Supporting Information

ABSTRACT: Zeolite-based catalysts are globally employed in many industrial processes, such as in crude-oil refining and in the production of bulk chemicals. However, to be implemented in industrial reactors efficiently, zeolite powders are required to be shaped in catalyst bodies. Scale-up of zeolite catalysts into such forms comes with side effects to its overall physicochemical properties and to those of its constituting components. Although fundamental research into “technical” solid catalysts is scarce, binder effects have been reported to significantly impact their catalytic properties and lifetime. Given the large number of additional (in)organic components added in the formulation, it is somehow surprising to see that there is a distinct lack of research into the unintentional impact organic additives can have on the properties of the zeolite and the catalyst bodies in general. Here, we systematically prepared a series of alumina-bound zeolite ZSM-5-based catalyst bodies, with organic additives such as peptizing, plasticizing, and lubricating agents, to rationalize their impacts on the physicochemical properties of the shaped catalyst bodies. By utilizing a carefully selected arsenal of bulk and high-spatial resolution multiscale characterization techniques, as well as specifically sized bioinspired fluorescent nanoprobe to study pore accessibility, we clearly show that, although the organic additives achieve their primary function of a mechanically robust material, uncontrolled processes are taking place in parallel. We reveal that the extrusion process can lead to zeolite dealumination (from acid peptizing treatment, and localized steaming upon calcination); meso- and macropore structural rearrangement (via burning-out of organic plasticizing and lubricating agents upon calcination); and abating of known alumina binder effects (via scavenging of Al species via chelating lubricating agents), which significantly impact catalytic performance. Understanding the mechanisms behind such effects in industrial-grade catalyst formulations can lead to enhanced design of these important materials, which can improve process efficiency in a vast range of industrial catalytic reactions.

KEYWORDS: zeolites, extrudates, additives, binder, catalysis, catalyst body

1. INTRODUCTION

The role zeolite-based catalysts play in producing many of our everyday needs, such as fuels, chemicals, and materials, cannot be stressed enough.^{1–4} Their excellent physicochemical properties, such as well-defined pores/channels and tailored acidity, allow them to function efficiently in a variety of essential catalytic processes, such as alkylation, isomerization, and cracking.^{5–10} Normally, in an academic setting, the focus is heavily on “research” solid catalysts. Examples include zeolite single crystals and/or powders, which provide necessary fundamental insights into their catalytic properties.^{11–14} However, if they are to be used in industrial reactors, then more often than not, they are required to be scaled-up into

shaped catalyst bodies. Here, the zeolite is dispersed in a binder/matrix/filler in a multiscale, multicomponent body, which, as compared to a powder, primarily limits pressure drop, enhances mechanical stability, and improves heat-mass transfer (among others).^{15,16} The process of forming shaped catalyst bodies, for example, catalyst extrudates, requires homogenization and densification of a proprietary formulation, to form a paste with an optimum solid-to-liquid ratio, prior to extrusion of green bodies and drying. Although experimental

Scheme 1. (a) Illustration of a Freshly Extruded Zeolite-Catalyst Body, and the Distribution of Components Therein;^a and (b) (Non)primary Processes That Have Been Found To Occur in This Work, upon the Use of Additives in Zeolite-Based Alumina-Bound Catalyst Body Formulations

^a(a) Examples are depicted of commonly employed inorganic components and organic additives burnt-off upon calcination. The primary role of each component/additive is as follows: zeolite is the active phase; binder provides mechanical strength to the technical body; peptizer disperses particles to achieve homogeneity; plasticizer enhances rheological behavior of the paste to be extruded; and lubricant aids the passage of the paste during extrusion into technical bodies. Typical amounts of each catalyst body are given on the basis of patent literature.^{19,20,42-46} (b) (i) Lubricating and plasticizing agents effectively act as pore forming agents after their removal upon calcination, leading to variations in mesopore and macropore diameters/volume; (ii) peptizing agents lower the pH of the paste below the point zero charge (PZC) of the boehmite binder (~ 9), causing hydrolysis of the oxobridges between particles and protonation of the surface of the alumina binder, creating repulsion between particles; (iii) depending on the peptizing agent selected (i.e., acids with different pK_a values), varying degrees of zeolite dealumination take place (with lower pK_a values (<1) leading to extra framework Al (EFAI) dissolution); (iv) Al migration taking place via mobile species from the γ - Al_2O_3 binder to the zeolite, reacting with silanol groups (terminal framework and/or silanol nests (via dealumination)) to create additional acid sites; and (v) the use of lubricating agents such as glycerol can disrupt the prior-mentioned Al migration process, given the chelating nature of glycerol, depleting mobile Al species from the binder that could potentially form new acid sites.

details on the scale-up process are particularly vague, it is known that a large number of components are added to the formulation, that is, active phase, binder, filler, lubricant, plasticizer, porogen, and peptizing agents.¹⁶⁻²¹ Each of these components is added with a specific role(s) in mind, with the overall goal to achieve an extrudate with high mechanical strength, so as to withstand harsh reactor conditions. The primary function(s) of the organic additives used in the formulation design stems from a great deal of knowledge in the ceramics industry²² and supported transition metal catalyst bodies.^{23,24} For instance, peptizing agents such as acetic acid and citric acid are present to homogenize and disperse particles, and can be added in the form of acid or base.²⁵ Lubricating and plasticizing agents like polyethylene glycol and cellulose are somewhat harder to distinguish from each other, as one compound can play both roles, but primarily their role is to reduce friction and decrease viscosity of the paste upon extrusion, with viscous oils and polar/nonpolar materials commonly employed.¹⁷ Unlike in ceramic extrudates/monoliths, components such as zeolites in catalyst bodies can potentially interact with organic additives prior to and during

their decomposition upon drying. It has already been shown that side effects such as solid-state ion exchange between intimate binder and zeolite interactions can occur when shaping with a binder in zeolite-based catalyst bodies, being either beneficial or detrimental to their catalytic properties.²⁶ Surprisingly, the binder component is often referred to as an inert material, mainly present to increase the mechanical properties of the catalyst body. However, past and more recent research has shed light on the significant impact the interaction of the binder can have on the zeolite active phase, such as entrapment of poisons, modification of deactivation characteristics, and neutralization of active sites, among others.²⁷⁻³⁶ Proximity of the binder and zeolite, together with the presence of water and heat treatment during shaping, ensure the transport of species from the binder to the zeolite (and vice versa), and solid-state ion exchange of the Brønsted acid sites takes place. The latter provides a definitive indication as to what consequences intimate contact between organic and inorganic components might have upon shaping.

