#### Abstract

Commercialization of $\mathrm{CH}_{4}$ valorization processes is currently hampered by the lack of suitable catalysts, which should be active, selective, and stable. $\mathrm{CH}_{4}$ oxychlorination is one of the promising routes to directly functionalize $\mathrm{CH}_{4}$, and lanthanidebased catalysts show great potential for this reaction, although relatively little is known about their functioning. In this work, a set of lanthanide oxychlorides (i.e., LnOCl with $\mathrm{Ln}=\mathrm{La}, \mathrm{Pr}, \mathrm{Nd}, \mathrm{Sm}$, $\mathrm{Eu}, \mathrm{Gd}, \mathrm{Tb}, \mathrm{Dy}$, and Ho ) and Er - and Yb -based catalysts were synthesized, characterized, and tested. All lanthanide-based catalysts can directly activate $\mathrm{CH}_{4}$ into chloromethanes, but their catalytic properties differ significantly. EuOCl shows the most promising catalytic activity and selectivity, as very high conversion levels ( $>30 \%$ ) and chloromethane selectivity values ( $>50 \%$ ) can be  reached at moderate reaction temperatures ( $\sim 425^{\circ} \mathrm{C}$ ). Operando Raman spectroscopy revealed that the chlorination of the EuOCl catalyst surface is rate-limiting; hence, increasing the HCl concentration improves the catalytic performance. The CO selectivity could be suppressed from 30 to $15 \%$, while the $\mathrm{CH}_{4}$ conversion more than doubled from 11 to $24 \%$, solely by increasing the HCl concentration from 10 to $60 \%$ at $450^{\circ} \mathrm{C}$. Even though more catalysts reported in this study and in the literature show a negative correlation between the $S_{\mathrm{CO}}$ and HCl concentration, this effect was never as substantial as observed for $\mathrm{EuOCl} . \mathrm{EuOCl}$ has promising properties to bring the oxychlorination one step closer to an economically viable $\mathrm{CH}_{4}$ valorization process.

KEYWORDS: lanthanide, methane, oxychlorination, reaction mechanism, operando spectroscopy

## 1. INTRODUCTION

The use of $\mathrm{CH}_{4}$ from natural gas in chemical industry is expected to grow in the coming years, especially in view of the lower $\mathrm{CO}_{2}$ footprint relative to other fossil-based resources, such as coal and crude oil. ${ }^{1} \mathrm{CH}_{4}$ is used in the synthesis of chemical building blocks, such as ammonia, methanol, and acetic acid. ${ }^{2,3}$ Central in the synthesis of these molecules is the partial oxidation of methane to CO and $\mathrm{H}_{2}$ via reforming reactions, followed by one or more synthesis steps to obtain the desired reaction product. ${ }^{4}$ A major drawback of this approach is the energy-intensive, multistep process to obtain the desired bulk chemicals. Direct conversion routes of $\mathrm{CH}_{4}$ into chemical building blocks could reduce the energy needed for $\mathrm{CH}_{4}$ upgrading. To this date, however, direct conversion routes have not been commercialized because high selectivity is often only achieved at low conversion levels, while high conversion levels lead to the formation of, for example, $\mathrm{CO}_{2}{ }^{2,5}$

The direct conversion of $\mathrm{CH}_{4}$ into halogenated $\mathrm{CH}_{4}$, such as $\mathrm{CH}_{3} \mathrm{Cl}$ and $\mathrm{CH}_{3} \mathrm{Br}$, via, for example, methane oxychlorination (MOC) ${ }^{6-11}$ and methane oxybromination, ${ }^{8,12-15}$ is a promising route for efficient hydrocarbon utilization. ${ }^{16}$ Compared to other direct conversion routes of $\mathrm{CH}_{4}$, high selectivity to the desired product and relatively high conversions can be achieved, while
being operated under moderate reaction conditions (i.e., in the $400-600{ }^{\circ} \mathrm{C}$ temperature range and with $\left.p=\sim 1 \mathrm{bar}\right) .{ }^{14}$ Chlorinated methanes (CMs) are commodity chemicals, and $\mathrm{CH}_{3} \mathrm{Cl}$ is especially of great interest due to the chemical analogy between $\mathrm{CH}_{3} \mathrm{Cl}$ and $\mathrm{CH}_{3} \mathrm{OH}$. ${ }^{9,17}$ It can serve as a building block for the production of added value commodity chemicals, such as ethylene, propylene, and acetic acid. ${ }^{5,18}$ Therefore, a high selectivity to the desired $\mathrm{CH}_{3} \mathrm{Cl}$ is of great interest in the open literature ${ }^{8-11,14,19-22}$ and in the patent literature. ${ }^{18,23-28}$ However, the selective conversion of $\mathrm{CH}_{4}$ into $\mathrm{CH}_{3} \mathrm{Cl}$ remains challenging. The polarized bonds in the functionalized molecule are often more reactive than the inert $\mathrm{C}-\mathrm{H}$ bonds present in $\mathrm{CH}_{4}$, resulting in undesired byproduct formation. ${ }^{2,5}$ For MOC, other chlorinated products, such as $\mathrm{CH}_{2} \mathrm{Cl}_{2}$, are thus also obtained. In the upgrading of $\mathrm{CH}_{3} \mathrm{Cl}$ into olefins, even small amounts of $\mathrm{CH}_{2} \mathrm{Cl}_{2}$ cause rapid zeolite deactivation and thus

[^0]
$\mathrm{CH}_{2} \mathrm{Cl}_{2}$ needs to be removed from the feedstock. ${ }^{20}$ This increases the cost to separate $\mathrm{CH}_{3} \mathrm{Cl}$ and requires the development of, for instance, the hydrodechlorination process to convert poly-chlorinated $\mathrm{CH}_{4}$ into $\mathrm{CH}_{3} \mathrm{Cl}^{29}$

Olah et al. found that inserting an electrophilic Cl atom catalytically over solid (super)acids could reverse $\mathrm{CH}_{4}$ overfunctionalization and obtain high yields toward $\mathrm{CH}_{3} \mathrm{Cl}$ for direct chlorination. ${ }^{30}$ However, the chlorination of $\mathrm{CH}_{4}$ via the oxychlorination reaction is preferred because it utilizes HCl , produced as a byproduct in chlorination reactions, with a $100 \%$ Cl atom efficiency. In comparison, the Cl atom efficiency of thermal chlorination reactions is only $50 \% .^{30}$ This concept of an electrophilic Cl atom was successfully adapted by Podkolzin, Lercher, and co-workers and applied in the MOC reaction over $\mathrm{LaOCl} .{ }^{10}$ Interestingly, a reaction mechanism was proposed where $\mathrm{La}^{3+}$ catalyzes the reaction without changing the oxidation state. ${ }^{22}$ The activation of terminal surface lattice Cl by the dissociative adsorption of $\mathrm{O}_{2}$ results in a surface hypochlorite $\left(\mathrm{ClO}^{-}\right)$, where the formal oxidation state of chlorine changes from -1 to $+1 . \mathrm{CH}_{4}$ coordinates to this hypochlorite, and an atom exchange occurs, leaving a hydroxyl group on the surface and the CM. This surface hydroxyl group reacts with HCl to regenerate the chlorinated surface, producing water. Bulk LaOCl catalysts with a $S_{\text {BET }}$ of around $20 \mathrm{~m}^{2} / \mathrm{g}$ were activated with HCl and were able to chlorinate $\mathrm{CH}_{4}{ }^{10}$ At moderate conversion levels $\left(X_{\mathrm{CH}_{4}}=10 \%\right), S_{\mathrm{CH}_{3} \mathrm{Cl}} \sim 80 \%$ was obtained with minor byproducts of $\mathrm{CH}_{2} \mathrm{Cl}_{2}$ (12\%) and CO ( $8 \%$ ), essentially free of $\mathrm{CO}_{2}, \mathrm{CHCl}_{3}$, and $\mathrm{CCl}_{4}{ }^{31}$

However, the high selectivity was only obtained at low conversion levels $\left(X_{\mathrm{CH}_{4}}=<10 \%\right)$. As the conversion of $\mathrm{CH}_{4}$ was increased $\left(X_{\mathrm{CH}_{4}}=\sim 18 \%\right)$, the CO yield would surpass the $\mathrm{CH}_{3} \mathrm{Cl}$ yield. ${ }^{11}$ Overoxidation of $\mathrm{CH}_{4}$ into $\mathrm{CO}_{x}$ at high conversion levels is the biggest challenge in the catalyst and process development for the MOC reaction. ${ }^{8,32}$ Controlling the degree of surface chlorination of the solid catalysts, while maintaining a high conversion level is crucial for an economically viable process. For lanthanum-based catalysts, it is known that the $\mathrm{CH}_{4}$ chlorination step leaves a terminal surface lattice oxygen, while the exact same site is also responsible for the catalytic destruction of polychlorinated hydrocarbons. ${ }^{33}$ Balancing the chlorination rate with HCl and dechlorination rate by the reaction with $\mathrm{CH}_{4}$ and $\mathrm{O}_{2}$ is crucial for controlling the catalyst selectivity.

