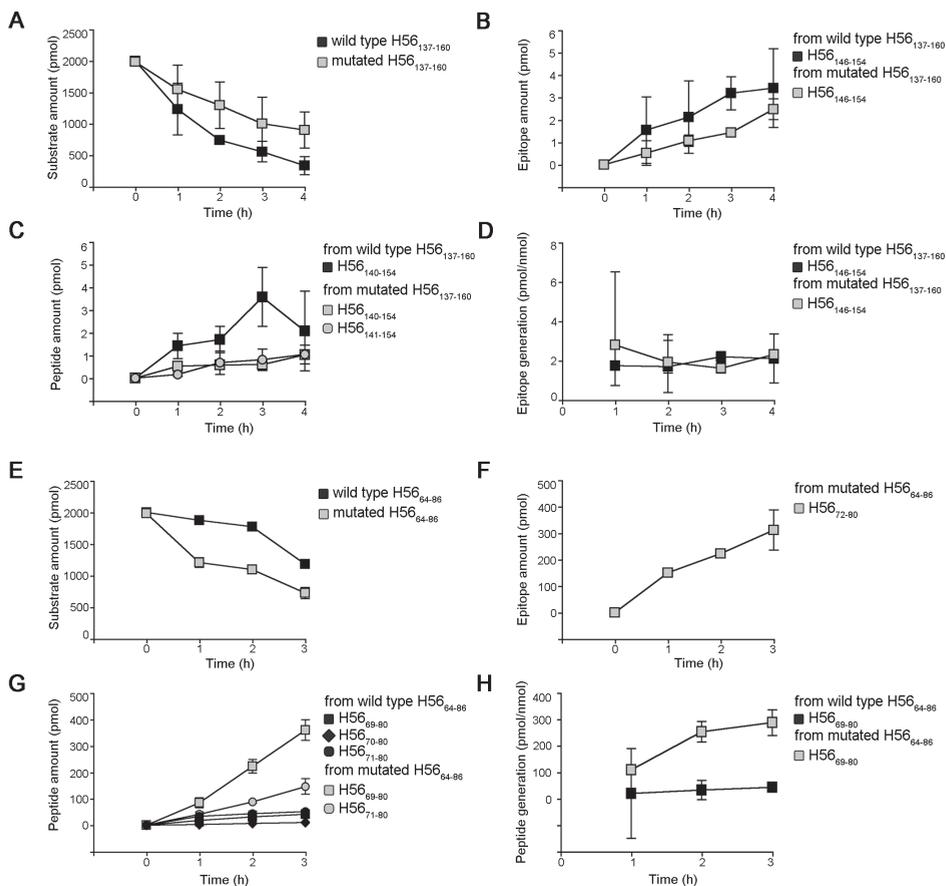

Figure 4. Substitution at the C-terminal flanking epitope residue affects the epitope production by 20S proteasomes. (A, E) Quantitative kinetics of substrate degradation and (B-D, F-H) generation of the immuno-relevant peptides of the synthetic wild type and mutated (A-D) H56₁₃₇₋₁₆₀ and (E-H) H56₆₄₋₈₆ substrates by mouse spleen 20S proteasomes. Peptide quantification was carried out by applying QME to the LC-MS analyses. Data are the mean and bars the SD of repeated measurements of a representative kinetics of two independent experiments. (D, H) The generation efficiency for the epitopes H56₁₄₆₋₁₅₄ and the potential precursor H56₆₉₋₈₀, measured as pmol peptide *per* nmol of substrate consumed over time, was compared between wild type and mutated substrates.

distant from the H56_{L₁₅₅}E or the Y₈₁E substitutions (Fig. 4 and Supplementary Fig. 2).

The H56_{L₁₅₅}E substitution decelerated the degradation of the synthetic substrate (Fig. 4A), which partially hampered the amount of the epitope H56₁₄₆₋₁₅₄ IYAGLSAL (Fig. 4B) and its potential precursor H56₁₄₀₋₁₅₄ (Fig. 4C), which was also produced *in vitro*. The altered substrate degradation was likely the only factor influencing the epitope and precursor generation since the epitope generation efficiency was unaffected (Fig. 4D). On the contrary, the Y₈₁E substitution enhanced the substrate degradation rate (Fig. 4E), the amount of the epitope H56₇₂₋₈₀ MPVGGQSSF (identified only in the mutated substrate H56₆₄₋₈₆ digestion; Fig. 4F) and of its N-extended potential precursors H56₆₉₋₈₀ and H56₇₁₋₈₀ (Fig. 4G). In contrast to the other epitopes the substitution in this case directly improved not only the absolute amount of the N-extended potential precursor but also its generation efficiency (Fig. 4H). Of note, N-extended versions of other self and virus epitopes have been demonstrated to be able to trigger a CD8⁺ T cell response even in absence of N-terminal trimming^{26, 42}. This *in vitro* quantitative analysis could thus explain the enhanced *in vivo* responses to E-flanked H56₇₂₋₈₀ MPVGGQSSF.

Discussion

Most vaccines aim to induce humoral responses, with immune protection mediated by neutralizing antibodies. In a number of diseases caused by intracellular pathogens, such vaccines provide insufficient protection. Because CD8⁺ T cells can provide protection in these cases, novel vaccination strategies are developed allowing the induction of effective CD8⁺ T cell responses. Modulation of antigen processing represents a strategy to enhance vaccine efficacy and here we report its applicability. In the model antigen H56 seven epitopes (H56₆₂₋₇₀ WYYQSGLSI, H56₉₅₋₁₀₃ QTYKWETFL, H56₁₆₁₋₁₆₉ MGPSLIGLA, H56₃₀₉₋₃₁₆ VTSIHSLI, H56₃₅₄₋₃₆₃ NALQNLARTI, H56₄₂₇₋₄₃₄ SQFTFSSR, H56₄₄₃₋₄₅₁ AGQSWCAIL) were discovered. Among them one – *i.e.* the epitope H56₆₂₋₇₀ WYYQSGLSI - was found as an epitope presented by HLA-A*24:02 MHC class I molecules⁴³. The processing of H56 was altered in order to increase immunogenicity. We report that fusion of H56 cDNA to cDNA encoding TTFC or UB (Fig. 2) alone or in combination with a change of the (hydrophobic) C-terminal epitope flanking residues to polar residues, improves the vaccine-induced epitope specific CD8⁺ T cell response (Fig. 3 and Fig. 4).

Numerous methods to enhance DNA vaccine potency have been reported in recent years, either by co-delivery of chemokines ⁴⁴, TLR agonists ⁴⁵ or co-stimulatory genes ⁴⁶. In the current study we report fusion to UB or TTFC to enhance immunogenicity. TTFC domain 1 has been shown to increase immunogenicity ^{27, 28, 47} and was therefore used in the current study to discover novel epitopes since H56 in itself is poorly immunogenic in cDNA tattoo immunization (Fig. 2C). We have no indications that TTFC affects the specificity of induced CD8⁺ T cell responses, since (i) the known epitopes H56₁₄₆₋₁₅₄ IYAGLSAL and H56₇₂₋₈₀ MPVGGQSSF ³¹⁻³³ were confirmed in our study, and (ii) immunization with the pVAX_H56 construct induced similar responses as immunization with the pVAX_TTFC_H56 fusion construct, but percentages of epitope specific CD8⁺ T cells were very low. The immunogenicity enhancing properties of TTFC is likely due to peptide P30 (TTFC₉₁₋₁₁₁) which contains multiple DR- and DP presented CD4⁺ T cell epitopes ^{34, 48} as well as mouse MHC class II presented epitopes ²⁸. CD4⁺ T cell help is crucial for CD8⁺ T cell responses in DNA vaccination ^{27, 28, 49}. In our study, we even found TTFC to be able to enhance the H56 specific CD4⁺ T cell response. UB naturally does not contain CD4⁺ T cell epitopes but was able to enhance H56 specific CD4⁺ T cells in the current study, as shown before for viral antigens ³⁶. This immunogenicity enhancement might be due to modified degradation kinetics when an antigen is fused to UB ²⁹ but also to a different antigen routing in cross-presenting professional antigen presentation cells, thereby leading to improved CD4⁺ and CD8⁺ T cell priming.

Besides by linkage to immunogenicity-enhancing sequences, a more immediate way of modulating antigen processing is directly influencing the cleavage by the proteasome by alteration of C-terminal flanking residues of epitopes. This can be tested accurately *in vitro*. Correlations between quantitative analysis of *in vitro* proteasome-mediated digestions and *in vivo* data have been shown ^{6, 43, 50} and are confirmed in this study. Noteworthy however, the E-substitutions in the mutated version had unpredictable effects on the usage of substrate cleavage-sites distant to the substitution and the substrate turnover as demonstrated in other examples ^{26, 51}. This can be caused by substitution-dependent alterations of the substrate transport in the proteasome cavity or the regulation of non-catalytic modifier sites, which have been described as driving factors of proteasomal dynamics ⁵.

In the current study an *Mtb* antigen was used as a model vaccine antigen but the proven strategies could be of help in vaccination against actual *Mtb* infection as well. Super immunogenic epitopes derived from conserved antigens, that induce vigorous responses associated with inflammation, immunopathology, and lung

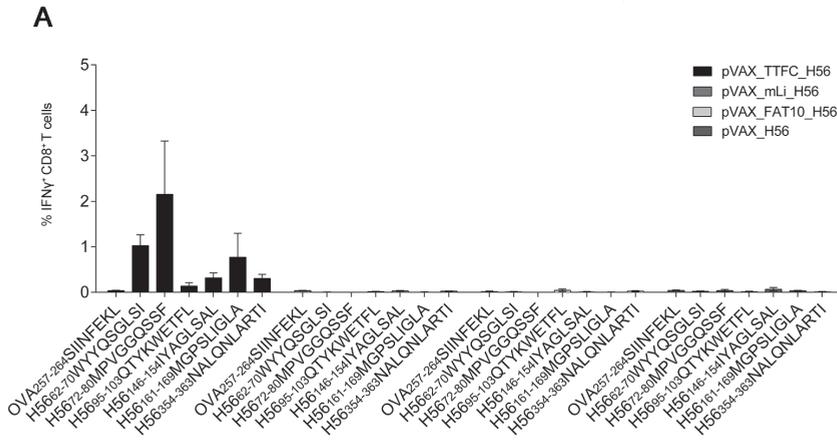

cavitation can be crucial for existence and transmission of *Mtb*⁵²⁻⁵⁴. It was therefore suggested to focus on variable antigens and target cryptic- or subdominant epitopes⁵⁴. In mice a reduction in *Mtb* bacterial load has already been shown following vaccination with different subdominant antigens in glucopyranosyl lipid adjuvant in stable emulsion⁵⁵. CD8⁺ T cells specific for a selection of the novel (subdominant) epitopes showed killing capacity until day 26 in this study. Whether these CD8⁺ T cell populations are effectively reactivated upon exposure with the pathogen remains to be determined. It should be noted however that, contrary to mice in which, depending on the strain, CD4⁺ or CD8⁺ T cells control infection³¹, in humans multifunctional CD4⁺ T cells seem to be more important than CD8⁺ T cells, as illustrated by findings that *Mtb*-infected HIV patients that lack CD4⁺ but still possess CD8⁺ T cells rapidly succumb to infection^{56,57}. When, as is the case in the current study, sufficient CD4⁺ T cell help is provided to the CD8⁺ T cells by successful vaccine design, vaccine improvement by eliciting CD8⁺ T cell responses specific for subdominant epitopes could increase *Mtb* vaccine efficacy.

Abstract

Tuberculosis (TB), caused by *Mycobacterium tuberculosis* (*Mtb*), remains a global health threat. *Mycobacterium bovis* bacillus Calmette-Guérin (BCG) was introduced as a vaccine in 1924 but lacks efficacy. Several antigens can be used to boost the effect of BCG, such as the multistage vaccine H56, which encodes Ag85B, ESAT-6 and Rv266oc of *Mtb*. In this study we tested different heterologous and homologous prime-boost strategies, based on subcutaneous injection of BCG and dermal H56 cDNA tattoo immunization, for their ability to boost *Mtb*-specific immune protection. We measured cellular- and humoral immune responses and correlated this to protective efficacy in a challenge model. Dermal H56 cDNA tattoo immunization induced mainly H56-specific CD4⁺ and CD8⁺ T cell responses, H56-specific IgG1 and expanded the CD4⁺ T_{CM} cell population. BCG immunization resulted in a broad cellular response, with increased frequencies of CD4⁺ T_{EM} cells, as well as an *Mtb* lysate-specific IgG1 and IgG2c responses. When combining these immunizations we found that the order in which the immunizations are given is important. The most promising reduction in bacterial loads in spleens was measured in mice primed by H56 cDNA *i.d.* and boosted with BCG ::H56 *s.c.*, while immunizations in reverse order were less effective. Additionally, this H56 cDNA *i.d.*/BCG ::H56 *s.c.* prime-boost group, as well as mice vaccinated with homologous BCG ::H56 in prime-boost showed a slight trend towards decreased bacterial loads compared to the standard, BCG vaccination. These results will contribute to successful vaccination against *Mtb*.

Introduction

Tuberculosis (TB) remains a global health threat, with 9.6 million infections and 1.5 million deaths reported in 2014^{1,2}. An attenuated form of the causative agent of bovine tuberculosis known as *M. bovis* bacillus Calmette-Guérin (BCG) was introduced as a live vaccine in 1924 and is widely administered in TB endemic countries³. BCG has contributed to a reduction in childhood mortality⁴ and provides protection against TB meningitis and other forms of disseminated TB. However, it is clear that BCG fails to adequately protect against the pulmonary form of disease⁵. As BCG is given at birth throughout the developing world, a new TB vaccine for children should take into account the fact that the majority of the population has already been BCG-vaccinated. For these reasons, new vaccine strategies aim to improve the efficacy of BCG by modifying it, combining it with boosting vaccines, administering it with different adjuvants or altering the route of vaccination⁶⁻¹¹.