It is therefore somewhat surprising to see that fundamental research into rationalizing the potential side effects of the

organic additives in zeolite-based catalyst bodies is clearly lacking. Due to their individual physical and chemical characteristics, for example, structural dimensions and pH, one can expect a large impact to the physicochemical properties of the zeolite and the catalyst body in general. For instance, the use of acidic solutions to dealuminate zeolites is well-known,^{37–39} so what happens to the zeolite acid sites in a shaped body when an acid peptizing agent is used in the formulation? Or indeed, what happens to the pore structure when lubricants of either short-chain polymers or long-chain polymers are burnt out upon drying? Each of these factors, among many possible others, has the potential to severely influence the catalytic properties of the final shaped catalyst bodies. Given the multidimensional nature of these important materials, together with the large number of components added, it is vital that a carefully chosen set of complementary, multiscale characterization techniques are used (e.g., electron microscopy, X-ray diffraction, solid-state nuclear magnetic resonance, etc.),^{40,41} as well as employing a rational approach to investigate the effect of formulations when preparing these catalyst bodies.

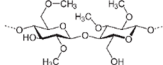

In this work, to elucidate the side effects organic additives can have on the catalytic properties of zeolite-based catalyst bodies, we have systematically prepared a series of alumina-bound zeolite ZSM-5 catalyst bodies, adding commonly employed additives both separately and combined (Scheme 1), together with multiple state-of-the-art and novel multiscale characterization techniques. Such knowledge can lead to improved design of these important materials, to enhance process efficiency in a multitude of industrial catalytic processes.

2. EXPERIMENTAL SECTION

2.1. Shaped Catalyst Body Preparation. Zeolite H-ZSM-5 (ACS Materials, M38) was mixed as a dry powder with alumina (Sasol, Catapal D (Boehmite)) and the required amount of Milli-Q water to ensure an optimum solid-to-liquid ratio for extrusion (measured using a Mixer Torque Rheometer, Caleva). The paste, containing a ratio of 70:30 wt % zeolite:binder, was extruded using a Mini-Screw Extruder (Caleva), through a 2 mm (\varnothing) cylindrical die plate. To determine the effect of additives (e.g., peptizing agents, plasticizing agents, and/or lubricating agents), 2 wt % acetic acid (Merck-Chemicals, glacial 100%), nitric acid (Fluka, >65%), methylcellulose (Sigma-Aldrich, 4000 CP), polyethylene glycol (Sigma-Aldrich, M_n 400), and glycerol (Acros Organics, 83.5–88.5 wt %) were either combined or added separately. After being dried overnight at room temperature, the extrudates were calcined in a tubular oven furnace at 600 °C for 6 h (5 °C min^{-1}) in flowing air. As a reference, a zeolite ZSM-5 extrudate was also prepared using the same method as above, but without the use of additives (i.e., only Milli-Q water). Sample names were labeled according to those in Chart 1.

2.2. Physicochemical Characterization. Ar physisorption of the catalyst bodies was performed using a Micromeritics TriStar 3000 instrument. Before the measurements, the samples were outgassed for 16 h at 300 °C under dry N_2 flow, with measurements performed using Ar at -196 °C . Hg porosimetry was measured in a Micromeritics Autopore IV 9500 instrument. A contact angle of 130° for Hg intrusion and a pressure equilibration of 10 s were applied. Scanning electron microscopy (SEM) was performed using a FEI Helios Nanolab

G3 instrument, and, prior to analysis, the extrudate cross sections were coated with a layer of Pt to increase the conductivity of the samples. X-ray diffraction (XRD) patterns of the catalyst bodies (crushed and flattened) were recorded on a Bruker D8 X-ray powder diffractometer equipped with a Co $K\alpha$ X-ray tube ($\lambda = 1.7902\text{ \AA}$). Prior to scanning transmission electron microscopy (STEM) analysis, samples were embedded in Epofix resin and dried in air at 60 °C overnight. The cured resin was then sliced into 70 nm thick sections with a Diatome Ultra 35° diamond knife using a Reichert-Jung Ultracut E ultramicrotome. The obtained sections were deposited on Formvar carbon TEM grids. High-angle annular dark-field (HAADF)-STEM imaging and EDX mapping were performed on a Talos F200X (FEI) microscope, operated at 200 kV, which is equipped with an X-FEG electron source and a Super-X detector. HAADF-STEM images were acquired with a frame time of 20 s using TIA software. STEM-EDX elemental maps of 512×512 pixels were acquired with 10 min acquisition time using Velox software. Crush strength measurements were performed on similarly sized single horizontal extrudates using a homemade load cell. To ensure reproducibility, extrudates were tested three times per sample, and the average crush strength was taken. Acidity measurements were recorded with a Nicolet iZ10-IR spectrometer at 2 cm^{-1} optical resolution using pyridine and collidine as probe molecules. Prior to the measurements, 20 mg of the catalysts was pressed in self-supporting discs (diameter: 1.6 cm) and pretreated in the IR cell attached to a vacuum line at 450 °C for 4 h up to 10^{-6} Torr. Adsorption of pyridine and collidine (2,4,6-trimethylpyridine) was performed at 100 °C at the pressure of 1 Torr for 30 min to reach saturation, followed by evacuation at the same temperature for 30 min. The desorption of the probe molecules was further monitored in the 100–450 °C temperature range with a 1 °C min^{-1} heating rate. All spectra were normalized to 20 mg wafers. Difference spectra were obtained by subtracting the spectrum of the zeolite before probe adsorption. The amount of adsorbed probe molecules was determined by using the integrated area of a given band with the molar extinction coefficients (Brønsted, 1.36 cm