While a handful of publications report on the use of lanthanum, ${ }^{10,11,21,22}$ cerium,,${ }^{7,9,19}$ and europium ${ }^{6}$ oxychlorides, the rest of the lanthanide series remains so far largely unexplored. Lanthanides are interesting due to their high stability in corrosive environments and tunable redox properties and are thought to exhibit comparable chemistry in the oxychlorination reaction. ${ }^{18}$ Europium-based catalysts were previously reported as promising ethylene/propylene oxychlorination and $\mathrm{CH}_{4}$ oxybromination catalysts. ${ }^{6,13}$ The welltailored redox properties of EuOX (with $\mathrm{X}=\mathrm{Cl}$ or Br ) were crucial in developing an active and selective catalysts. ${ }^{6}$ Less successful was the use of EuOCl in MOC, where overoxidation seemed to be a large issue. For example, a $S_{\mathrm{CO}}$ value of $\sim 20 \%$ was observed at similar $\mathrm{CH}_{4}$ conversion levels, which is too high for industrial application. ${ }^{6}$

In this work, we have performed a comprehensive study on the $\mathrm{CH}_{4}$ oxychlorination over a series of lanthanide-based catalysts with the general formula LnOCl , where $\mathrm{Ln}=\mathrm{La}, \mathrm{Pr}$, $\mathrm{Nd}, \mathrm{Sm}, \mathrm{Eu}, \mathrm{Gd}, \mathrm{Tb}, \mathrm{Dy}$, and Ho. Two other lanthanide
catalysts, Er- and Yb-based, were also synthesized with the same synthesis technique, which did not yield the LnOCl phase. Although not all lanthanide-based catalysts showed equally high activity, this study revealed that they can be used to directly activate $\mathrm{CH}_{4}$ into CMs. Moreover, we show that a EuOCl catalyst possesses unique characteristics that make it possible to develop catalysts with high conversions and low selectivity toward $\mathrm{CO}_{x}$ as unwanted byproducts. Central in this study is the possibility to operate a EuOCl catalyst in HCl -rich environments. The CO selectivity could be suppressed, while the $\mathrm{CH}_{4}$ conversion more than doubled, solely by increasing the HCl concentration. Even though more reported catalysts show this behavior (e.g., $\mathrm{CeO}_{2}$ when $\mathrm{HCl} \% 6 \% \rightarrow 15 \%, X_{\mathrm{CH}_{4}} \sim 31 \% \rightarrow$ $\sim 34 \%$ and $\left.S_{\text {CO }} \sim 17 \% \rightarrow \sim 15 \%\right)$, ${ }^{14}$ this effect was never as substantial as observed for EuOCl. Furthermore, new mechanistic insights into the working principles of this superior EuOCl catalyst material were obtained by using operando spectroscopy.

## 2. EXPERIMENTAL METHODS

2.1. Catalyst Synthesis. LnOCl (where $\mathrm{Ln}=\mathrm{La}$, $\mathrm{Pr}, \mathrm{Nd}$, $\mathrm{Sm}, \mathrm{Eu}, \mathrm{Gd}, \mathrm{Tb}, \mathrm{Dy}$, and Ho ) and Er- and Yb -based catalyst materials under study were prepared by dissolving the corresponding lanthanide(III) chloride salt ( $\mathrm{LnCl}_{3} \cdot x \mathrm{H}_{2} \mathrm{O}$, Fisher Scientific, >99\%) in ethanol (absolute, VWR), followed by a precipitation using stoichiometric amounts of ammonium hydroxide (Fisher Scientific, 25\% in $\mathrm{H}_{2} \mathrm{O}$ ) at room temperature. After the dropwise addition, the precipitates were stirred for an additional hour and subsequently centrifuged to obtain the gel. Then, the obtained gel was washed with ethanol (absolute, VWR) and dried at $80^{\circ} \mathrm{C}$. Lastly, the dried solids were calcined in a static oven at $500^{\circ} \mathrm{C}$ for 3 h using a ramp rate of $5^{\circ} \mathrm{C} / \mathrm{min}$.
2.2. Catalyst Characterization. X-ray diffraction (XRD) patterns were obtained with a Bruker-AXS D2 Phaser powder Xray diffractometer in Bragg-Brentano geometry, using $\mathrm{Co} \mathrm{K} \alpha_{1,2}$ $=1.79026 \AA$, operated at 30 kV . The measurements were carried out between 10 and $80^{\circ}$ using a step size of $0.05^{\circ}$ and a scan speed of 1 s , with a 2 mm slit for the source. $\mathrm{N}_{2}$ adsorption isotherms were measured at 77 K on a Micromeritics TriStar II Plus instrument. Prior to all measurements, samples were dried at 573 K under a flow of $\mathrm{N}_{2}$. Specific surface areas were calculated using the multipoint BET method ( $0.05<p / p_{0}<$ $0.25)$. Pore volumes were calculated by the $t$-plot method; pore size distributions were obtained by BJH analysis. Transmission electron microscopy (TEM) was performed on a FEI Tecnai 20 instrument operating at 200 kV .

Operando spectroscopy measurements were performed with an AvaRaman-532 HERO-EVO instrument ( $\lambda=532 \mathrm{~nm}$, laser output 50 mW , spectral resolution of $\left.10 \mathrm{~cm}^{-1}\right)$ equipped with an AvaRaman-PRB-FC-532 probe, capable of withstanding temperatures up to $500^{\circ} \mathrm{C}$. Spectra were collected every minute with the AvaSoft 8 software. The data were subsequently baseline corrected and normalized. The initial Raman intensity was optimized to obtain at least $50 \%$ of the saturation value. The operando Raman experiments were performed by a sequential chlorination, dechlorination and oxychlorination step. The chlorination reaction was performed at $450^{\circ} \mathrm{C}$ with a $\mathrm{HCl} / \mathrm{N}_{2}$ ratio of 20:20 ( $\mathrm{mL} / \mathrm{min}$ ) for 2 h . Subsequently, the reactor was heated to $500{ }^{\circ} \mathrm{C}$ under $\mathrm{N}_{2}$, and then, flows $\mathrm{CH}_{4} / \mathrm{HCl} / \mathrm{O}_{2} / \mathrm{N}_{2} /$ He of 2:0:1:1:16 and $\mathrm{CH}_{4} / \mathrm{HCl} / \mathrm{O}_{2} / \mathrm{N}_{2} / \mathrm{He}$ of 2:2:1:1:14 were applied for dechlorination ( 90 min ) and oxychlorination ( 2 h ), respectively. The operando photoluminescence spectroscopy
experiments were performed by two sequential ramp experiments from 450 to $520{ }^{\circ} \mathrm{C}$ at $1^{\circ} \mathrm{C} / \mathrm{min}$ under the $\mathrm{CH}_{4} / \mathrm{HCl} /$ $\mathrm{O}_{2} / \mathrm{N}_{2} / \mathrm{He}$ ratio of 2:2:1:1:14. Prior to the first ramp experiment, the catalyst was subjected to the ratio $\mathrm{CH}_{4} / \mathrm{HCl} /$ $\mathrm{O}_{2} / \mathrm{N}_{2} / \mathrm{He}$ of 2:2:1:1:14 for 2 h at $450^{\circ} \mathrm{C}$. Prior to the second ramp experiment, the catalyst was subjected to a $\mathrm{CH}_{4} / \mathrm{HCl} / \mathrm{O}_{2} /$ $\mathrm{N}_{2} / \mathrm{He}$ ratio of 0:4:0:1:14.
2.3. Catalyst Testing. All the catalytic tests and operando Raman measurements were performed in a lab-scale continuousflow fixed-bed quartz reactor. Details of the setup, including a schematic and some pictures, are shown in Figure S1.