A crucial starting point in improving vaccine strategies is knowledge of immune responses that correlate with protection in *Mycobacterium tuberculosis* (*Mtb*) infection. However, the precise mechanisms of *Mtb* control are not known. Nevertheless, it is known that the cellular response is important, as shown in reports studying the efficacy of recombinant BCG strains expressing the *hly* gene encoding for listeriolysin O (LLO) from *Listeria monocytogenes*, in combination with the deletion of urease C, which provides a pH closer to that optimal for LLO activity¹²⁻¹⁴. It was shown in vaccination studies with this BCG $\Delta ureC::hly$ that central memory CD4⁺ T cells (T_{CM}), which secrete cytokines such as IFN γ , IL-2 and TNF α , are important in protecting against infection¹³. Additionally, BCG $\Delta ureC::hly\Delta nuoG$ vaccinated mice, which were more protected than BCG $\Delta ureC::hly$ vaccinated mice, had relatively increased effector memory CD4⁺ T cells (T_{EM}), T follicular helper cells (T_{FH}) and germinal center B cells¹⁴. In other studies, Ag85B-specific CD4⁺ T_{EM} were also shown to control infection in the lungs¹⁵. Next to the CD4⁺ T cells, CD8⁺ T cells also appeared to protect against *Mtb*¹⁶⁻¹⁹. Additionally, there are studies that report about the role of B cells and antibodies in tuberculosis^{20,21}. However, although vaccination with the more protective BCG $\Delta ureC::hly$ strain leads to increased antibody responses in mice, passive transfer of serum from mice vaccinated with BCG $\Delta ureC::hly$ into naive mice did not increase protection to tuberculosis in initial studies¹³.

Next to genetic modification by insertion of *hly* or deletion of *ureC* or *nuoG*, efficacy of BCG can also be increased by use of adjuvants or boosting with

antigens encoding *Mtb* proteins^{6, 7, 9, 11}. Aagaard et al.²² created the multistage vaccine H56, which is composed of three antigens of *Mtb*: Ag85B, ESAT-6 and Rv266oc. Ag85B and ESAT-6 are both immunogenic proteins (with Ag85B also being present in BCG) and are secreted early in infection²³, while Rv266oc is a latency-associated secretory protein²⁴. As part of the ADITEC vaccine consortium²⁵, H56 was chosen as a model antigen for testing of different vector vaccines, adjuvants and vaccination strategies. When administered with adjuvant CAF01^{26, 27, 28} or IC31^{28, 29}, vaccination with H56 or H56-derived antigens, protected against *Mtb* infection in mice. Recently, Platteel et al.³⁰ showed that dermal tattoo administration³¹ of H56 cDNA fused to tetanus toxin fragment C (TTFC) cDNA elicited vigorous antigen-specific CD4⁺ T cell and CD8⁺ T cell responses targeted to H56, without the need for adjuvants.

In the present study we aimed to compare the efficacy of dermal DNA tattoo immunization to that of BCG immunization, and of different heterologous and homologous prime-boost strategies using dermal H56 cDNA tattoo immunization in combination with subcutaneous injection of BCG or BCG ::H56³² *in vivo*. Protective capacity in *M. tuberculosis* infection, and correlates of the induced, specific immune responses were determined.

Materials and methods

Mice

Six to eight weeks old CB6F1 mice were purchased from Charles River. All animal studies were ethically approved by the State Office for Health and Social Services, Berlin, Germany. We designed two protocols, one for single vaccination and one for prime-boost vaccination, each consisting of twenty mice divided into two groups of ten for manageability and performed in two separate experiments.

DNA and dermal DNA tattoo vaccination

The full length H56 cDNA²² was codon optimized and consists of tetanus toxin fragment C domain 1 (TTFC)^{33, 34} in pVAX1 vector (Invitrogen) as described before³⁰. DNA tattoo immunization was performed with 15 μ l cDNA (2 μ g/ μ l) in TE buffer with a 9-needle bar mounted on a tattoo rotary device (Cheyenne) on 100 Hz, at 1 mm depth for 1 minute³¹ under isoflurane anesthesia.

BCG vaccination and *M. tuberculosis* challenge

The *M. tuberculosis* H37Rv (American Type Culture Collection; catalog no. 27294), BCG Danish 1331 (BCG SSI) (American Type Culture Collection; catalog no. 35733) and BCG ::H56³² (made in house, on BCG SSI background), were grown in Middlebrook 7H9 broth (BD) supplemented with albumin-dextrose-catalase enrichment (BD), 0.2% glycerol, and 0.05% Tween 80 or on Middlebrook 7H11 agar (BD) containing 10% (vol/vol) oleic acid-albumin-dextrose-catalase enrichment (BD) and 0.2% glycerol. BCG and BCG ::H56 were grown to mid-log phase, washed with phosphate-buffered saline (PBS) and stored at 80°C in PBS-10% glycerol until vaccination for which they were administered with a dose of 10⁶ CFU in PBS for both subcutaneous and dermal routes. Aerosol challenge with *M. tuberculosis* was performed using a dose of 20-50 CFU.

Vaccine efficacy studies

For measurements of the bacterial load, lungs and spleens were harvested and serial dilutions were performed in PBS-0.05% Tween 80 (PBST) and plated on Middlebrook 7H11 agar.

Peptides

All peptides were synthesized using Fmoc solid phase chemistry. The sequence enumeration of the synthetic peptides referred to the vaccine H56²². The eighty-five 15mer peptides used as pool to measure the total amount of H56-specific T cells (provided as a kind gift from Dr Donatella Negri) spanned the entire amino-acid sequence of H56, overlapping by 10 amino acid residues, and were synthesized by PRIMM srl.

Analysis of specific CD8⁺ and CD4⁺ T cell responses using intracellular cytokine staining

For intracellular cytokine production, splenocytes were plated overnight with or without 1 µg/ml peptide at 37°C. During the last 4 hrs, brefeldin (5µg/ml, Sigma) was added to wells incubated with peptide or phorbol myristate acetate (50 ng/mL, Sigma) and ionomycin (250 ng/mL, Sigma) or to cells incubated with medium alone. Cells then were stained for the cell surface markers named below, fixed with 2% paraformaldehyde, permeabilized with saponin buffer (saponin, 1 g/liter; CaCl₂, 0.11 g/liter; MgSO₄, 0.125 g/liter; NaN₃, 0.5 g/liter; bovine serum albumin [BSA] 1 g/liter; 10 mM HEPES in PBS, pH 7.4), and stained for intracellular cytokine production as described³⁰. The cell surface- and intracellular cytokine panel consisted of TCRβ-A700 (Biolegend; clone H57-597), CD4-Pacific Blue (Biolegend; clone GK1.5), CD8-PerCP (Biolegend; clone 53-6.7), IL2-APC (Biolegend; clone

JES6-5H4), IFN γ -PE-Cy7 (Biolegend; clone XMG1.2), IL17-PE (Biolegend; clone TC11-18H10.1), TNF α -FITC (homemade; clone YT-22). Samples were acquired on a LSR II cytometer (BD Biosciences) with BD FACS Diva software and analyzed using FlowJo v10 (TreeStar).

Analysis of specific CD8⁺ T cell responses by IFN γ ELISpot

Multiscreen ELISPOT plates (Millipore) were coated with 2 μ g/ml AN18 in PBS overnight at 4 °C. Wells were washed and blocked with 5% BSA/PBS. 5×10^5 erythrocyte depleted lymph node cells were plated with or without 1 μ g/ml synthetic peptide overnight in IMDM with 10% fetal calf serum (FCS) Pen-Strep at 37 °C. Plates were washed with PBS plus 0.01% Tween 20 (PBS-T), and IFN γ was detected with biotinylated IFN γ (homemade; clone XMG1.2), followed by alkaline phosphatase-conjugated streptavidin (home-made), in PBS-T supplemented with 2% BSA. The assay was developed with NBT/BCIP substrate (Thermo fisher scientific) and analyzed using an Immunopost S6 Ultra-V Analyzer (CTL).

Analysis of T and B cell sub-populations

Spleens were collected and single-cell suspensions were generated in Iscove's modified Dulbecco's medium (IMDM) 10% fetal calf serum (FCS) Pen-Strep. Cells were surface stained to quantify cell populations. T cell panel: CD3-Alexa 700 (BioLegend; clone 17A2), CD4-PE-Cy7 (BioLegend; clone RM4-5), CD8-V500 (BD Horizon, clone 53-6.7), CD62L-APC (BD Pharmingen; clone MEL-14), CD44-Pacific Blue (homemade, clone IM7), CXCR5-PE (BioLegend; clone J252D4), CCR7-PerCP (BioLegend; clone 4B12), PD-1-FITC (BioLegend; clone 29F.1A12), KLRG1-CF594 (BD, clone 2F1). B cell panel: B220-PE (BioLegend; clone RA3-6B2), CD38 APC (BioLegend; clone 90), Fas-PE-Cy7 (BioLegend; clone Jo2), GL7-FITC (BioLegend; clone GL7), MHC II-Pacific Blue (BioLegend; clone M5/114.15.2), CD19-A700 (BioLegend; clone 6D5), CD138-Percp (BioLegend; clone 281-2). Central memory CD4⁺ T cells were CD3⁺ CD4⁺ CD44^{high} CD62^{high}, effector memory CD4⁺ T cells were CD3⁺ CD4⁺ CD44^{high} CD62L^{low}, T follicular helper cells were CD3⁺ CD4⁺ CXCR5⁺ PD-1⁺, germinal center B cells were B220⁺ CD19⁺ GL7⁺ Fas⁺ and plasma cells CD138⁺ CD38⁺.

Specific antibody responses

Mycobacterium-, Ag85B- and ESAT-6-specific antibodies in serum were measured by indirect enzyme-linked immunosorbent assay (ELISA) using *M. tuberculosis* H37Rv lysate (BEI Resources), Ag85B (BEI Resources), or ESAT-6 (BEI Resources) to coat and alkaline-phosphatase (AP) labelled anti-mouse IgG1 and IgG2c for detection (SouthernBiotech).

Heat maps

The scripts for figures 1, 4, S1 and S4 are available upon request. FACS data visualization was designed using R-package ggplot2 (v2.1.0; Springer-Verlag New York, 2009.) in R programming language (v3.2.3; R Development Core Team (2008)). The mean values of percentages of CD4⁺ or CD8⁺ T cells producing cytokines after peptide stimulation were normalized to control samples stimulated with medium and visualized using heat maps. ELISpot data visualization was designed using R-package ggplot2 (v2.1.0; Springer-Verlag New York, 2009) in R programming language (v3.2.3; R Development Core Team (2008)). The mean numbers of IFN γ producing cells per million cells after peptide stimulation were normalized to control samples stimulated with medium. For visualization purposes, the mean value for each experimental condition was transformed to square root of mean response signal and displayed as a heat map.

Statistics

Data were tested for normality distribution and homoscedasticity by Kolmogorov-Smirnov, Shapiro-Wilk and Levene tests. To identify differences between groups for the T- and B cell panels and humoral responses, data were analyzed using a one-way ANOVA with Tukey's post hoc correction. $P < 0.05$ was considered to be significant.

Results

Vaccination with dermal DNA tattoo immunization or subcutaneous injection with BCG induces different H56-specific T cell responses

We first measured the immune responses after a single vaccination with BCG or H56 cDNA (Fig. 1A). Subcutaneous (*s.c.*) injection with BCG is known to lead to an approximately 1 log protection in mouse models^{35,36} and was included as the standard against which the efficacy of BCG::H56 or dermal tattoo immunization (*i.d.*) with BCG or DNA were compared. The DNA vaccines included the canonical versions of H56 and H56_E, in which six CD8⁺ T cell epitopes have been optimized to enhance proteasome-mediated processing³⁰, and were administered at day 0, 3 and 6. The two BCG strains were administered by *s.c.* injection at day 0 (Fig. 1A). One group of mice was also vaccinated by tattoo immunization with BCG (day 0 only), in order to compare *s.c.* and *i.d.* administration of BCG. Immune responses were measured at day 21 and the efficacy of the methods was tested by subjecting the mice to an aerosol challenge with *Mtb* at day 60 (Fig. 1A).