μmol^{-1} ; Lewis, $2.22\text{ cm } \mu\text{mol}^{-1}$ in the case of pyridine;^{47,48} and Brønsted, $8.1\text{ cm } \mu\text{mol}^{-1}$ when collidine was used as a probe⁴⁹). More information on the calculation method can be found in Figures S4 and S5. Direct excitation ^{29}Si NMR spectra of catalyst extrudates were recorded on a Bruker 500 MHz wide-bore magnet with an AVANCE-III console and equipped with a 3.2 mm magic angle spinning (MAS) probe, using direct excitation with a 90° pulse (10 s recycle delay and 15 kHz MAS frequency). For all experiments, ^{29}Si spectra were averaged over 3200 scans. The silicon to aluminum (FAI) ratio was estimated using Lowenstein's Rule and using eq 1,⁵⁰ where I denotes the intensity of the ^{29}Si NMR signal and $n_{\text{max}} = 1$ in the present case.

$$\left(\frac{\text{Si}}{\text{Al}_F}\right)_{\text{NMR}} = \sum_{n=0}^4 \frac{I_{\text{Si}(n\text{Al})}}{\sum_{n=0}^4 0.25nI_{\text{Si}(n\text{Al})}} \quad (1)$$

2.3. Staining and Visualization. The ~ 20 and ~ 45 nm fluorescent nanospheres (FluoSpheres, carboxylate-modified microspheres in Milli-Q water, ThermoFisher Scientific) were impregnated into each of the extrudates until saturation and equilibration (24 h), before drying under atmospheric conditions, bisectioning, and imaging with a 488 and 642 nm laser, respectively. Imaging was performed using a confocal fluorescence Nikon Eclipse 90i microscope equipped with a pinhole to filter out-of-focus light, and dichroic mirrors corresponding with the relevant laser line wavelength were chosen. The microscope was equipped with a Nikon A1 scan head, accommodating the optics, which couple fiber optics for excitation and emission light with the microscope. A Nikon $10\times/0.30$ objective was used along with a spectral analyzer in the Nikon A1 system, equipped with 32 photomultiplier tubes (PMTs), set to collect emission light in the 487–720 nm region (resolution of 10 nm). 3-D reconstruction of the individual imaged slices produced volumes of $1.29 \times 1.29 \times \sim 0.5$ mm (x , y , z (depth), respectively), visualized as “top-view” images.

2.4. Thiophene Oligomerization Reaction. Time-resolved UV–vis diffuse-reflectance spectra were recorded using a high-temperature UV–vis fiber optics probe, connected to an AvaSpec 2048L spectrometer and an AvaLight-DH-S-BAL light source. The measurements were performed using an in situ cell (Linkam Scientific Instruments, FTIR 600) equipped with a temperature controller (Linkam Scientific Instruments TMS 94). $\sim 10\ \mu\text{L}$ of thiophene was dropped on the extrudates at room temperature and immediately heated to $120\text{ }^\circ\text{C}$ with a ramping rate of $30\text{ }^\circ\text{C min}^{-1}$. The absorption spectra were simultaneously recorded every 10 s for a total of 1000 s in reflectance mode.

3. RESULTS AND DISCUSSION

To systematically determine the potential side effects produced by organic additives included in zeolite-based alumina-bound catalyst bodies formulations, a selection of peptizing, plasticizing, and lubricating agents were added both individually and combined, prior to full characterization of their physicochemical properties, and finally evaluation of their effect on catalytic properties and performance.

3.1. Peptizing Agents. The main role of the peptizing agent (Figure 1) when preparing catalyst extrudates is to lower the pH of the paste (in relation to its point zero charge). This is done to break up agglomerates by creating positively charged particles (repulsion) that lead to lower viscosity, and favorable

Figure 1. The Al-energy dispersive X-ray (EDX) mapping of (a) full cross-section of EXT-1, with large clusters of Al heterogeneously distributed, representative of the $\gamma\text{-Al}_2\text{O}_3$ binder (dotted white circle indicates the outer surface of the extrudate cross-section); (b) representative magnification of (a), with clusters of Al_2O_3 clearly visible with sparse Al distribution; (c) full cross-section of EXT-2, with Al more homogeneously distributed upon peptization; and (d) representative magnification of (c), clearly displaying the homogeneous “honeycomb” network of the Al_2O_3 binder.

extrusion.¹⁶ An important factor to take into account is the need to homogeneously disperse the zeolite and binder throughout the resulting catalyst extrudate. When Al_2O_3 is selected as a binder, peptizing agents are considered necessary, so as to achieve a high zeolite dispersion. To determine the effect of peptizing agents on the physicochemical properties of alumina-bound zeolite ZSM-5-based extrudates, such catalyst bodies were prepared without and with acetic acid ($\text{p}K_a$ 4.75) (EXT-1 and EXT-2, respectively), a commonly used peptizing agent.^{23,24,51}