In a typical experiment, 500 mg of the catalyst material (with a $125-425 \mu \mathrm{~m}$ size fraction) was loaded in a quartz reactor and heated to $450{ }^{\circ} \mathrm{C}$ under $\mathrm{N}_{2}$ with $10{ }^{\circ} \mathrm{C} / \mathrm{min}$. The catalyst was activated in $20 \% \mathrm{HCl} / \mathrm{N}_{2}$ for 2 h prior to catalysis. For the isothermal experiments, the temperature was adjusted to reach $X_{\mathrm{CH}_{4}}=10 \%$ for the $\mathrm{CH}_{4} / \mathrm{HCl} / \mathrm{O}_{2} / \mathrm{N}_{2} / \mathrm{He}$ ratio of 2:2:1:1:14. When stable conversion was reached, the $\mathrm{HCl} / \mathrm{He}$ ratio was adjusted, so that the HCl concentration was increased to 20,40 , 60 , and $80 \%$, while keeping a constant flow of $20 \mathrm{~mL} / \mathrm{min}$. For the ramp experiments, the reactor was brought to $350^{\circ} \mathrm{C}$ and the desired feed mixture (i.e., $\mathrm{CH}_{4} / \mathrm{HCl} / \mathrm{O}_{2} / \mathrm{N}_{2} / \mathrm{He}$ of 2:2:1:1:14 or 2:16:1:1:0 in $\mathrm{mL} / \mathrm{min}$ ) was fed into the reactor. A stabilization period of 30 min was applied, and then, the ramp experiment of $1^{\circ} \mathrm{C} / \mathrm{min}$ was commenced at $550^{\circ} \mathrm{C}$. For the stability test, the temperature of the reactor was brought to $450{ }^{\circ} \mathrm{C}$ under $\mathrm{N}_{2}$. After a stabilization period of 15 min , the flow was adjusted to the $\mathrm{CH}_{4} / \mathrm{HCl} / \mathrm{O}_{2} / \mathrm{N}_{2} / \mathrm{He}$ ratio of 2:2:1:1:14 (in $\mathrm{mL} / \mathrm{min}$ ) and carried out for 10 h . Subsequently, the $\mathrm{HCl} / \mathrm{He}$ ratio was adjusted, so that the HCl concentration was increased to 20,40 , $60 \%$, and finally $80 \% \mathrm{HCl}$, while keeping a constant flow of 20 $\mathrm{mL} / \mathrm{min}$. Every feed ratio was tested for 10 h , except for $80 \%$ HCl , which was tested for 8 h . During the stability test, operando Raman spectroscopy measurements were performed.

The $\mathrm{CH}_{4}$ conversion, $X_{\mathrm{CH}_{4}}$, and $\mathrm{O}_{2}$ conversion, $X_{\mathrm{O}_{2}}$, are calculated according to eq 1

$$
\begin{equation*}
X_{\mathrm{a}}(\%)=\frac{x_{\mathrm{a}, \text { inlet }}-x_{\mathrm{a}, \text { outlet }}}{x_{\mathrm{a}, \text { inlet }}} * 100 \% * \text { ISCF } \tag{1}
\end{equation*}
$$

where $x_{\text {a, inlet }} x_{\mathrm{a}, \text { outlet }}$, and ISCF stand for the volumetric concentration of compound a at the inlet and outlet of the reactor and the internal standard correction factor, respectively. The yield of product $\mathrm{i}, Y_{\mathrm{i}}$, is calculated according to eq 2

$$
\begin{equation*}
Y_{\mathrm{i}}(\%)=\frac{x_{\mathrm{i}}}{x_{\mathrm{CH}_{4} \text { inlet }}} * 100 \% * \text { ISCF } \tag{2}
\end{equation*}
$$

where $x_{\mathrm{i}}$ and ISCF stand for the volumetric concentration of carbon-containing product $i$ and the internal standard correction factor, respectively. The selectivity of product $\mathrm{i}, S_{\mathrm{i}}$, is calculated according to eq 3 .

$$
\begin{equation*}
S_{\mathrm{i}}(\%)=\frac{Y_{\mathrm{i}}}{X_{\mathrm{CH}_{4}}} * 100 \% \tag{3}
\end{equation*}
$$

The $\mathrm{CH}_{4}$ reaction rate is calculated according to eq 4

$$
\begin{equation*}
R_{\mathrm{CH}_{4}}\left(\frac{\mathrm{mmol}}{\mathrm{~h}^{*} \mathrm{~g}_{\mathrm{cat}}}\right)=\frac{P^{*} F_{\mathrm{T}}^{*} x_{\mathrm{CH}_{4}, \mathrm{inlet}} * \frac{X_{\mathrm{CH}_{4}}}{100}}{R^{*} T^{*} W_{\mathrm{cat}}} \tag{4}
\end{equation*}
$$

where $P, F_{T}, R, T$, and $W_{\text {cat }}$ stand for the pressure, total flow, gas constant, ambient temperature, and catalyst weight. Finally, the carbon balance was calculated and measurements with their
carbon balance $> \pm 5 \%$ were removed. The carbon balance was calculated according to eq 5 .

$$
\begin{equation*}
\text { Carbon balance }=\sum Y(i)+100-X_{\mathrm{CH}_{4}} \tag{5}
\end{equation*}
$$

## 3. RESULTS AND DISCUSSION

3.1. Catalyst Properties. All synthesized lanthanide oxychloride ( LnOCl ) materials, made by precipitating $\mathrm{LnCl}_{3}$. $x \mathrm{H}_{2} \mathrm{O}$ with ammonium hydroxide, were characterized in detail with a battery of analytical methods. The result is a set of solid catalysts with surface areas, crystal phase, and particle morphology in the same order of magnitude. This enables us to study the role of the lanthanide ion within the LnOCl structure and its effect on MOC performances. As an example, Figure 1 shows the XRD patterns of the as-synthesized catalysts.

Figure 1. (A) XRD patterns of the catalyst materials under study, including $\mathrm{LaOCl}, \mathrm{PrOCl}, \mathrm{NdOCl}, \mathrm{SmOCl}, \mathrm{EuOCl}, \mathrm{GdOCl}, \mathrm{TbOCl}$, $\mathrm{DyOCl}, \mathrm{HoOCl}, \mathrm{ErOCl}$, and YbOCl . For each of these materials, they were obtained in their LnOCl phase, except for ErOCl and YbOCl and (B) zoom-in of the XRD patterns, revealing lanthanide contraction in the LnOCl materials, as indicated by the shift of the [101] diffraction in the $27-33^{\circ}$ region.

All LnOCl materials have the exact same crystal structure as LaOCl (ICDD 00-00800477). The general trend is that the peak positions (e.g., the [101] diffraction peak) shift toward higher angles with the increasing atom number, as can be concluded from Figure 1B. This reveals a contraction of the lattice parameters, which is caused by the lanthanide contraction effect. ${ }^{34}$ Significant contributions of $\mathrm{Ho}_{2} \mathrm{O}_{3}$ (COD 1537840)
and $\mathrm{Ho}_{3} \mathrm{O}_{4} \mathrm{Cl}^{35}$ were observed in the case of HoOCl , but the dominating phase is LnOCl . Unfortunately, for Er and Yb , we were not able to obtain a similar crystal phase, as indicated by the absence of the typical XRD peaks observed for the other LnOCl . In addition, the broadness of the XRD peaks suggests relatively small crystalline domains. For simplicity, we have labeled the Er and Yb catalyst as ErOCl and YbOCl , respectively, although this is formally incorrect.