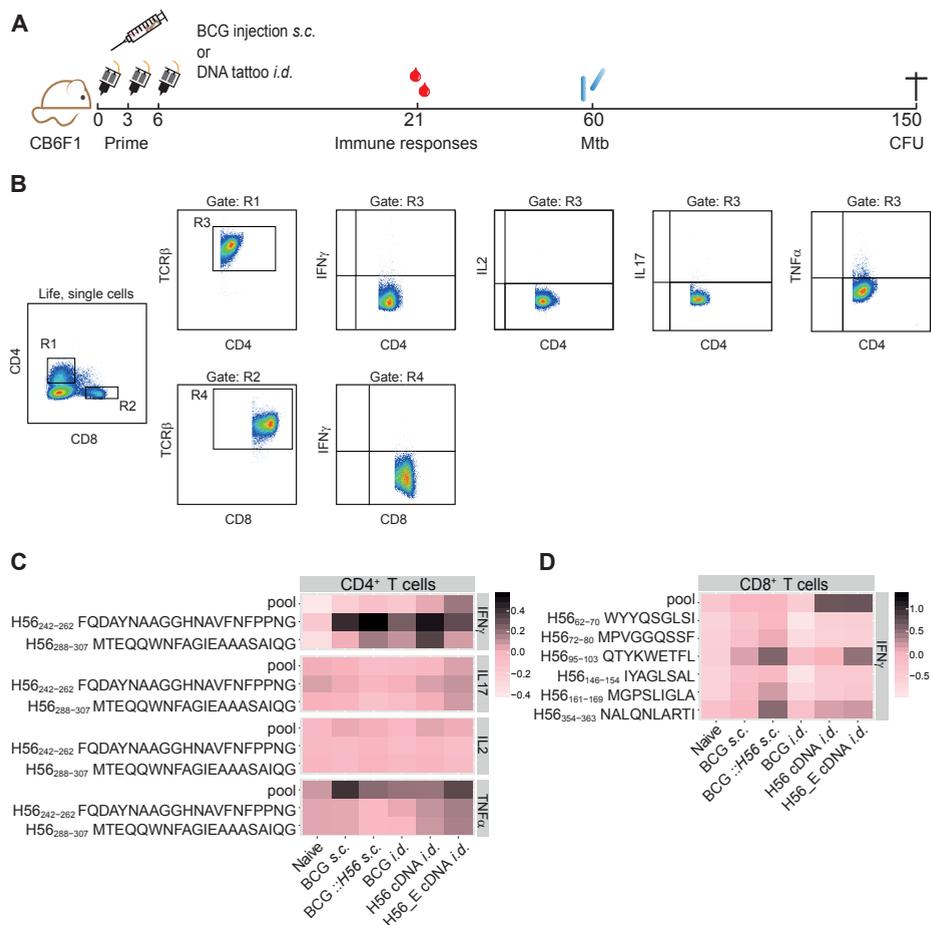

Fig. 1. Vaccination with dermal H56 or H56_E cDNA tattoo immunization or subcutaneous injection with BCG induces different H56 specific CD4⁺ and CD8⁺ T cell responses. Intracellular cytokine staining was performed on splenocytes harvested at day 21 post vaccination and re-stimulated with different H56 peptides. The peptide pools consisted of eighty-five 15-mer peptides spanning the entire sequence of H56, as a measure of the total percentage of H56-antigen specific cells. CD4⁺ T cell epitopes included H56₂₄₂₋₂₆₂ (Ag85B derived) and H56₂₈₈₋₃₀₇ (ESAT-6 derived). The CD8⁺ T cell epitopes included H56₃₅₄₋₃₆₃ (ESAT-6 derived) and five epitopes of Ag85B. Analysis was done using FACS. The results show pooled data from two independent experiments (n=10 in total). (A) Immunization scheme. (B) Gating strategy for FACS analysis. After gating on live, single cells, cells were gated on CD4⁺ (R1) or CD8⁺ (R2). Both R1 and R2 were gated on TCRβ⁺ cells (R3) and (R4). (C) Heat maps showing mean frequency of CD4⁺ T cells secreting IFN γ , IL-17, IL-2 or TNF α after peptide stimulation, normalized to medium incubated cells. (D) Heat maps showing mean frequency of CD8⁺ T cells secreting IFN γ , IL-17, IL-2 or TNF α after peptide stimulation, normalized to medium incubated cells.

To study H56-specific cellular responses, splenocytes or lymphocytes from vaccinated mice were re-stimulated *ex vivo* with Ag85B- and ESAT6-derived CD8⁺ and CD4⁺ 37,38 T cell epitopes and responses in the spleen were measured using ICS and flow cytometry (Fig. 1B) or in the draining lymph nodes by IFN γ ELISpot (Fig. S1). The mean values of percentages of CD4⁺ or CD8⁺ T cells producing cytokines after peptide stimulation were normalized to control samples stimulated with medium and were visualized using heat maps (Fig 1C-D). Incubation of splenocytes with the pool of 15-mers overlapping the H56 sequence mostly induced IFN γ production by CD4⁺ T cells from H56 and H56_E *i.d.* vaccinated mice which illustrates the total amount of H56-specific CD4⁺ T cells. When looking to single epitope specific cells, we found that CD4⁺ T cells from all vaccinated mice responded to the Ag85B-derived H56₂₄₂₋₂₆₂ epitope, mainly by production of IFN γ (Fig. 1C). ESAT-6-derived H56₂₈₈₋₃₀₇ was recognized by cells from the H56 cDNA *i.d.* and BCG ::H56 *s.c.* vaccinated mice while dermal tattoo immunization or subcutaneous injection with BCG did not generate CD4⁺ T cells recognizing this epitope because it is derived from ESAT-6, which is not present in BCG. A strong H56-specific response in H56 or H56_E cDNA *i.d.* vaccinated mice was also observed in IFN γ ELISpot analyses of lymph node cells (Fig. S1). No differences in IL-17 and IL-2 secretion by spleen CD4⁺ T cells were detected between the groups (Fig 1C). TNF α production was strongest in CD4⁺ T cells of mice vaccinated with H56_E DNA *i.d.* Since most TNF α production was measured after *ex vivo* incubation with the pool of 15-mers derived from H56, the two individual epitopes studied were not responsible for the activation of the majority of specific CD4⁺ T cells. In agreement to IFN γ production as a result of incubation with the pool of peptides by CD4⁺ T cells (Fig. 1C) and IFN γ ELISpot (Fig. S1), the H56 and H56_E *i.d.* vaccination regimens induced the highest percentages of total H56-specific cells (Fig.1D). Single H56 epitope specific CD8⁺ T cells were activated by all the vaccines containing H56 (Fig. 1D), *i.e.* BCG ::H56, H56 cDNA and H56_E cDNA. All CD8⁺ T cell epitopes were derived from Ag85B except for H56₃₅₄₋₃₆₃ which was derived from ESAT-6 and hence was not recognized by CD8⁺ T cells from mice vaccinated *s.c.* or *i.d.*, with BCG. Taken together these results show that dermal H56 cDNA tattoo immunization mainly induces H56-specific CD4⁺ and CD8⁺ T cells while BCG activates T cells specific for Ag85B in H56 because ESAT-6 and Rv266oc are not present.

(A-I) Significant differences between T- or B cell populations or antibody titers of treatment groups compared to the naive group are marked as * and significant differences between the groups with lines (ANOVA with Tukey's multiple comparison test; * p < 0.05; ** p < 0.01; *** p < 0.001; **** p < 0.0001; ≥ minimum amount of * for combined indicated groups).

5

Differential immune responses after vaccination by dermal H56 cDNA tattoo immunization or subcutaneous injection with BCG or BCG ::H56

In order to gain more information on the type of responses elicited by the different immunization strategies, we measured the T cell memory populations and B cell responses by flow cytometry (Fig. 2A). Compared too naive, and especially H56 cDNA *i.d.* vaccinated mice, *s.c.* vaccination with BCG or BCG ::H56 resulted in the highest percentages of CD4⁺ T_{EM} cells in the total CD4⁺ T cell population (Fig. 2B). CD4⁺ T_{FH} cell showed similar trends (Fig. 2C), while frequencies of CD4⁺ T_{CM} cells were higher in the DNA *i.d.* vaccinated mice (Fig. 2D). There were no significant differences in frequencies of CD8⁺ T_{EM} or CD8⁺ T_{CM} populations between the groups (data not shown).

Humoral responses may contribute towards protection against TB ^{20, 21}. We measured the frequencies of plasma cells and germinal center cells among the B cells by flow cytometry (Fig. 2E) and specific antibodies by ELISA (Fig. 2H-I). There was a trend towards more plasma cells in mice that were vaccinated with BCG or BCG ::H56 either *s.c.* or *i.d.* (Fig. 2F), and an elevation in the percentages of germinal center B cells in these groups compared to naive animals or mice of other groups (Fig. 2G). In accordance, levels of specific IgG antibodies against

Mtb H37RV lysate (*Mycobacterium* specific antibodies) were increased in these groups (Fig. 2H), suggesting that BCG elicits a broader response as it contains many mycobacterial proteins whereas the DNA vaccines only encode H56. BCG ::H56 appeared to preferentially induce IgG2c rather than IgG1, whereas BCG induced both IgG2c and IgG1. Highest Ag85B specific titers were measured in the groups that had been immunized with H56 cDNA *i.d.* (Fig 2I). ESAT-6 specific antibodies were not detectable (data not shown). Thus, profound differences in T cell populations resulting from the different vaccinations can be measured in which *s.c.* BCG vaccination induces CD4⁺T_{EM} cells while *i.d.* H56 cDNA vaccination induces CD4⁺T_{CM} cells. *Mtb* specific humoral responses are induced by BCG *s.c.* while H56 cDNA *i.d.* induces H56-specific humoral responses, mainly IgG1.

Subcutaneous BCG vaccination has higher protective efficacy than dermal H56 cDNA tattoo immunization

To score the protective efficacy of the different immunization strategies, bacterial loads were measured in lungs and spleens at day 90 following subcutaneous vaccination with BCG or BCG ::H56, or dermal tattoo immunization with BCG, H56 cDNA or H56_E cDNA. Mice vaccinated with BCG or BCG ::H56 *s.c.* tended to have lower bacterial burdens in the lung (Fig. 3A) and spleen (Fig. 3B) than naive mice, with BCG ::H56 *s.c.* vaccinated mice tending to have the lowest bacterial loads. H56 or H56_E cDNA *i.d.* vaccination did not protect mice, as there was no difference in bacterial loads compared to naive mice. From these data we infer that the broad responses elicited by BCG has higher protective efficacy than H56 cDNA tattoo immunization.

Heterologous prime-boost vaccination with dermal H56 or H56_E cDNA tattoo immunization and subcutaneous BCG ::H56 injection induces the broadest T cell responses

Although dermal DNA tattoo vaccination did not protect against tuberculosis, we hypothesized that it may increase the efficacy of the BCG vaccine in a prime-boost system, by specifically enhancing the cellular immune response. Therefore, we tested different homologous and heterologous prime-boost vaccination regimens to determine the combination that offers optimal vaccine efficacy (Fig 4A). Two groups of mice were subcutaneously vaccinated with BCG or BCG ::H56 at day 0 and then boosted by dermal H56_E DNA tattoo immunization at day 40. In other heterologous prime-boost regimens, mice were primed by dermal DNA tattoo with H56 cDNA or H56_E cDNA, and then boosted with subcutaneous BCG ::H56 injection. In homologous prime-boost vaccination, mice received subcutaneous BCG ::H56 or H56_E cDNA tattoo twice. Immune responses were

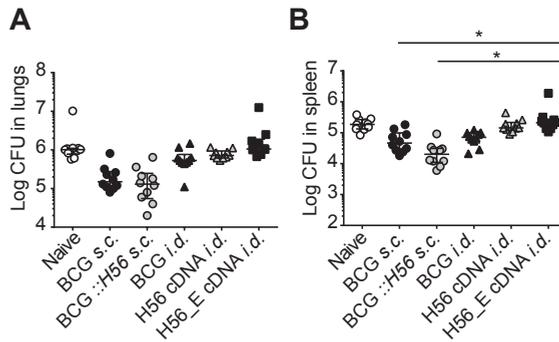

Fig. 3. BCG protects in *Mtb* infection while dermal H56 or H56_E cDNA tattoo is not protective. Lungs and spleens collected at day 90 post *Mtb* challenge were plated in serial dilution. Pooled data of two experiments with (n = 10 in total) is shown \pm SEM. (A) Bacterial loads in lungs and (B) spleen (30-70 CFU). (A-B) Significant differences between the groups are shown with * (ANOVA with Tukey's multiple comparison test; * p < 0.05).

measured two weeks after the booster vaccination. H56-specific CD4⁺ (Fig. 4B) and CD8⁺ T cells (Fig. 4C) were measured by flow cytometry and IFN γ ELISpot (Fig. S2). Relatively high frequencies of H56-specific CD4⁺ T cells were detected in mice that had received heterologous prime-boost with H56 cDNA/BCG::H56 or H56_E cDNA/BCG::H56, both specific to single epitopes, as activated by the pool of 15-mers (Fig. 4B). In comparison, mice that received homologous prime-booster with H56_E cDNA showed substantially weaker H56 peptide specific CD4⁺ T cell responses to the individual epitopes although the total amount of H56 CD4⁺ T cells, as measured with the pool of peptides, was still present. Mice which had been primed with BCG::H56 and boosted with DNA *i.d.* as well as mice immunized by homologous BCG::H56 vaccination also showed weak responses. A similar pattern was observed in the analyses of CD8⁺ T cell responses. Mice primed with DNA *i.d.* and boosted with BCG::H56 *s.c.* showed the highest frequencies of H56-specific CD8⁺ T cells, followed by the mice that had received homologous DNA *i.d.* vaccination (Fig. 4C). Using IFN γ ELISpot, we detected similar patterns in lymph nodes, except for BCG::H56 *s.c.* homologous vaccination, in which similar CD8⁺ T cell responses were similar to those in H56 cDNA *i.d.*/BCG::H56 *s.c.* vaccination (Fig. S2).