Although X-ray diffraction (XRD) patterns showed no change in phase and/or crystallinity of the zeolite ZSM-5 and $\gamma\text{-Al}_2\text{O}_3$ (Figure S1), scanning electron microscopy (SEM)-EDX mapping revealed the difference in the distribution of Al and Si before (EXT-1) and after (EXT-2) the peptization process vividly, as shown in Figures 1 and S2. In EXT-1 (Figure 1a), Al clearly visible in the SEM image as clusters is predominantly present as large particles of $\gamma\text{-Al}_2\text{O}_3$ in the range of $5\text{--}40\ \mu\text{m}$ (Figure 1b) heterogeneously distributed throughout the entire cross-section. The Si distribution (Figure S2a) is attributed to the location of zeolite ZSM-5 domains that are homogeneously distributed. However, EXT-2 (Figures 1c and S2b) has a far more uniform distribution of Al throughout the cross-section, with significantly fewer large clusters of $\gamma\text{-Al}_2\text{O}_3$ present. Taking a closer look at the interaction of the $\gamma\text{-Al}_2\text{O}_3$ with the ZSM-5 crystals/aggregates (Figure S2c and d), the binding role of the $\gamma\text{-Al}_2\text{O}_3$ is vividly clear in the peptized sample (EXT-2) as compared to the nonpeptized sample (EXT-1), with a “honeycomb” of $\gamma\text{-Al}_2\text{O}_3$ surrounding zeolite domains in the former (Figure 1d). This is also evidenced by the crush-strength testing of both extrudates (Table 1 and Figure S3), with the peptized sample displaying a far superior strength (13 Newton (force required to crush/break the catalyst bodies)) as compared to the nonpeptized (3.5 N) and the pure zeolite ZSM-5 extrudate (2.5 N).

To reveal a higher degree of detail about the location and interaction of zeolite ZSM-5 and γ-Al₂O₃ in both EXT-1 and EXT-2, transmission electron microscopy (TEM)-EDX studies were performed on 70 nm thin sections of extrudates prepared by ultramicrotomy, and are presented in Figures 2 and S4.

Figure 2. TEM images of (a) EXT-1 and (b) EXT-2. The ZSM-5 crystal (highlighted by blue dot centered in the crystal) in EXT-1 is coated with a thin layer of γ-Al₂O₃, while the remaining γ-Al₂O₃ appears to be isolated in large aggregates (inlay). In EXT-2, a significantly higher quantity of γ-Al₂O₃ is visible as smaller aggregates (magenta dot) binding ZSM-5 crystals. Pore space is indicated via a green dot. (c) EDX map (Al in magenta, Si in blue) of EXT-2, showing the homogeneous binding of the zeolites by γ-Al₂O₃. Pore space is displayed in black regions (note, small black “cracks” within the blue Si (zeolite) domains are an artifact of the TEM preparation procedure, not intrinsic zeolite porosity). (d) Magnified EDX map of a single ZSM-5 crystal very tightly bound with γ-Al₂O₃ along the very well-defined zeolite edge (corresponding TEM image displayed in Figure S4d).

Looking first at EXT-1, single zeolite ZSM-5 crystals are visible in Figure 2a, with no clear indication that γ-Al₂O₃ is present around the zeolite crystals. However, a more detailed analysis (Figure S4a) reveals a thin layer (20–40 nm in thickness) of γ-Al₂O₃ on the ZSM-5 crystal surface, and appears to be the case on a larger scale as well (Figure S4b). Therefore, it seems that smaller particles of γ-Al₂O₃ powder are gathered onto the external surface of ZSM-5 crystals/aggregates during the extrusion process and create a fixed zeolite–boehmite interaction upon subsequent calcination, while the larger γ-Al₂O₃ clusters remain unbroken, giving rise to limited binding properties in EXT-1. On the contrary, γ-Al₂O₃ is distinctly more dispersed in a similarly sized region within EXT-2 (Figures 2b,c and S4c). Single ZSM-5 crystals are fully enveloped by γ-Al₂O₃ (Figures 2d and S4d), due to a greater dispersion of γ-Al₂O₃ and thus smaller aggregates, which lead to higher zeolite–binder interconnectivity and hence stronger mechanical properties of EXT-2 (Table 1). Considering the higher crush strength attributes (Table 1 and Figure S3) of EXT-2, these extrudates are able to survive the dedicated TEM preparation procedure, and hence macro- and mesopore space is visible in EXT-2 (Figure 2b) as compared to that of the disintegrated region visible in EXT-1 (Figure S4b).

To probe bulk porosity characteristics, Hg intrusion analysis (Figure 3a and Table 1) was used to analyze both meso- and macroporosity in EXT-1 and EXT-2. Upon the use of acetic acid, there is a clear decrease in around one-half the macropore volume (0.60 cm³ g⁻¹ EXT-1 and 0.36 cm³ g⁻¹ EXT-2), accompanied by a doubling in mesopore volume (0.02 cm³ g⁻¹ for EXT-1 and 0.04 cm³ g⁻¹ EXT-2). This can be attributed to the hydrolysis of the oxobridges between alumina particles and protonation of the surface of the alumina binder, creating repulsion between particles (Figure 1).¹⁶ It is also possible to vary the acid/alumina ratio, to tailor the particle size distribution, and hence the final pore architecture.⁵² Deagglomeration of the alumina effectively decreases its aggregate size, and leads to more interparticle interactions with other alumina particles, as well as zeolite ZSM-5 particles, coinciding with an increase in mesopore volume/diameter.

Figure 3. (a) Hg intrusion analysis displaying pore diameter variations between EXT-1 (gray, ●) and EXT-2 (black, ▲). (b) Fluorescence top-view 3-D CFM images of cross sections of EXT-1 (top) and EXT-2 (bottom) impregnated with 45 nm fluorescent nanospheres (for 24 h) and excited with a 642 nm laser. EXT-1 shows a far higher penetration depth into the center of the extrudate as compared to EXT-2. (c) True fluorescence top-view cross-sectional 3-D CFM images of EXT-1 (top) and EXT-2 (bottom), impregnated with 20 nm fluorescence nanospheres (for 24 h) and excited with a 488 nm laser. The smaller size of the probe allows further penetration into the center of both extrudates, with a greater effect seen for EXT-1 (scale bars represent 500 μm). (d) TEM-EDX maps of sections of EXT-2 (black) and EXT-6 (light purple), with Si (light blue) attributed to zeolite domains and Al (magenta) mainly attributed to alumina binder domains (scale bar represents 5 μm). (e) Corresponding dark pixel intensity threshold images of those displayed in (d), with marked green regions highlighting the pore space observed. In line with Hg porosimetry data, EXT-2 reveals larger pore space overall as compared to EXT-6.