An overview of the physicochemical properties of the assynthesized catalysts is given in Table S1. The BET surface area ( $S_{\text {BET }}$ ) within the same order is obtained, albeit we noted some variations, ranging from $15.5 \mathrm{~m}^{2} / \mathrm{g}(\mathrm{YbOCl})$ to $50.2 \mathrm{~m}^{2} / \mathrm{g}$ $(\mathrm{SmOCl})$. Similarly, the determined pore volume $\left(V_{\text {pore }}\right)$ ranges from $0.05 \mathrm{~cm}^{3} / \mathrm{g}(\mathrm{PrOCl})$ to $0.23 \mathrm{~cm}^{3} / \mathrm{g}(\mathrm{EuOCl})$. All the other $S_{\text {BET }}$ and $V_{\text {pore }}$ values fall within this range and correspond well to the $S_{\text {BET }}$ reported for the same synthesis of LaOCl materials by a base precipitation method. ${ }^{10,17,21,22}$

As the catalysts are bulk materials and made with base precipitation, ill-defined particles with a particle size ranging from a few nanometers to hundreds of nanometers are obtained (Figures 2 and S2). Especially for the YbOCl material, smaller particles were absent and only larger irregularly shaped particles were observed (Figure S2).

Figure 2. TEM image of the as-synthesized EuOCl where ill-defined particles with varying particle sizes are observed.

The fact that the $S_{\text {BET }}$ values (Table S1) are in the same range ( $15.5-50.2 \mathrm{~m}^{2} / \mathrm{g}$ ) and that the catalyst materials are synthesized in the same crystal structure, allows us to fairly compare the set of synthesized catalyst materials and study the unique role of the lanthanide element on the activity and selectivity observed in the reaction. $\mathrm{HoOCl}, \mathrm{ErOCl}$, and YbOCl do not fully comply with these criteria, but because interesting catalytic behavior was observed, and a complete overview of the lanthanide series could be presented, these catalyst materials are also included in this study.
3.2. Catalytic Performances. The catalytic activity of the as-synthesized lanthanide-based catalyst materials was compared by performing temperature ramp experiments under standard oxychlorination conditions for the production of $\mathrm{CH}_{3} \mathrm{Cl} . X_{\mathrm{CH}_{4}}$ and selectivity are plotted versus the temperature in Figure 3 for every catalysts individually. The selectivity is plotted when both $\mathrm{CH}_{3} \mathrm{Cl}$ and CO were above the detection limit of the GC and the onset temperature at which the catalyst become active is determined as the temperature at which $X_{\mathrm{CH}_{4}}>2 \%$.

All catalysts tested in this study show activity in the MOC reaction. Furthermore, the catalyst materials follow the same trend that $X_{\mathrm{CH}_{4}}, S_{\mathrm{CO}}$, and $S_{\mathrm{CH}_{2} \mathrm{Cl}_{2}}$ increase with the increasing temperature, while $S_{\mathrm{CH}_{3} \mathrm{Cl}}$ decreases. Nevertheless, unique
catalytic behavior can be observed when comparing the catalyst materials, and large differences in activity and selectivity were observed.

LaOCl , known for its high $\mathrm{CH}_{3} \mathrm{Cl}{ }^{10,22}$ becomes active at 480 ${ }^{\circ} \mathrm{C}$ and reaches a maximum $X_{\mathrm{CH}_{4}}$ of $21 \%$ at $550{ }^{\circ} \mathrm{C}$. With the increasing temperature, $S_{\mathrm{CH}_{3} \mathrm{Cl}}$ decreases from 66 to $32 \%$ and $S_{\text {CO }}$ increases from 25 to $45 \%$. Substantial amounts of $\mathrm{CH}_{2} \mathrm{Cl}_{2}$ are formed at $550{ }^{\circ} \mathrm{C}\left(S_{\mathrm{CHCl}_{3}}=18 \%\right)$, while neither $\mathrm{CCl}_{4}$ nor $\mathrm{CO}_{2}$ was detected.

PrOCl also becomes active at $480^{\circ} \mathrm{C}$ and reaches a maximum $X_{\mathrm{CH}_{4}}$ of $20 \%$. However, the selectivity differs drastically compared to the selectivity obtained with LaOCl . Much of $\mathrm{CH}_{4}$ is converted to CO , which is the dominant product at temperatures $>495{ }^{\circ} \mathrm{C}$. All four CMs can be observed at temperatures $>535^{\circ} \mathrm{C}$, albeit in very low concentrations in the case of $\mathrm{CCl}_{4}\left(\mathrm{~S}_{\mathrm{CCl}_{4}}<2 \%\right)$.

For NdOCl , the same onset temperature as for LaOCl and PrOCl was found, namely, $480^{\circ} \mathrm{C}$. However, $X_{\mathrm{CH}_{4}}$ shows a sharp increase in activity from $495^{\circ} \mathrm{C}$ to $520^{\circ} \mathrm{C}\left(X_{\mathrm{CH}_{4}}: 5 \% \rightarrow 16 \%\right)$ after which the activity plateaus till $535^{\circ} \mathrm{C}$. During this sharp increase of $X_{\mathrm{CH}_{4}}$, the selectivity is also impacted quite drastically as $S_{\mathrm{CH}_{3} \mathrm{Cl}}$ decreases from 64 to $38 \%$ and $S_{\mathrm{CO}}$ is increased from 24 to $38 \%$. Subsequently, $X_{\mathrm{CH}_{4}}$ increases further and reaches a maximum $X_{\mathrm{CH}_{4}}$ of $22 \% . S_{\mathrm{CH}_{3} \mathrm{Cl}}$ decreases further to $28 \%$, while $S_{\mathrm{CO}}$ increases to $46 \%$. $S_{\mathrm{CH}_{2} \mathrm{Cl}_{2}}$ increases gradually from 10 to $19 \%$, while $\mathrm{CHCl}_{3}$ was only detected in minor amounts ( $\mathrm{CH}_{\mathrm{CH}_{3} \mathrm{Cl}}<6 \%$ ).

SmOCl shows higher activity at lower temperatures, as $X_{\mathrm{CH}_{4}}>$ $2 \%$ is reached at $465^{\circ} \mathrm{C}$. A gradual increase in the activity is observed up to $550{ }^{\circ} \mathrm{C}$, where it reaches a final $X_{\mathrm{CH}_{4}}$ of $16 \%$. $S_{\mathrm{CH}_{3} \mathrm{Cl}}$ decreases from 61 to $30 \%$, while $S_{\mathrm{CO}}$ increases from 28 to $46 \% . S_{\mathrm{CH}_{2} \mathrm{Cl}_{2}}$ increases with the same trend as $S_{\mathrm{CO}}$ from 11 to $20 \% . \mathrm{CHCl}_{3}$ was detected in minor amounts ( $S_{\mathrm{CH}_{3} \mathrm{Cl}}<3 \%$ ).

The catalytic behavior of EuOCl is unique in a number of aspects. EuOCl shows activity already at low temperatures, as $X_{\mathrm{CH}_{4}}>2 \%$ is reached at $385{ }^{\circ} \mathrm{C}$. A maximum $X_{\mathrm{CH}_{4}}$ of $26 \%$ is reached at $485{ }^{\circ} \mathrm{C}$, after which $X_{\mathrm{CH}_{4}}$ drops to $19 \%$ at $500{ }^{\circ} \mathrm{C}$. Once the temperature further increases, $X_{\mathrm{CH}_{4}}$ steadily increases to the maximum $X_{\mathrm{CH}_{4}}$ of $38 \%$, which is the highest value for all lanthanide-based catalysts tested here under standard oxychlorination conditions. The nature of this drop in $X_{\mathrm{CH}_{4}}$ is discussed in Section 3.4. The unique performance is also reflected in the selectivity plot, where EuOCl has a maximum $S_{\mathrm{CH}_{3} \mathrm{Cl}}$ of $75 \%$, which gradually decreases to $29 \%$ with the increasing temperature. Both $S_{\mathrm{CO}}$ and $S_{\mathrm{CH}_{2} \mathrm{Cl}_{2}}$ increase with the same rate with the increasing temperature, up till the onset of the activity drop at $485{ }^{\circ} \mathrm{C}$. $S_{\mathrm{CO}}$ further increases, while $S_{\mathrm{CH}_{2} \mathrm{Cl}_{2}}$ decreases simultaneously up till the end of the drop at $505^{\circ} \mathrm{C}$. From 505 to $550{ }^{\circ} \mathrm{C}$, $S_{\mathrm{CO}}$ plateaus at $42 \%$, while $S_{\mathrm{CH}_{2} \mathrm{Cl}_{2}}$ slightly increases to $24 \% . \mathrm{CHCl}_{3}, \mathrm{CCl}_{4}$, and $\mathrm{CO}_{2}$ were all detected, albeit in very low amounts ( $S_{\mathrm{CHCl}_{3}}<5 \%, S_{\mathrm{CCl}_{4}}<1 \%$, and $S_{\mathrm{CO}_{2}}<2 \%$ ).