Analysis of T cell subsets by flow cytometry indicated that the order of priming and boosting determined which type of immune responses generated. We

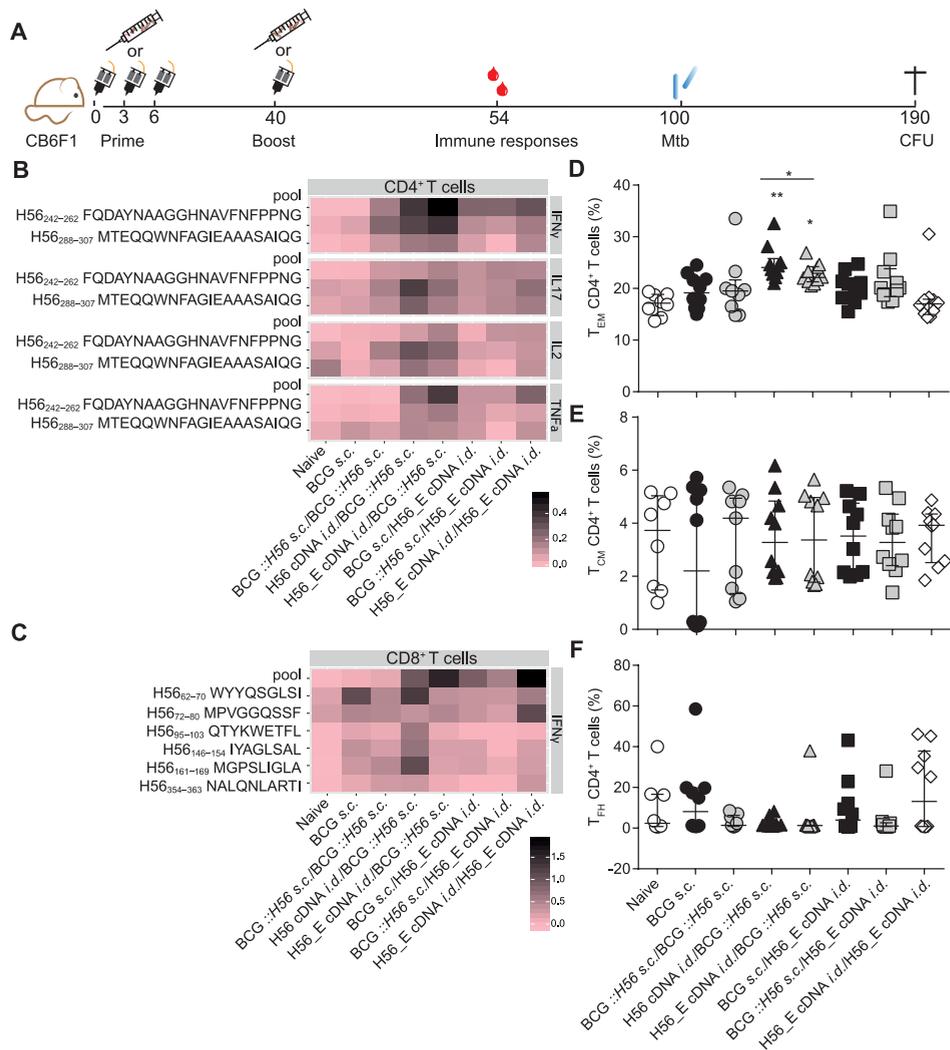

Fig. 4. Broadest H56-specific T cell responses are induced by heterologous prime-boost with H56 or H56_E cDNA *i.d.*/BCG ::H56 *s.c.* vaccination. (A) Immunization scheme. (B, C) Intracellular cytokine staining was performed on splenocytes harvested two weeks after the booster vaccination and re-stimulated with different H56 peptides. The peptide pools consisted of eighty-five 15-mer peptides spanning the entire sequence of H56 as a measure of the total percentage of H56-antigen specific cells. CD4⁺T cell epitopes included H56₂₄₂₋₂₆₂ (Ag85B derived) and H56₂₈₈₋₃₀₇ (ESAT6 derived). The CD8⁺T cell epitopes included H56₃₅₄₋₃₆₃ (ESAT6 derived) and five epitopes of the Ag85B portion. Analysis was done using FACS. The results show pooled data from two independent experiments (n=10 in total). Heat maps showing mean frequency of (B) CD4⁺T cells secreting IFN γ , IL-17, IL-2 or TNF α after peptide stimulation, normalized to medium incubated cells. (C) CD8⁺T cells secreting IFN γ after peptide stimulation, normalized to medium incubated cells. (D) Percentage of CD4⁺T effector memory (T_{EM}) cells in CD4⁺T cell population (E) Percentage of CD4⁺T_{CM} in CD4⁺T cell population (F) Percentage of CD4⁺T_{FH} in CD4⁺T cell population. (A-E) Significant differences between T cell populations of the splenocytes of treatment groups compared to the naive group are marked as * and significant differences in T cell populations between the groups with lines (ANOVA with Tukey's multiple comparison test; * p < 0.05; ** p < 0.01).

5

measured the highest frequencies of CD4⁺T_{EM} in mice primed with H56 or H56_E DNA *i.d.* and boosted with BCG ::H56 *s.c.* compared to the control group (Fig. 4D), in agreement with enhanced CD4⁺T_{EM} populations as measured in the single BCG vaccination experiments (Fig. 2B). BCG or BCG ::H56 primed mice boosted with H56_E cDNA and homologous BCG ::H56 prime- boosted mice showed lower frequencies of CD4⁺T_{EM}, similar to mice vaccinated with BCG only (Fig. 4D). The animals vaccinated with the homologous DNA *i.d.* regimen did not show an increase in CD4⁺T_{EM} compared to unvaccinated controls. While vaccinating once with H56_E cDNA *i.d.* resulted in higher percentages of CD4⁺T_{CM} cells compared to BCG *s.c.* vaccination (Fig. 2D), no differences between H56_E cDNA prime-boosted mice and BCG vaccinated mice were detected (Fig 4E). Groups boosted with H56_E *i.d.* tended to have elevated percentages of CD4⁺T_{FH} cells (Fig. 4F). Frequencies of CD8⁺T_{CM} cells and CD8⁺T_{EM} cells were not significantly different after single vaccination protocols with DNA *i.d.* or BCG *s.c.* or in different prime-boost combinations (data not shown). Thus, heterologous prime-boost immunization with H56 cDNA/BCG ::H56 or H56_E cDNA/BCG ::H56 induced the highest percentages of H56-specific CD4⁺ and CD8⁺T cells, as well as profound CD4⁺T_{EM} populations.

Heterologous prime-boost vaccination with dermal H56 cDNA tattoo immunization and subcutaneous BCG or BCG ::H56 injection results in *Mtb*- and H56-specific humoral responses

In the single vaccination protocols, the BCG vaccinations resulted in the highest titers of *Mycobacterium* specific antibodies (Fig. 2H) and the highest frequencies of plasma cells (Fig.2F) and germinal center B cells (Fig.2G), while the DNA vaccinations induced the highest titers of H56-specific antibodies (Fig 2I). Boosting BCG or BCG ::H56 primed mice with H56_E cDNA *i.d.* led to a tendency towards the highest percentages of plasma cells (Fig. 5A). This effect was not seen after homologous prime-boost with BCG or in mice primed with H56 or H56_E cDNA *i.d.* and boosted with BCG *s.c.* While single vaccination with BCG resulted in elevated percentages of germinal center B cells (Fig 2G), in the prime-boost regimens, in particular H56 DNA-primed/BCG ::H56 boosted mice tended to have relatively high percentages of germinal center B cells (Fig. 5B). This BCG-dependent effect on *Mycobacterium*-specific antibody levels was also seen after prime-boost vaccination because all groups that received a form of BCG in either prime or boost (all heterologous vaccinations) showed elevated titers specific for *Mtb* lysate compared to the naive group (Fig. 5C). Interestingly, *Mycobacterium*-specific antibody titers in H56_E cDNA/H56_E cDNA *i.d.* prime-boosted mice remained as low as in naive controls. Similar to single H56 cDNA *i.d.* vaccination, which induced Ag85B specific antibodies (Fig. 2I), the groups that were primed with H56 or H56_E cDNA *i.d.* and boosted with BCG *s.c.* showed the highest titers of Ag85B specific antibodies (Fig. 5D). However, some of the mice receiving homologous BCG ::H56 *s.c.* vaccination also produced Ag85B specific IgG1 and IgG2c, while homologous vaccination with H56_E cDNA *i.d.* induced Ag85B specific IgG2c only in a few mice, and no IgG1 (Fig. 5D). Thus, heterologous prime-boost immunization is dependent on BCG as priming or booster immunization for induction of *Mtb* specific antibodies while H56-specific antibodies are mainly elicited by heterologous prime-boost immunization with H56 cDNA/BCG ::H56 or H56_E cDNA/BCG ::H56 as well as BCG ::H56 homologous immunization, and not by the other regimens.

Homologous and heterologous vaccination with BCG has better protective efficacy than homologous vaccination using dermal H56_E cDNA tattoo immunization

To determine the protective efficacy of the different homologous- and heterologous prime-boost strategies, the bacterial loads in different organs were measured after challenge. Mice vaccinated with BCG and most homologous or heterologous prime-boost strategies showed reduced bacterial burdens in lung

(Fig. 6A) and spleen (Fig. 6B) compared to naive mice. The order of immunizations was important because we measured increased bacterial loads in spleens of mice primed with BCG ::*H56 s.c.* and boosted with H56_E cDNA *i.d.* compared to mice primed with H56 cDNA *i.d.* and boosted with BCG ::*H56 s.c.* (Fig. 6B). The same trend was visible in the lungs, suggesting that the last vaccination (boost) had the predominant effect on the outcome. Mice vaccinated with H56 or H56_E DNA *i.d.* and boosted with BCG ::*H56* as well as mice vaccinated with BCG ::*H56* in prime-boost showed a slight trend towards decreased bacterial loads in both spleen and lungs. Interestingly, the group that had received H56_E cDNA *i.d.* twice had similar CFU in lung and spleen as naive animals. Thus, efficacy is dependent on BCG immunization in the vaccination regimen and the order of immunizations in a prime-boost regimen has influence on the protective capacity.

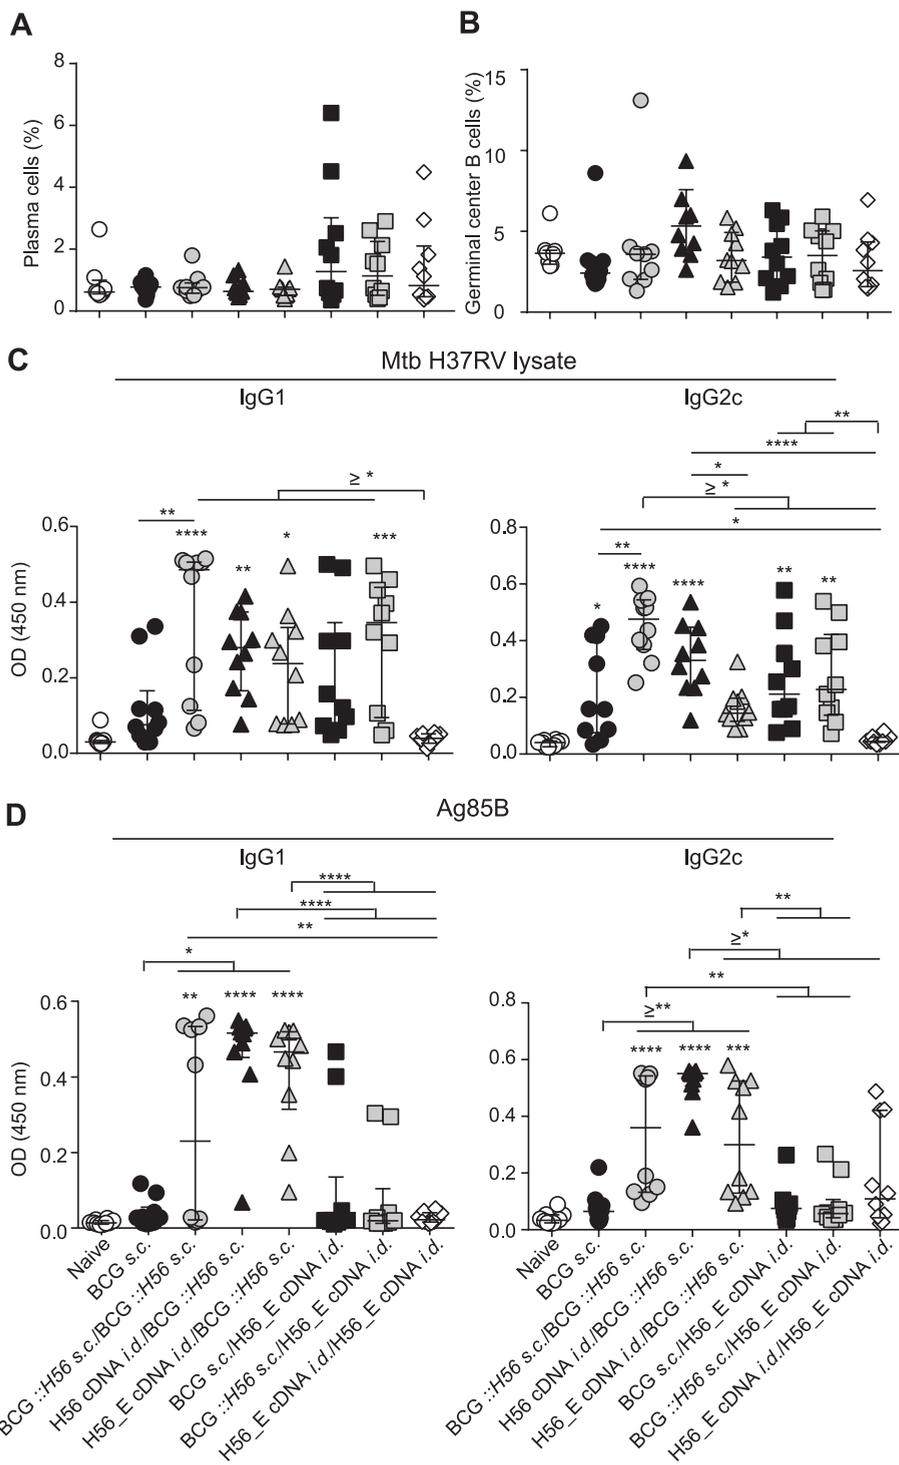

Fig. 5. Heterologous prime-boost vaccination using H56 cDNA *i.d.* and BCG *s.c.* injection favors production of both Ag85B- and *Mycobacterium*-specific antibody production. (A,B) Splenocytes were stained for different surface markers 14 days after the booster vaccination and analyzed for (A) percentage of plasma cells in B cell population and (B) percentage of germinal center B cells in B cell population by FACS. (C,D) IgG1 and IgG2c antibodies recognizing (C) H37RV lysate or (D) Ag85B were measured in blood of immunized mice at day 40. (A-D) Significant differences between treatment groups and the naive group are marked as * and significant differences between groups with lines (ANOVA with Tukey's multiple comparison test; * $p < 0.05$; ** $p < 0.01$; *** $p < 0.001$; **** $p < 0.0001$; \geq minimum amount of * for combined indicated groups).