Considering the porosity differences highlighted by Hg intrusion in EXT-1 and EXT-2, an attempt was made to visualize the accessibility of these pores using bioinspired fluorescent nanospheres of specific sizes, coupled with confocal fluorescence microspectroscopy (CFM) to visualize the nanosphere uptake/accessibility.⁵³ By impregnating EXT-1 and EXT-2 with a solution containing either ~ 45 or ~ 20 nm nanospheres, prior to excitation with a 642 nm laser or 488 nm laser, respectively, regions of accessibility can be visualized. Figure 3b compares the top-view 3-D cross sections of EXT-1 and EXT-2 impregnated with ~ 45 nm nanospheres, respectively. A more substantial penetration depth is observed for EXT-1, stopping at around 250–300 μm in the 2 mm (\varnothing) extrudate. Considering the expected larger macropore volume due to the heterogeneous $\gamma\text{-Al}_2\text{O}_3$ aggregate size in EXT-1, it is possible that, upon drying/calcination, water is first removed efficiently and rapidly from the outer region of the cylindrical catalyst extrudate, leaving a region of larger and more accessible pores than in the core. There is only minimal penetration into EXT-2 (~ 50 μm), suggesting that the narrower pore network formed upon $\gamma\text{-Al}_2\text{O}_3$ particle peptization exists throughout the majority of the catalyst

extrudate cross-section and is less accessible and/or less interconnected.

To probe accessibility into such smaller pore space in both extrudates, 20 nm fluorescent nanospheres were applied (Figure 3c), revealing an even deeper penetration into EXT-1 (>500 μm) and to a far lower extent in EXT-2 (<100 μm). It is clear, therefore, that a gradient of larger to smaller pores and/or a decrease in interconnected pores exists from outside to inside the extrudates, with the constituent particle sizes highly influential in determining the final pore architecture. Interestingly, the penetration of the nanospheres is not equal across all sides of EXT-1, which is most likely due to the heterogeneous drying nature of a tubular oven calcination setup (i.e., catalyst extrudates at the bottom of the calcination boat experience inconsistent heat/air flow).

It is clear that the use of a peptizing agent achieves its intended aim by producing a much stronger extrudate, with the active and binder components more homogeneously dispersed than when absent. However, as stated previously, the use of acid solutions and heat treatment is a well-known method of zeolite dealumination.^{37–39} Therefore, the use of an acid peptizing agent during the extrusion of alumina-bound zeolite ZSM-5 and its subsequent calcination should surely influence the final zeolite properties. Infrared (IR) spectroscopy of adsorbed probe molecules and solid-state ^{29}Si MAS NMR were employed to analyze the amount of both Brønsted (BAS) and Lewis (LAS) acid sites, as well as to determine if zeolite framework dealumination has taken place in the ZSM-5-based catalyst bodies. The amount of BAS present in the parent zeolite ZSM-5 extrudate and EXT-2 upon pyridine adsorption/desorption appears to be unchanged (Table 1 and Figure S5); however, it is clear that there is a large increase in the amount of LAS present in EXT-2 (176 $\mu\text{mol g}^{-1}$) as compared to the predicted value (129 $\mu\text{mol g}^{-1}$, using experimentally measured values of the pure zeolite and binder components). An increase in LAS is expected upon zeolite framework (FAI) dealumination, creating extra-framework aluminum (EFAI), which can act as LAS (Scheme 1).⁵⁴ Deconvolution of the ^{29}Si MAS NMR spectra enables a quantitative analysis of the Si tetrahedral sites, which can confirm if dealumination or dealumination has taken place within the zeolite framework.^{55,56} Four peaks arise from the spectra of ZSM-5 and EXT-2 (Figure 4), centered at -100 , -106 , and -112 and -116 ppm, which are attributed to (Q^2) SiOH, (Q^3) Si(3Si, 1Al), and (Q^4) Si(4Si), respectively. A decrease in Q^3 species, coupled with an increase in Q^2 species, is related to dealumination in the zeolite framework, which gives rise to a change in the framework Si:Al ratio from 20.9 (ZSM-5) to 21.8 (EXT-2) (via eq 1).

Given that the number of Lewis acid sites (LAS) increases upon shaping of ZSM-5 and its framework undergoes dealumination, the unchanged number of the Brønsted acid sites (BAS) from the parent ZSM-5 suggests a parallel process is also taking place. Although a full understanding of the mechanism is lacking, Si and/or Al migration has been reported upon the shaping of zeolites with an alumina or silica binder.^{29,30,57,58} In the case of an alumina binder, Al species have been proposed to migrate from the binder to the zeolite,⁵⁹ whereby upon the interaction with Si and O, additional acid sites can then be created (Scheme 1). However, there is some discrepancy in the mechanism of how this may occur, and also if these acid sites are created within the zeolite framework, or at the zeolite–binder interface. To observe if Al

Figure 4. Direct-excitation ^{29}Si solid-state MAS NMR spectra of parent zeolite ZSM-5 and shaped zeolite ZSM-5 extrudates prepared with varying formulations. Si-species identified as Q^4 (-112 and -116 ppm), Q^3 (-106 ppm), and Q^2 (-100 ppm), with corresponding Si:Al calculated (cf., eq 1).

migration has indeed taken place during shaping (and peptization) and also to determine if acid site creation is indeed located at the zeolite–binder interface, collidine (Figure S6 and Table 1) was employed as a probe molecule instead of pyridine, to selectively probe the external BAS at the surface of the zeolites. A 2-fold increase in BAS located outside the zeolite pores was measured for EXT-2 as compared to the parent zeolite ZSM-5 extrudates, suggesting that Al migration has indeed taken place, creating new acid sites at the interface. The presence of an acid peptizing agent (EXT-2) appears to form $+\text{AlOOH}$ species in the binder that are the species involved in Al migration (Scheme 1). Previously, it has been suggested that such species are capable of neutralizing BAS in the zeolite (via replacement of a BAS H^+ with AlO^+),⁶⁰ however, this was not observed in our materials.