GdOCl, TbOCl, DyOCl, HoOCl , and ErOCl qualitatively show the same trends in activity and selectivity. These catalysts become active at temperatures between 420 and $430{ }^{\circ} \mathrm{C}$, after which $X_{\mathrm{CH}_{4}}$ increases very gradually up to $500^{\circ} \mathrm{C}$. Finally, the

| $\square \mathrm{CCl}_{4}$ | $\square \mathrm{CO}$ | $\square \mathrm{CO}_{2}$ |

Figure 3. $X_{\mathrm{CH}_{4}}$ and corresponding selectivity plotted $v s$ the temperature for LnOCl where $\mathrm{Ln}=(\mathrm{A}) \mathrm{La},(\mathrm{B}) \mathrm{Pr},(\mathrm{C}) \mathrm{Nd},(\mathrm{D}) \mathrm{Sm},(\mathrm{E}) \mathrm{Eu},(\mathrm{F}) \mathrm{Gd},(\mathrm{G})$ $\mathrm{Tb},(\mathrm{H}) \mathrm{Dy}$, (I) Ho, (J) Er, and (K) Yb. Conditions: $\mathrm{CH}_{4} / \mathrm{HCl} / \mathrm{O}_{2} / \mathrm{N}_{2} / \mathrm{He}$ of 2:2:1:1:14 (in $\mathrm{mL} / \mathrm{min}$ ) from 350 to $550^{\circ} \mathrm{C}$ with a ramp rate of $1{ }^{\circ} \mathrm{C} /$ min. Selectivity is given when $\mathrm{CH}_{3} \mathrm{Cl}$ and CO were above the detection limit of the GC.
$X_{\mathrm{CH}_{4}}$ increase slightly levels off and reaches the maximum $X_{\mathrm{CH}_{4}}$ at $550^{\circ} \mathrm{C}$. For $\mathrm{GdOCl}, \mathrm{TbOCl}, \mathrm{DyOCl}, \mathrm{HoOCl}$, and ErOCl, the maximum $X_{\mathrm{CH}_{4}}$ is $23,30,26,22$, and $19 \%$, respectively. Furthermore, these catalysts show similar selectivity profiles. $S_{\mathrm{CH}_{3} \mathrm{Cl}}$ steadily decreases over the tested temperature range, with the best performance for $\mathrm{ErOCl}\left(S_{\mathrm{CH}_{3} \mathrm{Cl}} 76 \% \rightarrow 40 \%\right)$ and the worst performance for $\mathrm{DyOCl}\left(S_{\mathrm{CH}_{3} \mathrm{Cl}} 55 \% \rightarrow 16 \%\right)$. $S_{\mathrm{CO}}$ first sharply increases up till $\sim 440^{\circ} \mathrm{C}$ and then gradually increases to an $S_{\mathrm{CO}}$ of $51-62 \%$ with the best performance again for ErOCl.
$S_{\mathrm{CH}_{2} \mathrm{Cl}_{2}}$ increases up till $\sim 500^{\circ} \mathrm{C}$ after which it levels off/slightly decreases and reaches a final $S_{\mathrm{CH}_{2} \mathrm{Cl}_{2}}$ of $10-20 \% . \mathrm{CHCl}_{3}$ was only detected in reasonable amounts for TbOCl and did not increase above $6 \%$ over the tested temperature range. $\mathrm{CCl}_{4}$ and $\mathrm{CO}_{2}$ were not detected.

Lastly, YbOCl shows relatively low overall activity, as $X_{\mathrm{CH}_{4}}>$ $2 \%$ is reached at $465{ }^{\circ} \mathrm{C}$ and reaches a maximum $X_{\mathrm{CH}_{4}}$ of $11 \%$. $S_{\mathrm{CH}_{3} \mathrm{Cl}}$ decreases from 72 to $56 \%$, and $S_{\mathrm{CO}}$ increases from 16 to $26 \%$. Furthermore, only $\mathrm{CH}_{2} \mathrm{Cl}_{2}$ is detected, which grows from

12 to $18 \%$. No higher CMs were observed, and no $\mathrm{CO}_{2}$ was detected.

The $\mathrm{CH}_{4}$ conversion rate and the corresponding selectivity for every catalyst material tested in this study at a temperature of $480{ }^{\circ} \mathrm{C}$ are plotted in Figure 4. This comparative plot clearly

Figure 4. (A) $\mathrm{CH}_{4}$ conversion rate and (B) selectivity toward $\mathrm{CH}_{3} \mathrm{Cl}$, $\mathrm{CH}_{2} \mathrm{Cl}_{2}, \mathrm{CHCl}_{3}, \mathrm{CCl}_{4}$, and CO for LnOCl (with $\mathrm{Ln}=\mathrm{La}, \mathrm{Pr}, \mathrm{Nd}, \mathrm{Sm}$, $\mathrm{Eu}, \mathrm{Gd}, \mathrm{Tb}, \mathrm{Dy}, \mathrm{Ho}, \mathrm{Er}$, or Yb ) at a reaction temperature of $480^{\circ} \mathrm{C}$. Note that for $\mathrm{LaOCl}, \mathrm{NdOCl}$, and YbOCl , the CO yield was below the detection limit, and therefore, the selectivity is not displayed. For all catalysts, the $\mathrm{CO}_{2}$ levels were below the detection limit.
shows that, even though the catalysts are chemically and physically comparable, large differences in both the activity and selectivity are induced by the lanthanide element. The highest $\mathrm{CH}_{4}$ conversion rate of $2.43 \mathrm{mmol} \mathrm{CH}_{4} * \mathrm{~h}^{-1 *} \mathrm{~g}^{-1}$ cat was observed for EuOCl , which is $\sim 13 \times$ times higher than that for LaOCl . Based on the $\mathrm{CH}_{4}$ conversion rate, the following activity ranking was found: $\mathrm{Eu}>\mathrm{Tb}>\mathrm{Gd} \sim \mathrm{Ho} \sim \mathrm{Er}>\mathrm{Dy}>\mathrm{Sm}>\mathrm{Pr} \approx$ $\mathrm{Nd} \approx \mathrm{La} \approx \mathrm{Yb}$ with a maximum $X_{\mathrm{CH}_{4}}$ of $24 \%$ for EuOCl and a minimum $X_{\mathrm{CH}_{4}}$ of $2 \%$ for LaOCl (Figure 4). A similar ranking can be constructed based on $S_{\mathrm{CO}}(\mathrm{Eu}>\mathrm{Pr} \sim \mathrm{Sm} \sim \mathrm{Er}>\mathrm{Gd}>\mathrm{Ho}$ $\sim \mathrm{Tb}>\mathrm{Dy})$ and $S_{\mathrm{CH}_{3} \mathrm{Cl}+\mathrm{CH}_{2} \mathrm{Cl}_{2}}(\mathrm{Eu} \sim \mathrm{Pr} \sim \mathrm{Sm} \sim \mathrm{Er}>\mathrm{Gd}>\mathrm{Ho} \sim$ $\mathrm{Tb}>\mathrm{Dy})$ at $480^{\circ} \mathrm{C}$. $\mathrm{La}, \mathrm{Nd}$, and Yb are not considered with the selectivity ranking, as the CO yield was below the detection level.