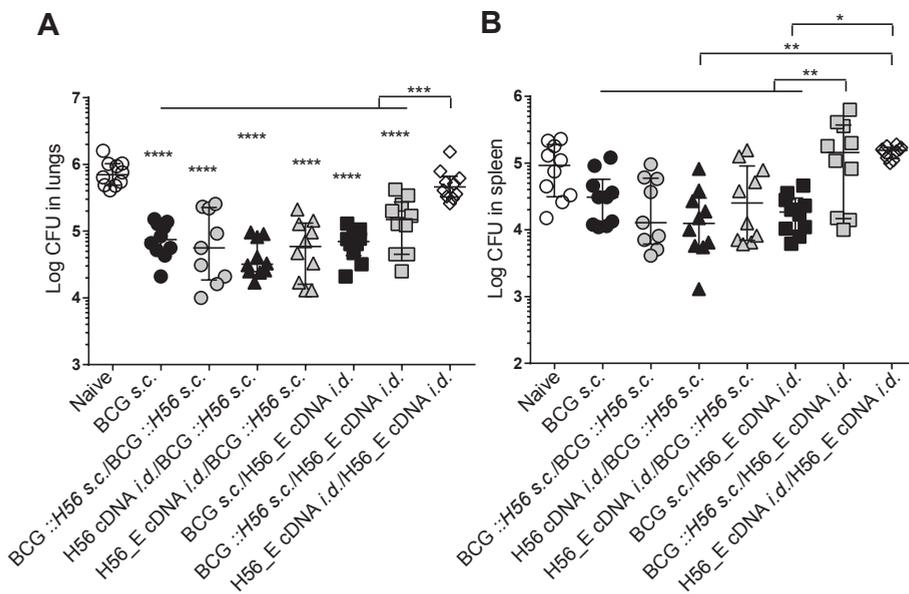

Fig. 6. Heterologous prime-boost with H56 cDNA *i.d.* and BCG *s.c.* in different combinations has protective efficacy while homologous prime-boost vaccination with H56_E cDNA does not. Lungs and spleens collected at day 90 post *Mtb* challenge were plated in serial dilution. Pooled data of two experiments with ($n = 10$ in total) is shown \pm SEM. (A) Bacterial loads in lungs and (B) spleen (± 30 CFU). One mouse in the BCG::H56 prime-boost group died early in the experiment due to unknown reasons, therefore there were $n=9$ in this group. (A-B) Significant differences between the groups are shown with * (ANOVA with Tukey's multiple comparison test; * $p < 0.05$; ** $p < 0.01$; *** $p < 0.001$; **** $p < 0.0001$).

Discussion

BCG is the only licensed vaccine against tuberculosis, but provides inadequate protection⁵. Therefore, other types of adjuvants, different routes of vaccination and prime-boost regimens are being investigated for their ability to boost the immunogenicity and efficacy of the BCG vaccine^{6-8, 10, 11, 27-29, 39}. Aagaard et al.²² found that two times boosting of BCG vaccination with CAF01-adjuvanted *Mtb* fusion protein H56 (encompassing Ag85b, ESAT6 and Rv2660) increased BCG-induced protection against tuberculosis in a murine model. In order to test other routes of delivery and prime-boost strategies, we cloned H56 into BCG³² and generated a H56 encoding DNA vaccine which was shown to induce H56-specific CD4⁺ and CD8⁺ T cell responses³⁰. We determined whether vaccination by dermal H56 cDNA tattoo has protective efficacy against tuberculosis infection in mice, and whether subcutaneous injection of BCG (including BCG ::H56) and dermal H56 cDNA tattoo could be used in a heterologous prime-boost strategy to increase protection. We found that dermal H56 cDNA dermal tattoo vaccination did not protect against tuberculosis in our model, although it enhanced immune responses in heterologous regimens when used as a prime vaccination in combination with a BCG ::H56 boost. Overall, our results suggested that the order of immunizations in prime boost regimens determines the immune response that is elicited and that T- and B cell responses with broad specificity, rather than H56-specific responses, were associated with protection.

Studying the immune responses elicited by different vaccination regimens and evaluating them in light of the resulting efficacy provides important insights for guiding rational vaccine design. Our experiments comparing dermal DNA vaccination with H56 or H56_E constructs and subcutaneous vaccination with BCG or BCG ::H56 demonstrated that the two vaccines elicited distinct immune responses, due to vaccine differences. BCG shares numerous mycobacterial antigens with *Mtb*, including Ag85B (but not ESAT6 or Rv2660c) and thus contains multiple vaccine antigens, while the DNA tattoo immunization elicits specific responses only against H56. Mice vaccinated with BCG or BCG ::H56 accordingly had relatively high levels of *Mycobacterium*-specific antibodies, while mice administered cDNA *i.d.* (particularly the unmodified H56 sequence) developed mainly Ag85B specific antibody responses. All vaccines containing H56 (either BCG ::H56 or the H56 and H56_E cDNA) elicited H56-specific CD4⁺ and CD8⁺ T cells, but CD8⁺ responses against H56 were most pronounced in mice vaccinated with DNA intradermally. Ultimately, mice vaccinated with BCG *s.c.*, and particularly BCG ::H56, tended to be more protected against *Mtb* challenge

than mice that received H56 cDNA *i.d.* in a homologous regimen, suggesting that broader anti-mycobacterial responses were more protective than a strong specific responses to H56. The observed improved immune protection in BCG-vaccinated mice may be due to the persistence and dissemination of live BCG within the host, compared to the short-lived availability of the DNA vaccines. Previously we found that BCG disseminates to the lungs after *s.c.* vaccination, where it persists for about 45 days¹⁴. Dermal tattoo vaccination with BCG showed a trend towards lower efficacy than subcutaneous vaccination, potentially because the BCG are killed during the tattoo procedure.

Following testing of the single vaccine candidates, we tested heterologous and homologous prime-boost combinations. Priming with H56_E or H56 cDNA *i.d.* followed by a *s.c.* boost with BCG ::H56 appeared to boost the expansion of CD4⁺ T_{EM} cells, H56-specific CD4⁺ T cells secreting IFN γ , IL17, IL2 and TNF α , and to lead to the most consistently high Ag85B specific antibody responses. This regimen also induced H56-specific CD8⁺ T cells, targeting the majority of epitopes studied. Homologous H56_E cDNA prime-boost *i.d.* induced the most vigorous H56-specific CD8⁺ T cell responses, but these mice showed the highest bacterial burdens after *Mtb* challenge, indicating that this response was not protective.

Interestingly, homologous H56_E prime-boosted mice hardly produced any *Mtb*- and Ag85B-specific IgG, with only a few mice producing Ag85B-specific IgG2c. Mice receiving BCG ::H56 at the boost (either homologous prime or heterologous prime) produced higher levels of Ag85B specific antibodies than mice receiving H56_E cDNA *i.d.* at the boost in a heterologous regimen. *Mycobacterium* specific antibodies in these groups must therefore be induced by BCG. It can be speculated that alterations to the H56_E sequence may have led to a change in B cell Ag85B epitopes or skewing of immune responses away from Ag85B antibody-producing conditions, since also in the single dose vaccination experiments, H56 cDNA led to higher antibody production than H56_E cDNA. Remarkably, H56 or H56_E cDNA *i.d.* primed BCG ::H56 *s.c.* boosted mice produced anti-Ag85B specific IgG1 and IgG2c whereas BCG ::H56 vaccinated mice did not produce much Ag85B-specific antibodies in single vaccine dose experiments. Since antibodies produced following single vaccination were measured only at early time points, it is possible that antibodies against BCG ::H56 –derived Ag85B are generated later after vaccination, due to the persistence of BCG.

Understanding the underlying mechanisms leading to immune protection against *Mtb* will assist in the rational design of efficacious vaccines. In our model,

protection appeared to be associated with increased $CD4^+T_{EM}$ and *Mycobacterium*-specific antibody levels, although mice vaccinated by intradermal BCG tattoo showed increased levels of antibodies without increased protection, indicating that the higher antibody titers in other protected groups may not correlate with protection. It is possible that in our study $CD4^+T_{EM}$ play a dominating role due to the relatively short time course of our vaccination regime, and that $CD4^+T_{CM}$ by virtue of their capacity to generate new $CD4^+T_{EM}$ are important in the long term. Recently it was reported that boosting of a BCG primed immune response with the subunit Apa, a cell-surface adhesion factor which is a secreted glycoprotein of all members of the *Mtb*-complex⁴⁰⁻⁴², was more successful if the booster was given once the primary response was contracted, rather than at the peak of the BCG-induced response³⁹. Therefore, it is possible that the H56_E cDNA *i.d.* boosters may boost the immune response more effectively if administered in the memory phase. Although H56 or H56_E cDNA did not induce protective responses when given as a single vaccine, implying that it does not induce optimal responses required for immunity against tuberculosis in mice, it did appear to lead to stronger immune responses when given as a *i.d.* prime in combination with *s.c.* BCG or BCG ::H56 boost.

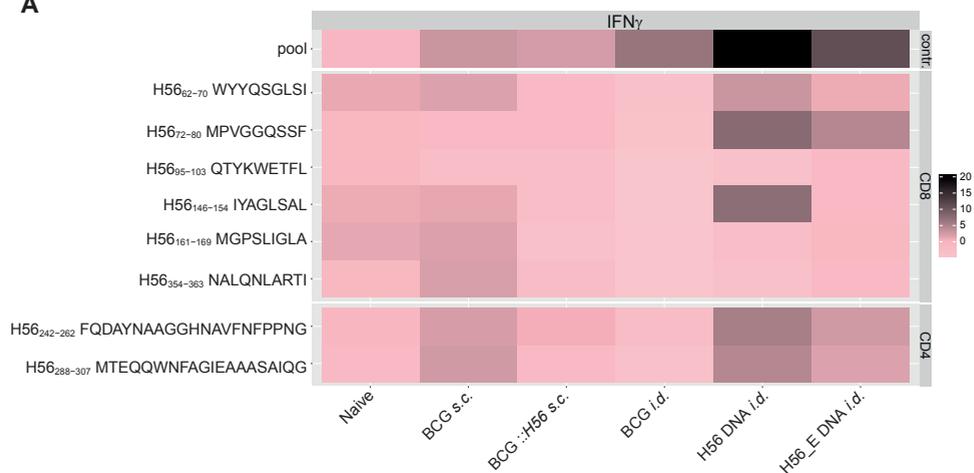

In summary, we have tested intradermal DNA tattoo vaccination using H56 and H56_E constructs in combination with subcutaneous injection of BCG or BCG ::H56. Our data suggests that broader specificity of T cell responses is more effective in controlling TB infection compared to highly specific responses targeted to a specific antigen. In addition, the sequence of different immunizations determines the magnitude of induced responses and should be carefully considered when designing vaccine regimens.

Supplementary Figure 1. Heat map of H56-specific IFN γ producing cells in lymph nodes after different vaccination methods. The heat map represents mean number of IFN γ - producing cells per million lymph node cells after peptide stimulation, normalized to medium incubated cells. IFN γ ELISpots were performed at day 21 post vaccination on lymph node cells re-stimulated with peptides. The peptide pools consisted of eighty-five 15-mer peptides spanning the entire sequence of H56. CD4⁺ T cell epitopes included H56₂₄₂₋₂₆₂ (Ag85B derived) and H56₂₈₈₋₃₀₇ (ESAT6 derived). The CD8⁺ T cell epitopes included H56₃₅₄₋₃₆₃ (ESAT6 derived) and five epitopes of Ag85B. The results show pooled data from two independent experiments (n=10 in total).

Summarizing discussion

6

Together with the discovery of antibiotics and improved hygiene practices, the introduction of vaccines has had major impact on human longevity and health and is therefore considered as the most significant and cost-effective health achievement of the 20th century ¹. In the present century however, it has become clear that vaccines against causative agents of global pandemics such as HIV, malaria and tuberculosis require a more in depth understanding of the interaction between the pathogens and the host immune system. Extended knowledge and clearer definitions are needed of ways to modulate immune responses in order to accomplish protective immunity. The work described in this thesis can contribute to this knowledge because we studied new ways of MHC class I antigen processing as well as strategies to modulate this process, and consequences for the CD8⁺ T cell response.

Opportunities for the modulation of antigen processing

Vaccine design against intracellular pathogens often focuses on activation of the cellular arm of the immune system, in particular the CD8⁺ T cell response. The proteasome plays a key role in generating the epitopes that are targeted by these CD8⁺ T cells. Modulation of the proteasome results in an altered peptide pool and this can lead to altered CD8⁺ T cell responses.