3.2. Plasticizing and Lubricating Agents. In most cases of zeolite shaping, particularly during extrusion, the use of additives such as plasticizing and lubricating agents is essential. Plasticizing agents (Scheme 1) offer a means to enhance the rheological behavior of the paste to be extruded, and are inorganic (e.g., clay) or organic (e.g., cellulose) in nature. The latter appears to be far more popular, given the range of possibilities, such as poly alcohols, alginates, celluloses, and sugars, among others.¹⁷ The choice is dependent on the material at hand, but it is not uncommon to include a vast number of these additives in a proprietary mixture.¹⁹ The same can be said for lubricating agents, which are used to aid the passage of the paste as it passes along the inner wall of the extrusion equipment, in effect lowering shear pressure.¹⁶ The role of the lubricating agent is sometimes not discernible from

the plasticizing agent, and similar organic compounds are available, such as ethylene glycol and propylene glycol.

As with peptizing agents, these additives are used with a primary role in mind, and being organic in nature, are burnt out during drying/calcination of the shaped bodies, which can lead to unintentional physicochemical changes in the components of the extrudate. To discriminate the beneficial and detrimental roles of the plasticizing agent, methylcellulose was added to the formulation (without peptizing agent) prior to the extrusion of the paste (EXT-3). As compared to EXT-1 (no additives), a significant decrease in macropore volume from 0.60 to $0.43 \text{ cm}^3 \text{ g}^{-1}$ (Table 1) and pore diameter within the macroporous region was observed (Figure 3a). The combustion of methylcellulose upon drying leads to it being driven out of the extrudate after initially lying between particles, which can cause interparticulate sintering, and hence macropore collapse. Measuring the crush strength of EXT-1 and EXT-3, it is clear that the primary role of the plasticizing agent has been achieved, with an increase from 3.5 to 17 N , respectively. However, comparing the amount of BAS measured via pyridine adsorption of EXT-3 with that of the pure ZSM-5 extrudate, a slight decrease is observed, but is consistent with the decrease observed in EXT-1. For both EXT-1 and EXT-3, this decrease could be attributed to zeolite dealumination due to localized steaming of the zeolite from the water/methyl cellulose added during extrusion. This is observed by ^{29}Si MAS NMR in Figure 4 for EXT-3, with an even larger degree of zeolite FAI dealumination observed (Si:Al = 23.5) as compared to those of EXT-2 (21.8) and the parent ZSM-5 (20.9). It is possible that the decomposition products of methylcellulose formed during calcination⁶¹ and their subsequent combination with water can locally dealuminate the zeolite crystals.

Although we have now investigated the effects of peptizing and plasticizing agents individually, these are commonly added jointly in a formulation. Interestingly, the combination of acetic acid and methylcellulose (EXT-4) leads to significant changes in physicochemical properties when compared to their separate use (EXT-2 and EXT-3, respectively). In terms of macropore properties, it appears that acetic acid has the bigger influence over methylcellulose, with $0.35 \text{ cm}^3 \text{ g}^{-1}$ measured for EXT-4, consistent with $0.36 \text{ cm}^3 \text{ g}^{-1}$ measured for EXT-2 (Table 1), and similar pore size distribution (Figure 3a). However, EXT-2 presents a mesopore volume of $0.04 \text{ cm}^3 \text{ g}^{-1}$, which has now decreased to $0.02 \text{ cm}^3 \text{ g}^{-1}$ upon incorporation of methylcellulose to the formulation (EXT-4), revealing the dominant role of the plasticizing agent on the mesopore properties (as observed in EXT-3). This suggests that acetic acid is still able to protonate the alumina binder particles, but as the methylcellulose is burnt out during calcination, the interparticle porosity, attributed to the mesopore volume, is decreased. The result of a decrease in both macropore and mesopore volume coincides with a further increase in extrudate strength, with a value of 25 N measured for EXT-4, as compared to that of 13 N (EXT-2) and 17 N (EXT-3), showing the beneficial combination of additives in this case.

Pyridine adsorption IR spectroscopy of EXT-4 revealed a remarkable increase in the amount of BAS ($396 \mu\text{mol g}^{-1}$) when compared to those of parent ZSM-5 ($342 \mu\text{mol g}^{-1}$), EXT-2 ($345 \mu\text{mol g}^{-1}$), and also EXT-3 ($321 \mu\text{mol g}^{-1}$) (Table 1 and Figure S5). The large increase in BAS for EXT-4 as compared to that of EXT-2 indicates the combination of methylcellulose with the acetic acid further promotes Al

Figure 5. (a) Scheme displaying the oligomerization (top) and ring-opening (middle and lower) pathways taking place in zeolite Brønsted acid site-catalyzed thiophene oligomerization reaction. (b) Time-resolved 345 nm absorbance changes and (c) 655 nm absorbance changes, for each extrudate measured, showing that the trend in amount of total BAS (Table 1) is directly related to the absorbance intensity (normalized to ZSM-5 content) of the thiophene dimer, and that of the pentamer is directly related to the amount of external BAS (Table 1). (See Figure S8 for further details.)