Based on the activity and selectivity performance, EuOCl shows the most promising catalytic behavior, as the highest $X_{\mathrm{CH}_{4}}$ and the best selectivity at reasonable conversion levels are found. Interestingly, LaOCl is often reported for its high $S_{\mathrm{CH}_{3} \mathrm{Cl}}$ at
reasonable conversion levels, but compared to the other lanthanide catalysts tested, its catalytic performance is mediocre under the reaction conditions applied here. ${ }^{10,11,22}$

Based on the abovementioned experimental findings, it is important to better understand the parameters that tune the reaction selectivity. Four key processes occurring during the MOC reaction for LnOCl materials are schematically depicted in Figure 5. These four processes, namely, the oxychlorination of $\mathrm{C}_{1}$ (arrows 1-4), ${ }^{21}$ a possible pathway for the catalytic destruction of $\mathrm{CR}_{2} \mathrm{Cl}_{2}$ (arrows 5-8), ${ }^{33,36}$ chlorination of terminal lattice oxygen (arrow 9), and bulk diffusion of $\mathrm{O} / \mathrm{Cl}$ (arrow 10), are connected, as they transition over the same surface compositions. The premise is to skip the catalytic destruction cycle and accelerate the oxychlorination cycle. In the catalytic chlorination of methane, surface chlorination via HCl plays a crucial role. Surface hydroxyl groups react with HCl to form surface chlorine and $\mathrm{H}_{2} \mathrm{O}$ (arrows 1-2). The surface hydroxyl groups regenerated as $\mathrm{C}_{1}$ and $\mathrm{O}_{2}$ react over the surface chlorine (arrows 3-4). However, the oxychlorination cycle can be skipped, once terminal lattice oxygen is formed via condensation via the hydrolysis of surface hydroxyl groups (arrow 5). ${ }^{37}$ The catalytic destruction of CMs over terminal lattice oxygen of La is well described, ${ }^{38}$ and it is hypothesized that a similar mechanism plays a role for the lanthanide-based catalysts tested in this study. When the CM catalytically destructs (arrows 6-7), surface chlorination is again obtained, where it crosses paths with the oxychlorination cycle again. $\mathrm{H}_{2} \mathrm{O}$ formed during the oxychlorination reaction and surface condensation can react with the formed surface chlorine, regenerating the surface hydroxyl groups (arrow 8). Important to note is that terminal lattice oxygen, over which catalytic destruction of CMs can occur, can either be chlorinated with HCl (arrow 9) or exchanged with mobile bulk chlorine (arrow 10). In the case of nonsteady state behavior of the catalyst composition, bulk diffusion of ions is partly accountable for changing catalyst surface compositions. ${ }^{38}$ Pivotal in the envisaged reaction cycles is the regeneration of the surface chlorine on which MOC can occur and the catalytic destruction of CMs is prevented.

A direct way to influence the degree of surface chlorination is by altering the HCl concentration under isothermal conditions. To investigate this effect, the catalysts were brought to $X_{\mathrm{CH}_{4}} \approx$ $10 \%$ and the concentration of HCl in the feed was increased. $X_{\mathrm{CH}_{4}}, S_{\mathrm{CH}_{3} \mathrm{Cl}}, S_{\mathrm{CO}}$, and $S_{\mathrm{CH}_{2} \mathrm{Cl}_{2}}$ are shown in Figure 6, while $S_{\mathrm{CHCl}_{3}}$ and $S_{\mathrm{CCl}_{4}}$ can be found in Figure S3. Generally, four types of responses can be identified for the different catalyst materials tested on the basis of their measured $X_{\mathrm{CH}_{4}}$ values: (1) increased activity (Figure 6, first row), (2) steady activity (Figure 6, second row), (3) slowly decaying activity (Figure 6, third row), and (4) instantaneous deactivation (Figure 6, bottom row).

We ascribe EuOCl to the first category; increased activity with the increasing HCl concentration. $X_{\mathrm{CH}_{4}}$ is increased from 11 to $25 \%$ going from 10 to $60 \% \mathrm{HCl}$ in the gas feed. Thereafter, the activity seems to plateau up to $80 \% \mathrm{HCl}$. The increase in HCl concentration does not only boost the activity but also suppresses $S_{\mathrm{CO}}$ from 28 to $14 \%$. Furthermore, $S_{\mathrm{CH}_{3} \mathrm{Cl}}$ decreases slightly, while $S_{\mathrm{CH}_{2} \mathrm{Cl}_{2}}$ and $S_{\mathrm{CHCl}_{3}}$ increase with the increasing HCl concentration. The formation of CO is largely caused by the catalytic destruction of $\mathrm{CH}_{2} \mathrm{Cl}_{2}$ and $\mathrm{CHCl}_{3}$, as $S_{\mathrm{CO}}$ and $S_{\mathrm{CH}_{2} \mathrm{Cl}_{2}} /$ $S_{\mathrm{CHCl}_{3}}$ are negatively correlated. The prevention of the catalytic

Figure 5. Schematic representation of relevant processes occurring during the MOC reaction over LnOCl materials. The oxychlorination cycle (green, arrows 1-4) and catalytic destruction cycle (red, arrows 5-8) are in competition with one another. The chlorination of terminal lattice oxygen (purple, arrow 9) is an important step because terminal lattice oxygen is held responsible for the catalytic destruction of higher chloromethanes. The surface composition is determined not only by the reactants but also by bulk diffusion of ions (gray, arrow 10).
destruction of higher CMs is evidenced by the observed $S_{\mathrm{CCl}_{4}}$ for EuOCl. The increase in HCl concentration thus has a doublesided effect: (1) less surface oxygen where higher CMs can be catalytically destructed on and (2) the generation of more active sites where chlorination of $\mathrm{C}_{1}$ can occur. Carefully choosing the $\mathrm{CH}_{4} / \mathrm{HCl} / \mathrm{O}_{2}$ ratio is thus of great importance for optimal catalytic activity.
$\mathrm{SmOCl}, \mathrm{DyOCl}$, and YbOCl show similar activity response with the increasing HCl concentration, although the exact values differ significantly. Their $X_{\mathrm{CH}_{4}}$ is rather insensitive to the HCl concentration in the feed and only increases slightly. $S_{\mathrm{CH}_{3} \mathrm{Cl}}$ and $S_{\mathrm{CO}}$ slightly decrease or remain constant, which is in line with $X_{\mathrm{CH}_{4}} \cdot S_{\mathrm{CHCl}_{3}}$ seems inversely proportional to $S_{\mathrm{CO}}$ and $S_{\mathrm{CH}_{3} \mathrm{Cl}}$ for DyOCl and YbOCl because it shows an upward trend with the increasing HCl concentration (Figure S 3 A ). For SmOCl , no formation of $\mathrm{CH}_{3} \mathrm{Cl}$ was observed, indicating that no $\mathrm{CH}_{3} \mathrm{Cl}$ was formed or that all formed $\mathrm{CHCl}_{3}$ was destructed. For these catalyst materials, $S_{\mathrm{CO}}$ could not be suppressed as dramatically as for EuOCl (for $\mathrm{DyOCl} 49 \% \rightarrow 37 \%$ vs for $\mathrm{EuOCl} 29 \% \rightarrow 14 \%$ ). A higher degree of surface chlorination mainly results in preventing the catalytic destruction of higher CMs for DyOCl and YbOCl , and to a lesser extent, the generation of more active sites for all three catalysts. The generation of more active sites
did not result in a higher $X_{\mathrm{CH}_{4}}$ but in a higher overall degree of chlorination of methane. The reactivity of $\mathrm{C}_{1}$ increases with the increasing chlorine content, ${ }^{21}$ and it appears that $\mathrm{CH}_{4}$ and the other CMs are in competition over the same active site(s).
$\mathrm{LaOCl}, \mathrm{GdOCl}, \mathrm{TbOCl}, \mathrm{HoOCl}$, and ErOCl all show a decaying activity profile with the increasing HCl concentration in the feed. The activity drops the most for $\mathrm{TbOCl}\left(X_{\mathrm{CH}_{4}} 12 \% \rightarrow\right.$ $4 \%)$ and the least for $\mathrm{LaOCl}\left(X_{\mathrm{CH}_{4}} 10 \% \rightarrow 7 \%\right)$. When further comparing these five catalysts based on their selectivity, LaOCl and ErOCl show very similar behavior and $\mathrm{GdOCl}, \mathrm{TbOCl}$, and HoOCl show very similar behavior. While $X_{\mathrm{CH}_{4}}$ of LaOCl and ErOCl decreases gradually, $S_{\mathrm{CH}_{3} \mathrm{Cl}}, S_{\mathrm{CO}}$, and $S_{\mathrm{CH}_{2} \mathrm{Cl}_{2}}$ are not significantly affected. The largest difference in selectivity of these two catalysts can be observed for LaOCl where $\mathrm{S}_{\mathrm{CH}_{3} \mathrm{Cl}}$ is reduced by $7 \%$. The higher HCl concentration causes $\mathrm{CH}_{3} \mathrm{Cl}$ to be further chlorinated to $\mathrm{CH}_{2} \mathrm{Cl}_{2}$. The additional $\mathrm{CH}_{2} \mathrm{Cl}_{2}$ is catalytically destructed, either directly or indirectly via the formation of $\mathrm{CHCl}_{3}$. For $\mathrm{GdOCl}, \mathrm{TbOCl}$, and HoOCl , however, larger differences in selectivity are observed, as $S_{\mathrm{CO}}$ decreases from 51 to $33 \%$ for TbOCl , while $S_{\mathrm{CH}_{3} \mathrm{Cl}}$ simultaneously increases from 33 to $52 \%$. $\mathrm{GdOCl}, \mathrm{TbOCl}$, and HoOCl are the only catalysts that show an increase in $S_{\mathrm{CH}_{3} \mathrm{Cl}}$ with the