The efficiency of antigen processing *i.e.* how fast epitopes are generated and how many antigen is needed for that, has major consequences for the CD8⁺ T cell response. It is known that these efficiencies can vary extensively ^{2,3}. Differences in efficiency of antigen processing can be caused by immunosubunit incorporation, as shown in [Chapter 3](#), in which we identified CD8⁺ T cells that can be cross-reactive to LLO_{294/297-304}⁴ that shares sequence similarity with LLO₂₉₆₋₃₀₄. We showed that all potential spliced epitopes from LLO were generated by immunoproteasomes. We compared these digests with digests of proteasomes from spleens of LMP7^{-/-} MECL1^{-/-} mice and found that the generation efficiency, measured as pmol peptide *per* nmol of substrate consumed over time, of LLO_{291-298/300-304} and LLO_{291-300/302-304} (N-terminally extended precursors of LLO_{295-298/300-304}, LLO_{296-298/300-304} and LLO_{296-300/302-304}) was decreased in the proteasomes from LMP7^{-/-}MECL1^{-/-} mice. This decreased efficiency can be one of the underlying mechanisms for the fact that we did not detect a specific CD8⁺ T cell response targeted to these epitopes because low efficiency can result in low abundance or delayed presentation of epitopes on the cell surface. The correlation between delayed presentation and the failure to induce a CD8⁺ T cell response was already reported ⁴. These authors used infection with a recombinant *Listeria monocytogenes* strain expressing an earlier identified Adeno virus- derived fusion antigen, which encompasses the

immunoproteasome-dependent E1B₁₉₂₋₂₀₀ and immunoproteasome-independent E1A₂₃₄₋₂₄₃ epitope. It was shown that antigen presenting cells of LMP7^{-/-}MECL1^{-/-} mice processed and presented the immunoproteasome dependent E1B₁₉₂₋₂₀₀, but they did so with delayed kinetics⁵. These delayed kinetics were responsible for the failure of the mice to respond in infection with rLM-E1 to the immunoproteasome dependent E1B₁₉₂₋₂₀₀, while they mounted normal responses to E1A₂₃₄₋₂₄₃. Using splenocytes from the infected LMP7^{-/-} MECL1^{-/-} mice, taken at later time points in infection and transferred into naïve LMP7^{-/-} MECL1^{-/-} mice, it was shown that the recipient mice responded normally to E1B₁₉₂₋₂₀₀. This illustrates that there were sufficient quantities of the epitope on the cell surface and there is no gap in the T cell repertoire. The delayed presentation kinetics were responsible for the failure of the infected LMP7^{-/-} MECL1^{-/-} mice to respond to the immunoproteasome dependent epitope⁴. Besides the presentation kinetics, the epitope abundance at the cell surface is also directly correlated with the magnitude of the CD8⁺ T cell responses, as illustrated in viral models^{6,7}. In the study of La Gruta et al., the influenza-derived epitopes NP₃₆₆₋₃₇₄ and PA₂₂₄₋₂₃₃ were shifted within the same viral context, which equalized the epitope abundance on the cell surface, and hence altered the CD8⁺ T cell response specific for these epitopes⁷. These data illustrate the influence of generation efficiency on the CD8⁺ T cell response via the presentation kinetics or abundance of epitopes on the cell surface.

Flanking residue modulation, in which amino acids adjacent to the epitope are changed, is a way to modulate efficiency of antigen processing and has been shown to have major consequences for the immune responses⁸⁻¹³. Characteristics of amino acids close to the cleavage site have been studied¹⁴, although the studied dataset does not allow for generalizations. The authors found that immuno- and constitutive proteasomes favor cleaving between hydrophobic large residues and polar large/small residues. Several of the six H56-derived epitopes we used in [Chapter 4](#) to illustrate a complete strategy to enhance immunogenicity, displayed hydrophobic residues at both P1 and P1'. In order to liberate them from the H56 protein context, the proteasome has to cleave between these two hydrophobic residues. We hypothesized that proteasome-mediated liberation might be increased if the residue at P1' was substituted for a polar glutamic acid. For H56₇₂₋₈₀ MPVGGQSSF, we proved that the efficiency was indeed enhanced. Unfortunately, this effect was not seen for all epitopes, potentially due to substitution-dependent alterations of the substrate transport or regulation of non-catalytic modifier sites¹⁵. These authors showed that substrate transport and regulation sites greatly influence hydrolysis by the proteasome. If the substitutions alter the transport through the cavity of the proteasome which

6

results in decreased hydrolysis, the amount of epitope produced is less, which might cause a decrease in the magnitude of the specific CD8⁺T cell response. These studies show that modulation of antigen processing can be very adequately done by C-terminal flanking residue modulation of epitopes but that more research is needed to unravel all underlying mechanisms.

More indirect ways of antigen processing modulation are also known, *e.g.* those affecting the stability of the antigen¹⁶ or providing CD4⁺T cell help by linking the antigen of interest to an antigen that has a strong CD4⁺T cell epitope, which is of uttermost importance in DNA tattoo immunization¹⁷⁻¹⁹. In our studies described in [Chapter 4](#), we adapted the latter strategy and linked the cDNA encoding antigen H56 to the cDNA of proteins with immunogenicity enhancing properties. We found an enhancement of H56-targeted CD4⁺ and CD8⁺T cell response when this antigen was linked to tetanus toxin fragment C (TTFC) or ubiquitin (UB). The immunogenicity enhancing effect of TTFC is probably due to the presence of a strong CD4⁺T cell epitope¹⁸, but this cannot be the case for UB, since this is a self-derived protein. It has, however, already been reported before to enhance immunogenicity²⁰. These observations are in contrast with an earlier study by Wolkers et al., who concluded that successful vaccination is significantly hampered if the cDNA of the antigen is linked to cDNA of a self-derived protein¹⁹. Wolkers et al., used vaccination with GFP containing constructs in GFP-transgenic mice that express GFP in all nucleated cells, or vaccination with Dby in male mice in which Dby is located on the Y chromosome. The reason that these authors did not find an immunogenicity enhancing effect with these self-derived antigens, while we did find a positive effect using UB, potentially lies in different function of UB under steady state conditions. Additionally, unlike Wolkers et al., who used truncated versions of influenza- or papilloma virus antigens¹⁹, in our studies H56 cDNA was used which encodes for 3 full length proteins in which known CD4⁺T cell epitopes are present^{21, 22}. These CD4⁺T cell epitopes could have been of beneficial influence in our experimental setup. This work shows that providing CD4⁺T cell help is an effective way to modulate the responses elicited by the antigens but that differences in the study set-up and choice of vaccine-antigens is of great influence and should be studied more.

By mathematical modelling of proteasome behavior, consequences of attempts to modulate antigen processing can be studied more effectively. This modelling is based on detailed *in vitro* kinetics of epitope generation. The more such knowledge is gathered, the more the prediction of how the epitopes are generated becomes accurate. By modelling proteasome behavior, novel epitopes

can also be predicted, as already widely used for linear epitopes ²³. In **Chapter 2** we developed a multi-level strategy, based on an *in silico* based prediction algorithm, to identify epitopes generated by proteasome-catalyzed peptide splicing (PCPS) within antigens. Additionally, we successfully tested this in a murine *L. monocytogenes* infection model. Two Listeria PlcB-derived spliced epitopes, composed of sequences that in their linear context are not recognized by CD8⁺ T cells, were identified. As described in the supplementary figures, the prediction algorithm was further specified for HLA haplotypes and would make it possible to synthesize HLA specific - *i.e.* personalized - vaccines. For example, minigene constructs that encode a series of epitopes ²⁴, or a cocktail of DNA constructs, each containing individual epitopes ²⁵, could be used.

Currently, our understanding of antigen processing and how to modulate it is growing. However, by further developing new tools such as *in silico* prediction algorithms this can be further enhanced, which contributes to rational vaccine design.

Possibilities for the navigation of CD8⁺ T cells towards a desired response

In order to navigate the CD8⁺ T cells towards a response which is protective in a vaccine setting, modulation of antigen processing can be performed, but the responding CD8⁺ T cells to an antigen display kinetics that also impose possibilities for further steering. In vaccine design, usually the aim is to elicit a broad response in which both vaccine-derived immunodominant, but also subdominant epitopes are targeted. In this way the chances of immune evasion are smaller and massive IFN γ production, which results in side effects such as tissue damage, are also decreased. Additionally, vigorous responses specific for an immunodominant epitope are not necessarily protective, and can even be associated with increased fitness of the pathogen ²⁶⁻²⁸ or with higher viral load ²⁹, whereas responses specific for subdominant epitopes have been associated with lower viral- or bacterial loads ^{30, 31}. If more knowledge becomes available on how activation kinetics of CD8⁺ T cells and the subsequent immunodominance hierarchy can be modulated, the desired, broad response is easier accomplished.

The activation kinetics of CD8⁺ T cells responding to natural infection are complex phenomena of which not all influencing factors have been identified. The complexity in the activation kinetics of a total CD8⁺ T cell response is mainly due the fact that the contribution to responses in primary- and recall infection of one T cell family, *i.e.* one naive T cell and its progeny, differs from

the function of another T cell family³²⁻³⁴. These differences arise from the fact that on an individual cell level, proliferation and differentiation of CD8⁺ T cells occurs heterogeneously. After a primary infection, the immunological memory is maintained in CD8⁺T_{CM'}, CD8⁺T_{EM} and CD8⁺T_{RM} populations that develop from CD8⁺T_{EFF} cells, while in recall expansion, the individual CD8⁺T cells follow the CD8⁺T_{CM} population → CD8⁺T_{EM} population → CD8⁺T_{EFF} population model^{35,36}. The differentiation-variability of an individual CD8⁺T cell in this population model has been shown to be tremendous³⁷ and it is tempting to speculate how the different families of CD8⁺T cells are channeled to proliferate and differentiate in specific phases of infection. This is probably influenced by intrinsic variation as well as variation in extrinsic signals, such as the specific environment. Asymmetric division is also believed to contribute to assigning different functions to different families³⁸, but more research is needed to study the contribution of these underlying mechanisms. Knowledge on how to channel the responses can be used for vaccine design against e.g. pathogens, for which the characteristics of the memory populations that confer protection at certain specific sites are known. In the murine *Mycobacterium tuberculosis* model, especially the CD4⁺T_{CM} cells, which secrete IFN γ and TNF α , have been shown to be protective in the lungs³⁹. The different vaccination strategies used in [Chapter 5](#), in which we studied homologous and heterologous prime-boost regimens with dermal DNA tattoo and subcutaneous injection with BCG, were shown to elicit different CD8⁺ and CD4⁺T cell responses. BCG vaccination results in a broad immunological effect compared to the narrow and specific response which is elicited by the H56 cDNA tattoo immunization. By combining the two we found that especially a prime with dermal H56 or H56_E cDNA tattoo immunization, followed by a boost with BCG ::H56 given subcutaneously, resulted in immune responses that are associated with protection. We found enhanced H56 specific secretion of IFN γ , IL17, IL2 and TNF α by CD4⁺T cells and increased CD4⁺T_{EM} populations compared to the other vaccination regimens. Additionally, H56-specific antibodies in these mice were found to be higher in comparison to mice of other groups that were vaccinated with homologous regimens. The heterologous regimens were effective in decreasing bacterial burdens however, the absolute necessity of at least one subcutaneous injection of BCG is shown, by the fact that a homologous regimen using H56 cDNA tattoo immunization did not result in any protective effect. These examples illustrate that by varying immunization regimes, a desired response can be successfully and safely channeled.

Timing of immunization in a vaccine setting can also greatly influence CD8⁺ and CD4⁺T cell responses. As illustrated in an earlier prime-boost study by

Nandakumar et al., BCG drives persistent immune-activation and this should be taken into account in vaccine strategies ⁴⁰. The authors studied T cell responses specific for the cell-surface adhesion factor Apa, which is a secreted glycoprotein of all members of the *Mtb*-complex ⁴¹⁻⁴³, in BCG- or Apa subunit-primed mice. In the study by Nandakumar et al., the animals were boosted during the peak- or contraction phase of this response in a homologous- or heterologous regimen with BCG or Apa-subunit vaccine, and the protective capacity was measured. The authors concluded that boosting with a heterologous vaccine may be ideal once the specific persisting effector responses have contracted, but in this model this was achieved after only 78 weeks ⁴⁰. This result might explain the fact that in [Chapter 5](#) we detected more specific CD4⁺ and CD8⁺ T cells in the DNA primed and BCG boosted animals compared to the BCG primed and DNA boosted animals. Probably, in the BCG primed-DNA boosted animals, the immune response elicited by the prime was not contracted enough to have a significant effect of the boost, since the boost took place six weeks after the prime. In the human population there can be years between various vaccinations, which is not easily mimicked in a mouse model, however, such studies should be considered with respect to timing or sequence of the different immunizations.

Activation kinetics of CD8⁺ T cells responding to pathogen-derived antigens in infection are complex phenomena. It is important to study these kinetics in order to acquire knowledge as a basis for rational vaccine design.

Future perspectives of navigating immune responses for improvement of vaccine design

Modulation of antigen processing and the navigation of CD8⁺ T cell responses is aimed to result in improved vaccine design. The immune system is then successfully steered towards a desired and broad response with subsequent memory that is protective upon infection with the real pathogen. Cross-reactive CD8⁺ T cells, that are specific for one pathogen-derived epitope but can also be activated by a different pathogen-derived epitope that shares sequence similarity with the initial epitope, can enhance vaccine efficacy in this setting. However, these cross-reactive CD8⁺ T cells can also impose risks such as induction of auto-immunity.

Positive effects of CD8⁺ T cell cross-reactivity have been described with cross-reactive CD8⁺ T cells that recognize epitopes derived from the same pathogen. In our study described in [Chapter 3](#) we detected spliced epitope LLO_{294/297-304} - specific CD8⁺ T cells *ex vivo*. This spliced epitope shares sequence similarity with

the linear epitope LLO₂₉₆₋₃₀₄⁴⁴. We stained splenocytes from infected mice *ex vivo* with MHC class I multimers folded with the two epitopes and found a double positive population and some cells still recognizing LLO₂₉₆₋₃₀₄ while all LLO_{294/297-304} had shifted into the double positive population. From this we inferred that most likely a portion of CD8⁺ T cells primed by LLO₂₉₆₋₃₀₄ can also recognize LLO_{294/297-304} but it is unclear whether LLO_{294/297-304} is presented and participates in CD8⁺ T cell priming during infection as well. However, these cross-reactive CD8⁺ T cells may decrease the immune evasion by the pathogens.