migration from the binder to the zeolite, creating a greater amount of additional BAS. However, the comparable amount of external BAS measured using collidine of EXT-4 ($12 \mu\text{mol g}^{-1}$) and EXT-2 ($11 \mu\text{mol g}^{-1}$) suggests that not all newly created acid sites in EXT-4 are located at the zeolite–binder interface. This adds doubt to the theory that Al migration creates acid sites solely at the zeolite–binder interface, and realumination of the zeolite is now also a possibility. An increase in LAS was also observed ($165 \mu\text{mol g}^{-1}$) for EXT-4 as compared to the predicted value calculated from the pure components ($129 \mu\text{mol g}^{-1}$). This means that, although extra BAS are being created in EXT-4, dealumination of its zeolite FAI is still taking place, as expected and previously observed for EXT-2 and EXT-3, due to the presence and thermal treatment of acid, water, and methylcellulose upon calcination. This is again confirmed using the zeolite framework sensitive ^{29}Si MAS NMR (Figure 4), with an increase from Si:Al = 20.9 (ZSM-5) to 23.1 (EXT-4). Given the combination effect of the acetic acid and methylcellulose on the physicochemical properties of EXT-4, the effect of combining an alternative peptizing agent with methylcellulose was also investigated. Acetic acid was replaced by nitric acid (EXT-5), and a similar trend is observed, with some key differences. Not only is a larger decrease in macropore volume observed in EXT-5 as compared to EXT-4 (0.30 and $0.35 \mu\text{mol g}^{-1}$, respectively), but also a narrowing of the macropore diameter, as well as a slight increase in mesopore volume, and a decrease in the amount of LAS (Table 1). In each case, the higher acid strength of nitric acid ($\text{p}K_{\text{a}} < 1$) as compared to acetic acid ($\text{p}K_{\text{a}} 4.75$) is the cause of these differences, as it creates a greater degree of particle deagglomeration and also leads to the

dissolution of EFAl species upon dealumination,⁶² which will have drastic implications for its performance in BAS/LAS-catalyzed reactions.

To determine the effects of lubricating agents, two commonly used organic compounds were added separately to the formulation of EXT-4, polyethylene glycol (EXT-6) and glycerol (EXT-7). Although both compounds achieved their primary goal by easing the extrusion process considerably, their overall physicochemical properties were markedly (and unintentionally) impacted. Pore volume analysis via Hg porosimetry (Table 1 and Figure 3a) shows a decrease in macropore volume in both EXT-6 ($0.30 \text{ cm}^3 \text{ g}^{-1}$) and EXT-7 ($0.33 \text{ cm}^3 \text{ g}^{-1}$) as compared to EXT-4 ($0.35 \text{ cm}^3 \text{ g}^{-1}$), with only a minor change in mesopore volume. However, their pore diameters differ significantly, with the macropore size distribution EXT-6 being substantially narrower (peak maxima centered at 282 nm, as compared to 323 nm in EXT-7 and 390 nm in EXT-4). Furthermore, the mesopore diameter range in EXT-7 shifts to much larger diameters than all other extrudates (peak maxima at 7.7 nm), specifically as compared to that of EXT-6 (peak maxima at 5.6 nm). Such changes might not be expected from the primary role of these lubricating agents; however, these compounds are well-known pore forming agents (Scheme 1) in porous membrane synthesis, and pore sizes can even be tailored in the case of PEG, by altering its molecular weight.⁶³

Although TEM cannot be solely relied upon for visualizing/determining pore structure (due to sample preparation and region of interest (ROI) dimensions, representation, etc.), there is a clear indication that the macropore structure in EXT-6 is much more compact than that in EXT-2 (Figure 3d and e),

which could also explain the large decrease in BET surface area for EXT-6 (Table 1). This is further strengthened by pore accessibility measurements using fluorescent nanospheres in each of the above samples (Figures 3c and S7). Evidently, ~20 nm nanospheres have difficulty in penetrating into EXT-6, which, due to the macropore diameters present in the region of 150–400 nm, suggests that these pores are not well interconnected or accessible from the outside of the extrudate, as compared to that of EXT-2, where an increasing amount of penetration of the nanospheres is observed (complementing Hg porosimetry and TEM results).

Probing of LAS in EXT-6 and EXT-7 using pyridine IR spectroscopy (Table 1) (171 and $147 \mu\text{mol g}^{-1}$, respectively) and ^{29}Si MAS NMR (Figure 4) (Si:Al = 23.2 and 23.1, respectively, as compared to Si:Al = 20.9 for the pure ZSM-5) again reveals a large degree of zeolite dealumination, similar to that of EXT-4 (LAS = $165 \mu\text{mol g}^{-1}$ and Si:Al = 23.1). However, a substantially lower amount of BAS is observed for EXT-6 ($328 \mu\text{mol g}^{-1}$) and EXT-7 ($340 \mu\text{mol g}^{-1}$) as compared to EXT-4 ($396 \mu\text{mol g}^{-1}$). Given the similar amounts of BAS of EXT-6 and EXT-7 to that of the parent ZSM-5 ($345 \mu\text{mol g}^{-1}$), it suggests that Al migration upon peptization and hydrothermal treatment is hindered in the presence of these lubricating agents (as compared to EXT-4). Considering that both PEG and glycerol are chelating agents, it is possible that their interaction with Al species inhibits their migration to the zeolite, effectively scavenging excess Al that would, in the case of EXT-4, create additional acid sites.

Given these dramatic physicochemical changes witnessed for EXT-4, EXT-6, and EXT-7, it is crucial to carefully investigate the choice of plasticizing/lubricating agents not only for their primary role, but also for their unintentional side effects in combination with other organic additives.