Figure 6. $X_{\mathrm{CH}_{4}}, S_{\mathrm{CH}_{3} \mathrm{Cl}}, S_{\mathrm{CH}_{2} \mathrm{Cl}}$, and $S_{\mathrm{CO}}$ over LnOCl materials (with $\mathrm{Ln}=\mathrm{La}, \mathrm{Pr}, \mathrm{Nd}, \mathrm{Sm}, \mathrm{Eu}, \mathrm{Gd}$, Tb , Dy, Ho, Er, or Yb ) plotted $v s$ the HCl concentration for the four different categories of catalytic behavior under study. The elements with their corresponding symbol are displayed in the $X_{\mathrm{CH}_{4}}-\mathrm{HCl}$ concentration plot.

Figure 7. (A) $X_{\mathrm{CH}_{4}}$ plotted vs the temperature for EuOCl under $10 \%$ (black) and $80 \%$ (red) HCl . Selectivity toward $\mathrm{CH}_{3} \mathrm{Cl}^{2}, \mathrm{CH}_{2} \mathrm{Cl}_{2}, \mathrm{CHCl}_{3}, \mathrm{CCl}_{4}$, CO , and $\mathrm{CO}_{2}$ is plotted versus the temperature for EuOCl tested in (A) $10 \% \mathrm{HCl}\left(\mathrm{CH}_{4} / \mathrm{HCl} / \mathrm{O}_{2} / \mathrm{N}_{2} / \mathrm{He} 2: 2: 1: 1: 14\right)$ and (B) $80 \% \mathrm{HCl}(\mathrm{CH} / \mathrm{HCl} /$ $\mathrm{O}_{2} / \mathrm{N}_{2} / \mathrm{He} 2: 16: 1: 1: 0$ ).
increasing HCl concentration. The lower $X_{\mathrm{CH}_{4}}$ causes less $\mathrm{CHCl}_{3}$ to form (Figure S3A), which is subsequently destructed to CO. The lower activity also affects the degree of methane chlorination and thus lowers the quantity of higher CMs present in the system that can be destructed. ${ }^{33,36}$

PrOCl and NdOCl fall within the last category having a catalytic activity that is almost completely lost with the increasing HCl concentration. As the activity is correlated to the selectivity observed in the reaction, we observe that $S_{\mathrm{CH}_{3} \mathrm{Cl}}$ drastically increases. However, $X_{\mathrm{CH}_{4}}(<5 \%)$ is too low for commercial use and, therefore, the selectivity observed is irrelevant. The nature of this rapid $X_{\mathrm{CH}_{4}}$ decrease is not investigated in this study, but it is hypothesized that a completely chlorinated surface inhibits the activation of $\mathrm{O}_{2}$ and/or $\mathrm{CH}_{4}$ by a change in material acidity/basicity.

Unlike the other catalyst materials tested in this study, the catalytic performance of EuOCl can be steered by tuning two key parameters, namely, temperature and HCl concentration. The extreme HCl concentrations applied in this study, 10 and $80 \%$, are compared in the temperature range of $350-550{ }^{\circ} \mathrm{C}$. $X_{\mathrm{CH}_{4}}$ of EuOCl is plotted versus the temperature, as shown in Figure 7A, for the two tested HCl concentrations. Immediately visible is the enhancement of activity from the HCl increase over the entire tested temperature range. Under $10 \% \mathrm{HCl}$, the maximum $X_{\mathrm{CH}_{4}}$ of $38 \%$ is reached at $550^{\circ} \mathrm{C}$. The increase in HCl concentration simultaneously lowers the temperature at which the maximum $X_{\mathrm{CH}_{4}}$ is reached to $505^{\circ} \mathrm{C}$ and increases the max $X_{\mathrm{CH}_{4}}$ to $42 \%$. Furthermore, the observed activity drop is delayed by $20^{\circ} \mathrm{C}$; the nature of this drop will be discussed in Section 3.4. To further demonstrate the remarkable activity increase of

Figure 8. Temperature ramp experiments where $X_{\mathrm{O}_{2}}$ is plotted $v s$ the temperature for HCl oxidation reaction (black) and MOC (red) for (A) LaOCl with $10 \% \mathrm{HCl}$ in the feed, (B) EuOCl with $10 \% \mathrm{HCl}$ in the feed, and (C) EuOCl with $80 \% \mathrm{HCl}$ in the feed.

EuOCl upon increasing the HCl concentration, $X_{\mathrm{CH}_{4}}$ is plotted versus the temperature for all catalyst materials at a HCl concentration of 10 and $80 \%$, as shown in Figure S4A,B, respectively. Except for $\mathrm{EuOCl}, X_{\mathrm{CH}_{4}}$ of all catalysts was negatively influenced by the increase in HCl concentration over the entire temperature range. This coincides with the results presented in Figure 6, where EuOCl was the only catalyst that showed an increase in $X_{\mathrm{CH}_{4}}$ when increasing the HCl concentration. The maximum $X_{\mathrm{CH}_{4}}$ of all catalysts dropped significantly, for example, from 31 to $19 \%$ for TbOCl .

When further comparing the temperature-dependent performance of EuOCl at 10 and $80 \% \mathrm{HCl}$ concentration, large selectivity differences are observed (Figure 7B,C). $S_{\mathrm{CO}}$ is suppressed below $15 \%$ at $80 \% \mathrm{HCl}$, even at very high conversion levels ( $X_{\mathrm{CH}_{4}}=\sim 40 \%$ ). To our best knowledge, such a low CO selectivity at high conversion levels is yet unreported and makes the EuOCl material in this study a potential catalyst material for practical applications. The result of the lower CO selectivity is an increase in selectivity toward higher CMs. At $80 \% \mathrm{HCl}$ concentration and $475{ }^{\circ} \mathrm{C}$, all four CMs are produced. One major drawback from operating the EuOCl system at such high conversion levels is that the selectivity toward $\mathrm{CH}_{3} \mathrm{Cl}$ drastically decreases. The generation of more active sites by fast chlorination due to the excess HCl causes the formed $\mathrm{CH}_{3} \mathrm{Cl}$ to react further to higher CMs . In that regard, the HCl concentration does not have a significant effect on the $\mathrm{CH}_{3} \mathrm{Cl}$ selectivity when comparing two different ratios. At $10 \%$ conversion, both ratios have $S_{\mathrm{CH}_{3} \mathrm{Cl}}=\sim 60 \%$ at $X_{\mathrm{CH}_{4}}=10 \%$. $\mathrm{CO}_{2}$ was only detected at high temperatures ( $>500{ }^{\circ} \mathrm{C}$ ), and the selectivity was very low ( $<1.2 \%$ ).