Several studies have also reported positive effects of CD8⁺ T cells activated in one infection to be protective in another infection, as shown for cross-reactive CD8⁺ T cells specific for lymphocytic choriomeningitis virus which were functionally activated during acute infection with vaccinia virus⁴⁵ or pichinde virus⁴⁶. In [Chapter 2](#) we used *Listeria*-derived PlcB as a model antigen to prove that our *in silico* prediction method worked and successfully predicted and identified spliced epitopes that are important immunological targets in infection while their N- and C-terminal parts were not immunogenic in the context of their natural flanking sequences. No linear peptides with full sequence similarity were found with identified spliced epitopes PlcB_{189-191/163-167} or PlcB_{189-192/164-167} in any proteome of prokaryotes or eukaryotes, but the amino acid sequence from which the epitopes are generated by PCPS shares similarity with a sequence found in other bacteria. This domain conveys a zinc dependent phospholipase C activity and is found in a monomeric phospholipase C of *Bacillus cereus* (62% similarity with binding motive for H-2K^b XXXXF/MZZL⁴⁷ present as well as 3 out of 4 amino acids of C-terminal part):

L.monocytogenes PlcB₁₆₂₋₁₉₆ AFYKLGLAIHYYTDISQPMHANNFTAISYPPGYH

Sequence of *B. cereus* AFFYLGLSLHLYLGDVNQPMHAANFTNLSYPQGFH

The binding motive for H-2K^b as well as 3 out of 4 amino acids of the C-terminal part are also found in the Phospholipase C precursor of *Streptococcus pneumoniae* which displays 61% similarity with the PlcB sequence of *Listeria monocytogenes*. In all these pathogenic bacteria the function of the proteins is associated with haemolysis and cell rupture. Sequence similarity of 50% is found in the alpha toxin of *Clostridium perfringens* and *Clostridium bifermentans* but then the binding motive for H-2K^b is not maintained. In a study in which variants of NP₄₁₈₋₄₂₆ were studied in a human population⁴⁸, the authors found *in vivo* existence of CD8⁺ T cells cross-reactive with homo- or heterosubtypic variants of the epitope in other

influenza viruses. They showed that certain positions in these epitopes were the crucial determinants of T cell specificity, which resulted in sequence similarity of approximately 50%. Whether the PlcB-derived epitopes in our study, which share the same degrees of similarity with phospholipase C of other bacteria, are immunogenic in infection with those bacteria as well, remains to be determined but it might indicate an additional immunological relevance of PCPS.

Cross-reactive T cells have also been described in infection as the cause of disease, which is a great risk when modulating antigen processing of vaccine-derived antigens. Influenza specific CD8⁺ T cells have been shown to also recognize an epitope from Epstein Barr virus (EBV) despite only 33% sequence similarity. This results in massive proliferation and subsequently the overzealous CD8⁺ T cell responses as seen in EBV-associated infectious mononucleosis ⁴⁹. Influenza specific CD8⁺ T cells were also shown to cross-recognize a peptide derived from hepatitis C virus by which they contribute to immune mediated liver pathology ^{50, 51}. Next to immune mediated pathology, the risk often associated with cross-reactivity is auto immune disease. In many auto-immune diseases in which CD8⁺ T cells play a role, epitope specificity and the underlying processes leading to the initial activation of auto-reactive CD8⁺ T cells, are unclear.

The fact that few studies are describing cross-reactive CD8⁺ T cells that are cross-reactive to self-antigens and thereby induce auto-immunity, should not lead to neglecting the potential dangers. However, the opportunities should also be explored, especially by identifying responses that can be protective in infections with other pathogens.

Conclusion

Knowledge of new ways of antigen processing as well as strategies to modulate it, forms the basis for successful and rational vaccine design. Vaccine efficacy can be greatly enhanced if the immune system is neatly navigated towards development of the desired response. However, negative consequences with respect to cross-reactivity should not be neglected.

Summary

Cover

The sailboat on the cover embodies the immune system. Using results presented in this thesis about new ways of antigen processing and strategies to modulate it, the immune system, mainly CD8⁺ T cells, can be navigated or steered towards a specific response. In this way the harbor is safely reached. The harbor of Den Helder symbolizes this desired place as the situation in which the appropriate immune response is accomplished. The gained knowledge can therefore be used in vaccine design.

In this thesis

This thesis can roughly be divided into two parts. In the first part we study a new mechanism of antigen processing and its immunological consequences. In a series of two chapters we discuss our research on proteasome-catalyzed peptide splicing (PCPS) and its immunological relevance in *Listeria monocytogenes* infection. In the last two chapters we focus on modulation of antigen processing in order to enhance CD8⁺ T cell responses for vaccine design. We first present a complete strategy to increase immunogenicity of a *Mycobacterium tuberculosis* cDNA encoded antigen and subsequently test this in a heterologous prime-boost vaccination regimen. The latter was performed at the Max Planck Institute of Infection Biology in Berlin. These results will be briefly summarized per chapter and are followed by the main conclusions.

In [Chapter 2](#) we show how we developed a novel approach to identify spliced epitopes in a bacterial infection. More and more evidence of spliced epitopes is available but due to insufficient tools to predict them, their identification remains challenging. We developed a reverse immunology-based multi-level approach to identify spliced epitopes that are targeted by CD8⁺T cells in *Listeria monocytogenes* infection. Our data show that we can predict such epitopes with high accuracy, and also demonstrate the immunological relevance of PCPS in infection. The spliced epitope-specific CD8⁺ T cells detected in our studies recognized only the spliced epitopes, not the peptides in their natural flanking residues. This opens a whole range of opportunities for immunotherapies or vaccine design.

We continue with PCPS in studies described in [Chapter 3](#). Here, by digestion of substrates with purified 20S proteasomes, we show that PCPS indeed increases the variety of peptides that is produced. Both immuno- and constitutive proteasomes were found to produce spliced peptides next to linear peptides.

Furthermore, we show that CD8⁺ T cells that are activated by a linear epitope derived from a *Listeria monocytogenes* antigen, can be cross reactive to spliced epitopes that share sequence similarity with the linear epitope and are derived from the same antigen. Such a mechanism may reduce the chances of immune evasion because infected cells can present multiple versions of one epitope that can be recognized by the same CD8⁺ T cells.

T cell priming by vaccines is often not optimal. We therefore aimed to increase vaccine-specific T cell responses in the studies reported in [Chapter 4](#). In this chapter we show a complete strategy to enhance vaccine' immunogenicity. The multistage cDNA vaccine H56, encoding three secreted *Mycobacterium tuberculosis* (*Mtb*) antigens, was used as a model vaccine and delivered using dermal DNA tattoo immunization. We started by predicting H56 epitopes. Their antigen processing was optimized using flanking residue modulation and immunogenicity was increased by linkage of the cDNA of the antigen to cDNA of proteins with immunogenicity enhancing properties. This complete strategy can be used for vaccine design.

The H56 cDNA was also used in studies described in [Chapter 5](#), in which we studied the effectiveness of a heterologous prime-boost strategy using dermal H56 DNA tattoo immunization in combination with BCG::*H56* subcutaneous injection. BCG is the only licenced vaccine against *Mtb* but it lacks efficacy in certain situations. We therefore tested whether we can successfully boost the effect of BCG by incorporating it in a heterologous prime boost regimen. We first measured the immunization strategies separately and scored cellular and humoral responses as well as efficacy. We continued by testing different combinations of the immunization strategies and scored the same immunological parameters. We conclude that broad immune responses are necessary to fight *Mtb*. Heterologous prime-boost using a combination of a dermal H56 cDNA prime and a subcutaneously given BCG::*H56* boost resulted in immune responses associated with protection. We show that responses differ depending on the sequence and type of the immunizations that are given, and that this has consequences for the disease burden.

In conclusion

In this thesis, antigen processing and CD8⁺ T cell activation was studied. In the first chapters we proved the immunological relevance of PCPS in bacterial infection and in the last chapters we showed a complete vaccination strategy that will contribute to effectively fight *Mycobacterium tuberculosis*. We can conclude that these results give more insight in how modulation of antigen processing influences immune responses, mainly CD8⁺ T cells. This knowledge will contribute to improved vaccine design.

Samenvatting

Op de voorkant

De zeilboot op de voorkant symboliseert het immuunsysteem. Met behulp van kennis over nieuwe mechanismen of strategieën die beschreven zijn in dit proefschrift, kan je het immuunsysteem beïnvloeden, voor o.a. vaccinatie doeleinden. Het immuunsysteem wordt op deze manier in de goede richting gestuurd ofwel genavigeerd. De boot komt dan op de gewenste plek, de haven, aan. De haven van Den Helder symboliseert deze gewenste situatie waarin het immuunsysteem verkeert nadat het succesvol beïnvloed is. Hierin is de sturing van het immuunsysteem door bijvoorbeeld een vaccinatie succesvol geweest en kan het lichaam toekomstige ziekteverwekkers zonder veel schade uitschakelen.

CD8⁺ T cellen

Het immuunsysteem is een complex systeem met allerlei cellen die samenwerken en met elkaar communiceren. Sommige cellen zijn deel van de aangeboren afweer. Deze cellen zijn de eersten die maatregelen nemen als er een ziekteverwekker, bijvoorbeeld een bacterie of virus, binnen komt, maar ze zijn niet specifiek voor die ziekteverwekker. Deze cellen kunnen de groei van de ziekteverwekker beperken maar voor echte opruiming is vaak de hulp nodig van cellen die horen bij de aangeleerde afweer, die wel specifiek zijn voor de ziekteverwekker. Het duurt echter even voordat deze cellen gemobiliseerd zijn. Cellen van de aangeboren afweer nemen stukjes van de ziekteverwekker mee en presenteren die op major histocompatibility complex (MHC) moleculen, een soort dienblaadjes, aan cellen van de aangeleerde afweer. Een klein deel van deze cellen kan het stukje herkennen en gaat delen. Door deze vermenigvuldiging ontstaat een relatief groot percentage specifieke cellen voor deze ziekteverwekker. Het duurt echter ongeveer een week voordat dit hele proces voltooid is en daarom is het effect van de aangeleerde afweer pas later merkbaar. Dit effect kan echter wel heel lang voortbestaan omdat de aangeleerde afweer immunologisch geheugen aanlegt. Hierdoor word je de volgende keer dat de ziekteverwekker je lichaam binnen komt niet meer ziek, we zeggen dan dat je 'immuun' bent voor die specifieke ziekteverwekker. Tegen verschillende soorten ziekteverwekkers heb je verschillende soorten cellen nodig van de aangeleerde afweer. Er zijn daarom verschillende cellen in deze populatie, bijvoorbeeld B cellen of T cellen. Binnen deze populatie cellen van de aangeleerde afweer bestaan er verschillende soorten T cellen, de CD8⁺ T cellen zijn de cellen waar dit proefschrift over gaat. Deze cellen zijn in staat

cellen te herkennen die geïnfecteerd zijn met bijvoorbeeld virussen. Virussen zijn ziekteverwekkers die in de cellen zitten en zijn daardoor voor andere cellen niet te zien aan de buitenkant.

Vaccinaties

Vaccinatie, of wel inenting, tegen virussen of andere ziekteverwekkers die in de cellen van het lichaam zitten in plaats van vrij rondzwemmen tussen de cellen, is vaak gericht op het activeren van T cellen, onder andere de CD8⁺ T cellen. Vaccinatie berust op het feit dat je het lichaam al in contact brengt met een stukje van de ziekteverwekker. Het eerder beschreven proces van presentatie aan T cellen vindt dan al plaats wat betekent dat er al immunologisch geheugen wordt aangelegd. Als de werkelijke ziekteverwekker dan het lichaam binnen komt, kunnen de specifieke T cellen meteen in actie komen en is er wel sprake van infectie, maar zijn de ziekteverschijnselen veel minder erg.

In dit proefschrift

In het onderzoek beschreven in dit proefschrift hebben we onderzocht hoe CD8⁺ T cellen geactiveerd raken en hoe ze kunnen worden beïnvloed en gestuurd. In de eerste twee hoofdstukken bestuderen we een nieuw mechanisme waarop de stukjes ziekteverwekker door het lichaam worden samengesteld om vervolgens aan het immuunsysteem te worden gepresenteerd. We laten zien dat dit mechanisme immunologisch relevant is omdat we CD8⁺ T cellen aangetoond hebben die de stukjes die op deze nieuwe manier gemaakt worden, ook echt kunnen herkennen. In het tweede deel van het proefschrift wordt beschreven hoe het immuunsysteem beïnvloed kan worden voor vaccinatie doeleinden. We laten een strategie zien hoe de stukjes ziekteverwekker kunnen worden veranderd ter verbetering van de CD8⁺ T cel respons. Tenslotte tonen we aan dat ook de manier waarop het vaccin, wat bestaat uit deze gemodificeerde stukjes van de ziekteverwekker, wordt gegeven van belang is voor het opwekken van de gewenste immuun respons. Hier volgt een samenvatting van wat er is onderzocht in de verschillende hoofdstukken en wat de belangrijkste conclusies waren.