3.3. Catalytic Thiophene Oligomerization. To probe the effect of the physicochemical differences induced by the extrudate formulations on catalytic properties, a suitable acid-catalyzed reaction was selected. Previous work has shown that the oligomerization of thiophene is a probe reaction that can gain insight into how the nature and/or number of BASs (and also porosity), in zeolites and zeolite-shaped bodies, influence catalytic reactivity and intermediate/product selectivity.^{27–29,64–66} Given that a large majority of oligomer species produced during the acid-catalyzed reaction are light-absorbing, they can be distinguished and followed in a time-resolved manner using in situ UV–vis absorption diffuse-reflectance spectroscopy.^{67,68} Figure 5a provides a general reaction scheme for the thiophene oligomerization reaction on a zeolite BAS, with the predominant intermediate and product species shown, and their respective absorption wavelengths (nm). Upon adsorption and protonation of the thiophene monomer, at least two reaction pathways are then undertaken: (i) oligomerization and (ii) ring-opening. Under the reaction conditions employed, it is likely that initial conversion of thiophene will take place on the external BAS, with the internal BAS also playing a significant role as thiophene monomers diffuse into the zeolite channels over time. Furthermore, the molecular dimensions of the oligomer species formed during the reaction are also an indication of which BAS are responsible, but can be related to the meso-/macropore dimensions of the extrudate under consideration.

Figure S8 reveals the time-resolved absorption spectra recorded during ~15 min of reaction for each zeolite-based extrudate prepared with distinct formulations (Chart 1). It is

clear that all zeolite-based extrudates produce a mixture of both thiol-like species (ring-opening pathway) and oligomer species (oligomerization pathway); however, there are distinct differences between the samples. Considering each extrudate sample contains the same weight ratio of the active zeolite component, and the fact that the additives used (or not) in each sample are primarily present to improve the mechanical strength of the extrudates, it is surprising to observe the extent of their impact on the catalytic performance.

Looking first at the species that can form on both external and internal zeolite BAS, for example, the thiophene dimer (345 nm) (Figure 5b), the ZSM-5 extrudate displays the highest rate of formation initially (<200 s), as compared to the composite extrudates. This is attributed to the high accessibility (high surface area and mesopore volume (Table 1)) of thiophene monomers to the high number of BAS available ($342 \mu\text{mol g}^{-1}$) in the pure ZSM-5 extrudate, with the composite extrudates displaying a lower initial rate of formation due to initial limitations in mass transfer. However, either due to the sequential conversion of these dimers to larger oligomers, or due to the limitation in mass transfer of these larger species in the ZSM-5 extrudate (as compared to the composite extrudates that have macroporosity), the ZSM-5 extrudate displays the lowest overall absorbance for the thiophene dimer over the total reaction time. Considering EXT-5 and EXT-4 also have the high numbers of BAS (408 and $396 \mu\text{mol g}^{-1}$) but contrarily have high macroporosity and display the highest overall absorbance for this dimer species during the reaction (Figure 5a), it suggests that limitations in mass transport in the ZSM-5 extrudate are responsible for the lowest concentration of such species.

However, the trend is not only associated with the porosity characteristics of the samples, as there is indeed a correlation between the number of total BAS and the overall absorbance of the dimer species for the composite extrudates (with EXT-3 appearing to be an exception to this trend).

To observe the impact of the additives in relation to the zeolites external BAS and how they impact the catalytic performance, the formation of the pentamer thiophene oligomer (645 nm) was tracked during the reaction and is displayed in Figure 5c. Considering the large molecular dimensions of this oligomer, and its impossibility to fit inside ZSM-5 pores, it can be exclusively used as a direct means to study differences in external BAS between the samples. Similarly to the dimer species, the pure ZSM-5 extrudate has the highest initial rate of formation toward this species, due to the high initial accessibility of the external BAS sites. However, given the larger interparticle porosity and the close proximity of the Al_2O_3 binder to the zeolites in the composite extrudates, together with the larger meso- and macropore volume (Table 1), these properties allow for the transport and retention of a larger concentration of the thiophene pentamer (and larger oligomers $\lambda > 655 \text{ nm}$).²⁸ For the composite extrudates, there is indeed a direct trend in the number of external BAS and the absorbance of the 645 nm band (external BAS: EXT-5 = EXT-4 > EXT-2, matching the top three extrudates with the highest absorbance to the pentamer).

Considering that the concentration of oligomers and the degree of oligomerization are directly related to the amount/proximity of BAS for many oligomerization reactions,^{66,69} this is a clear proof-of-concept that, dependent on the additives used in the formulation, the product selectivity of a reaction can be tuned accordingly, and therefore the role of the

additives should go beyond just enhancement in mechanical strength.

4. CONCLUSIONS

By systematically adding and combining commonly employed organic additives to formulations of zeolite-based catalyst bodies, together with their thorough physicochemical characterization on multiple length scales, we have revealed the significant impact they can have on the catalytic properties of these industrial-grade catalysts. In terms of chemical alterations, the addition of acidic peptizing agents, such as acetic acid, leads to the dealumination of the ZSM-5 crystals, and the creation of additional Brønsted acid sites via Al migration from the binder. Such binder effects were effectively hindered when lubricating agents were incorporated into the formulation, possibly due to their chelating properties, effectively scavenging Al species. Moreover, replacing acetic acid with nitric acid had a substantial impact on the amount of Brønsted and Lewis acid sites, with the latter reduced considerably due to leaching of EFAl. Upon combination with plasticizing agents, such as methylcellulose, the degree of zeolite dealumination increased significantly, most likely due to the decomposition products formed upon its breakdown during heat-treatment, effectively dealuminating the zeolite. Aside from their impact on catalytic acid sites, each organic additive significantly influenced the pore architecture of the catalyst bodies. Specifically, the choice of plasticizing and lubricating agents distinctly tailored the meso- and macroporosity of the final catalyst body, mainly due to the “skeleton” pore structure left behind upon the “burning off” of the organics upon heat-treatment. Collectively, each individually altered physical and chemical attribute has dramatic benefits and consequences for the catalytic performance of the materials (as shown by the acid-catalyzed thiophene oligomerization reaction). Given the industrial importance of these zeolite-based catalyst bodies, such fundamental insights can lead to enhanced formulations and design, such as tailoring BAS/LAS (key to optimum product selectivity), to achieve enhanced process efficiency.