In het onderzoek beschreven in [Hoofdstuk 2](#) hebben we een nieuwe manier bestudeerd hoe stukjes ziekteverwekker aan het immuunsysteem worden gepresenteerd. We hebben ontdekt dat dit niet alleen gebeurt met een schaar die de ziekteverwekker opdeelt in stukjes, zoals tot nu toe bekend, maar dat er ook een soort plakstift is die kleine stukjes ziekteverwekker samen kan plakken zodat ze groot genoeg zijn om aan het immuunsysteem te laten zien. Dit fenomeen van knippen en plakken kan worden voorspeld met wiskundige modellen. We

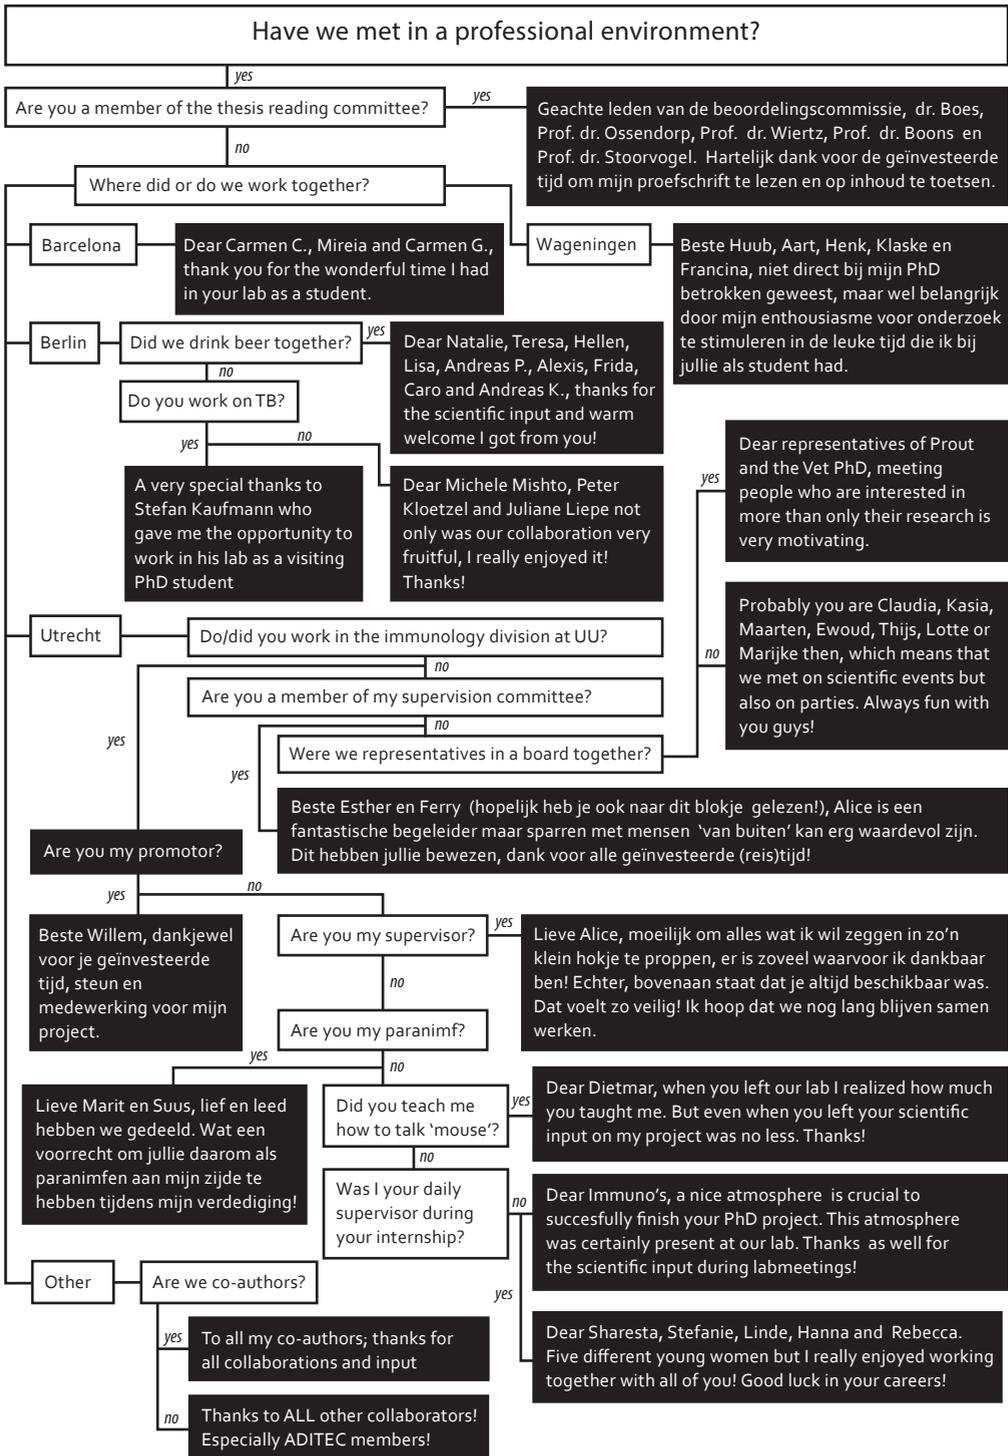

hebben laten zien dat het model wat wij hebben ontwikkeld werkt, en dat het kan voorspellen welke stukken worden gepresenteerd. Vervolgens hebben we aangetoond dat deze stukken van belang zijn bij immuun responsen tegen een ziekteverwekker. Het feit dat het immuunsysteem dit kan, betekent dat er tegen veel meer stukjes immuun responsen kunnen worden opgebouwd dan wat we tot nu toe dachten, en dit kan van groot belang worden in vaccinatie strategieën. We gaan verder met het principe van knippen en plakken in het onderzoek beschreven in [Hoofdstuk 3](#) waarin we hebben laten zien dat CD8⁺ T cellen die 'ouderwets' geknipte stukjes ziekteverwekker herkennen, ook stukjes kunnen herkennen die hierop lijken maar gemaakt zijn door knippen én plakken. Dit herkennen van meerdere stukjes door één CD8⁺ T cel noemen we kruis reactiviteit. Het belang van het knip-en-plak mechanisme wordt hierdoor groter. De reden hiervoor is dat als CD8⁺ T cellen meerdere stukjes kunnen herkennen die op elkaar lijken, het minder gevaarlijk is als de ziekteverwekker een deel van zijn stukjes verandert. Sommige ziekteverwekkers veranderen, ook wel muteren genoemd, heel vaak en snel waardoor het immuunsysteem altijd achter de feiten aan loopt en de infectie niet goed kan worden gestopt. Aangezien CD8⁺ T cellen stukjes kunnen herkennen die op elkaar lijken maar via verschillende mechanismen worden gemaakt, kan het immuunsysteem je beter beschermen tegen deze snel veranderende ziekteverwekkers.

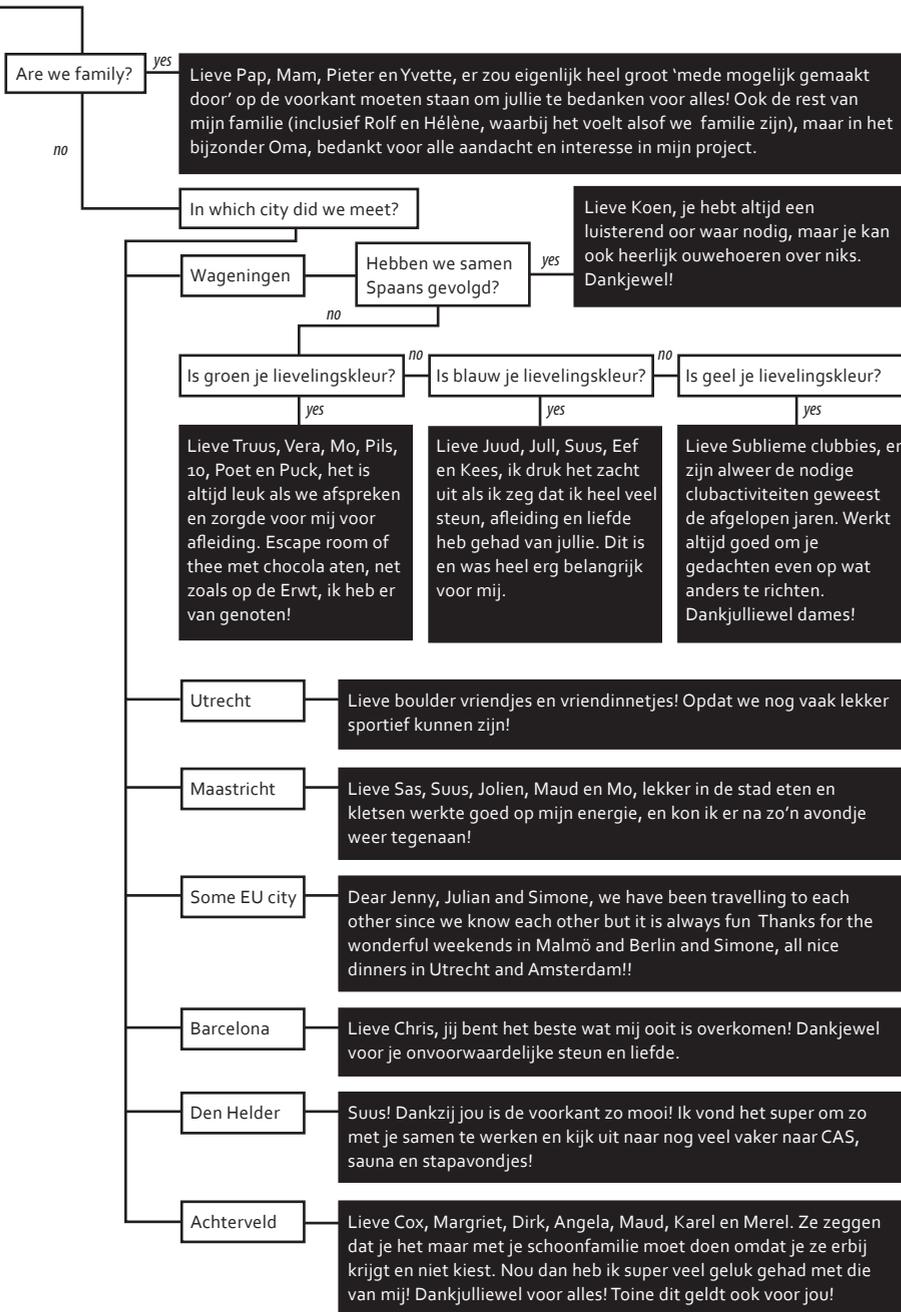

In de studies beschreven in [Hoofdstuk 4](#) hebben we gewerkt aan een streng genetische informatie, DNA, wat codeert voor stukjes van de ziekteverwekker die tuberculose veroorzaakt. Dit stuk DNA kan worden gebruikt als model-vaccin. We hebben een strategie laten zien hoe dit stuk DNA kan worden verbeterd, waardoor er meer CD8⁺ T cellen geactiveerd worden. Door het ontwikkelen van dit soort strategieën kunnen bestaande vaccins verbeterd worden, opdat ze meer CD8⁺ T cellen activeren.

Dit verbeterde model-vaccin hebben we ook gebruikt voor het project beschreven in [Hoofdstuk 5](#). Deze studies zijn gedaan aan het Max Planck Instituut voor Infectie Biologie in Berlijn. We hebben getest of het model-vaccin een goede combinatie kan zijn met het huidige vaccin voor tuberculose. De achterliggende gedachte is dat wanneer je niet één, maar twee keer vaccineert, en op verschillende plaatsen in het lichaam, er een betere activatie is van het immuunsysteem. We hebben geconcludeerd dat dit inderdaad het geval is maar ook dat het uitmaakt in welke volgorde je de vaccins geeft. Deze kennis kan goed toegepast worden op het huidige vaccinatie regime tegen tuberculose.

Conclusies

In dit proefschrift stonden de CD8⁺ T cellen centraal. We kunnen concluderen dat de beschreven resultaten meer inzicht geven in hoe ze functioneren en beïnvloed kunnen worden. Ten eerste omdat we de immunologische relevantie aan hebben getoond van een nieuw mechanisme hoe de ziekteverwekkers worden verwerkt en gepresenteerd aan het immuunsysteem. Ten tweede omdat we een direct toepasbare strategie hebben laten zien die werkt tegen tuberculose. Deze kennis zal bijdragen aan het verbeteren van vaccins.

CV

Anouk Cecile Maria Platteel was born on February 6, 1987 in Den Helder, the Netherlands. In September 2005 she started her studies in Animal Sciences at Wageningen University, Wageningen. She wrote her bachelor thesis under supervision of Prof. dr. ir. H.F.J. Savelkoul and obtained her degree in 2008. During her master Anouk was active as a member of the Student Council and student representative in the board of the Education Institute of Wageningen University and European Students' Union. She was admitted to the Research Master track of Animal Sciences in which Anouk fulfilled her first internship at the Adaptation Physiology department of Wageningen University under supervision of dr. A. Lammers. She worked on the immunomodulatory influence of lectins in the diet of young laying hens. Anouk went to Barcelona, Spain to IDIBELL (Bellvitge Biomedical Research Institute) for her second internship, which she did under supervision of dr. C. Cabellos. She studied the activities of combination treatment with daptomycin and fosfomycin against methicillin resistant *Staphylococcus aureus* in rats. Her supervisor in the Netherlands for this internship was dr. H.K. Parmentier. For her third internship, Anouk worked on the effect of systemic inflammation on muscle of elderly at Nutricia Research, now based in Utrecht, the Netherlands, under supervision of dr. K. van Norren and Ing. F. Dijk. Prof. dr. ir. H.F.J. Savelkoul was her supervisor from Wageningen University. In June 2012 Anouk graduated in both specializations Animal Health and Applied Zoology.

Anouk started her PhD training in September 2012 at the "Infection & Immunity Center Utrecht" in Utrecht, the Netherlands and performed her research in the lab of dr. E.J.A.M. Sijts at the department of Infectious Diseases and Immunology, Division of Immunology of Utrecht University. She studied new ways of antigen processing as well as strategies to modulate it, in order to elicit robust and broad CD8⁺ T cell responses for vaccine design. Part of these studies were conducted in the lab of Prof. dr. S.H.E. Kaufmann at the Max Planck Institute of Infection Biology in Berlin, Germany. For these studies Anouk received short stay fellowships grants from Boehringer Ingelheim Fonds and the European Federation of Immunological Societies (EFIS). The results obtained during this PhD project are presented in this thesis. Also during her PhD project, Anouk was active in education policy. She was a member of the Infection & Immunity educational board, Prout (Promovendi Overleg Utrecht) and Veterinary PhD council, aiming at contributing to the education of Life Science master students and PhD candidates of Utrecht University.

Currently Anouk is working at the department of Infectious Diseases and Immunology, Division of Immunology of Utrecht University.