With such large formations of $\mathrm{CH}_{2} \mathrm{Cl}_{2}$ and $\mathrm{CHCl}_{3}$ and noticeable amounts of $\mathrm{CCl}_{4}$ observed at high conversion levels at $80 \% \mathrm{HCl}$, thermal chlorination might be a viable route instead of surface-catalyzed reaction. This is supported by the fact that a discrepancy in the product selectivity was observed when comparing 10 and $80 \% \mathrm{HCl}$ in the feed (Figure 7B,C). A previous work by Pérez-Ramírez and co-workers already investigated the HCl oxidation over $\mathrm{EuOCl} .{ }^{6}$ Based on these findings, the thermal chlorination of methane with $\mathrm{Cl}_{2}$ seems to only have a minor contribution to the total chlorination of methane at the used temperature range in this study. However, the reaction mechanism proposed for LaOCl does not explain how such a high selectivity toward, for example, $\mathrm{CHCl}_{3}$ can be obtained as observed for EuOCl. A previous work by our group already proposed a mechanism where La is shortly reduced by accepting a H from $\mathrm{CH}_{2} \mathrm{Cl}_{2} .{ }^{33}$ The proven presence of the redox couple $\mathrm{Eu}^{2+} / \mathrm{Eu}^{3+}$ could participate in the reaction via a similar
role, and a mechanism can be proposed for EuOCl where Eu changes the oxidation state during the reaction. ${ }^{39}$ Furthermore, the presence of substantial amounts of $\mathrm{Eu}^{2+}$ was proven under oxychlorination conditions at $T>753 \mathrm{~K}$. To investigate what the contribution of the gas-phase chlorination of methane is to the total catalytic performance of LaOCl and EuOCl , the oxygen conversion $\left(\mathrm{X}_{\mathrm{O}_{2}}\right)$ was determined in a reaction mixture with and without the presence of $\mathrm{CH}_{4}$. The HCl oxidation results are compared to the oxychlorination reaction with the same $\mathrm{HCl} /$ $\mathrm{O}_{2}$ feed ratio. For LaOCl (Figure 8A), $X_{\mathrm{O}_{2}}$ was below $5 \%$ over the entire tested temperature range. For the oxychlorination reaction over LaOCl , a sharp increase in $X_{\mathrm{O}_{2}}$ is observed from 500 to $550{ }^{\circ} \mathrm{C}$, where $X_{\mathrm{O}_{2}}$ reaches a final value of $35 \%$. As expected from the literature, no $\mathrm{Cl}_{2}$ seems to evolve, and thus, the gas-phase chlorination of methane does not contribute to the overall activity of $\mathrm{LaOCl}{ }^{10} \mathrm{HCl}$ oxidation over EuOCl was tested at 10 and $80 \% \mathrm{HCl}$ in the feed (Figure $8 \mathrm{~B}, \mathrm{C}$ respectively), as large differences in activity and selectivity were observed when the HCl concentration was varied. At $10 \% \mathrm{HCl}$ in the feed, $X_{\mathrm{O}_{2}}$ for the oxychlorination reaction is significantly higher than that for the HCl oxidation over the entire temperature range. However, some consumption of $\mathrm{O}_{2}$ is visible for the HCl oxidation with a maximum $X_{\mathrm{O}_{2}}$ of $13 \%$, thus contributing to the overall performance, although the activity and selectivity are predominantly governed by the surface-catalyzed reaction. The discrepancy between $X_{\mathrm{O}_{2}}$ of the HCl oxidation and MOC reaction is reduced when the HCl concentration is increased to $80 \% . X_{\mathrm{O}_{2}}$ of both reactions increased, and the relative difference is decreased. Solely by increasing the HCl concentration, the maximum $X_{\mathrm{O}_{2}}$ is enhanced from 13 to $55 \%$ for the HCl oxidation reaction. The HCl oxidation reaction is accelerated by the large excess of chlorine present on/in the catalyst, and HCl oxidation plays a major role in the overall performance of the catalyst. The large difference in HCl oxidation potency at 10 and $80 \% \mathrm{HCl}$ also partly explains why the degree of methane chlorination is enhanced when a high HCl concentration is used.

The total product selectivity here is partly governed by the free radical reaction, which offers very limited control over the selectivity ${ }^{16,45}$ Further research is needed to investigate if the reducibility of $\mathrm{Eu}^{3+}$ is enhanced by the excess of HCl . Up till so far, we have demonstrated the excellent performance of EuOCl and compared it to the other catalyst materials reported in this study. However, the reducible $\mathrm{CeO}_{2}$ is arguably the best performing catalyst in MOC with a combined yield of $\mathrm{CH}_{3} \mathrm{Cl}$ and $\mathrm{CH}_{2} \mathrm{Cl}_{2}$ of $\sim 27 \% .^{14}$ For EuOCl , a remarkable maximum combined yield of $24 \%$ is obtained at $485{ }^{\circ} \mathrm{C}$ at $80 \% \mathrm{HCl}$. We

Figure 9. Chlorination (minute $0-120, \mathrm{CH}_{4} / \mathrm{HCl} / \mathrm{O}_{2} / \mathrm{N}_{2} / \mathrm{He} 0: 20: 0: 1: 19, T=450{ }^{\circ} \mathrm{C}$ ), dechlorination (minute $120-210, \mathrm{CH}_{4} / \mathrm{HCl} / \mathrm{O}_{2} / \mathrm{N}_{2} / \mathrm{He}$ 2:0:1:1:16, $T=500^{\circ} \mathrm{C}$ ), and oxychlorination (minute $210-330, \mathrm{CH}_{4} / \mathrm{HCl} / \mathrm{O}_{2} / \mathrm{N}_{2} / \mathrm{He} 2: 2: 1: 1: 14, T=500^{\circ} \mathrm{C}$ ) steps were investigated with operando Raman spectroscopy for (A) LaOCl and (B) EuOCl materials. The Raman spectra are plotted as contour plots, and the intensity of key vibrations is plotted above. For 3-D plots and individual spectra, see Figure S6.
hypothesize that by altering the reducibility, ${ }^{46}$ enhancing the surface area of the active phase, ${ }^{22,47}$ and/or increasing the rate of chlorination by adding additives, the benchmark performance of $\mathrm{CeO}_{2}$ can be matched and potentially exceeded.

Lastly, the response to the change in HCl concentration in the MOC reaction differs quite drastically from one lanthanide material to another. For catalysts that have the same chemical composition (e.g., supported catalysts with different particle sizes), $S_{\text {BET }}$ of the active phase is often correlated to an increase in activity. ${ }^{48,49}$ However, in this study, the element is varied, while the physical properties of the materials are kept within the same order. To evaluate whether the activity is correlated to $S_{\text {BET }}$, the as-synthesized $S_{\text {BET }}$ was taken and correlated to the temperature, where $X_{\mathrm{CH}_{4}}=10 \%$ at $10 \% \mathrm{HCl}$ flow (Figure S5). The calculated $R^{2}$ was negative, indicating that there is no correlation between the activity of the various lanthanide materials and $S_{\text {BET }}$. Thus, the difference in catalytic performance is due to the unique properties of the lanthanide element. Correlating the activity to physical properties of lanthanidebased catalyst materials was attempted in the literature for oxychlorination ${ }^{22}$ and $\mathrm{C}_{1}$ catalytic destruction, ${ }^{33,38,47}$ but this did not yield conclusive results. Due to the fact that the oxychlorination reaction is composed of two noncatalytic reactions coupled in a catalytic cycle, we must also study the catalyst condition because a more complex mechanism is most probably present that determines the catalyst performance.
3.3. Operando Raman Spectroscopy. In the next stage of our study, we have performed operando Raman spectroscopy to study the occurring phase changes during the chlorination, dechlorination, and oxychlorination reactions of LaOCl and EuOCl . The chlorination and dechlorination steps are studied separately, as both steps occur simultaneously and form the catalytic cycle of MOC. LaOCl and EuOCl were selected, as EuOCl shows the most promising catalytic performance of the catalysts tested in this study and LaOCl is often reported for its high $S_{\mathrm{CH}_{3} \mathrm{Cl}}$ at reasonable conversion levels. ${ }^{10,11,22}$ Moreover, both catalysts react differently to a changing HCl concentration in the feed, and hence, detailed characterization studies could provide further insights into the differences between both systems. The results of the operando Raman study are shown in Figure 9. The corresponding Raman spectra are 3-D plotted in Figure $\mathrm{S} 6 \mathrm{~A}, \mathrm{C}$ for LaOCl and EuOCl , respectively. Individual spectra with 60 min time intervals are given in Figure S6B,D for

LaOCl and EuOCl materials, respectively. The band attribution is summarized in Table 1.

Table 1. Frequencies in Raman Shift ( $\mathrm{cm}^{-1}$ ) of Raman Vibrational Modes Observable for $\mathrm{LaOCl}, \mathrm{EuOCl}, \mathrm{LaCl}_{3}$, and $\mathrm{EuCl}_{3}$

|  | $\mathrm{E}_{\mathrm{g}}$ | $\mathrm{A}_{1 \mathrm{~g}}$ | $\mathrm{E}_{\mathrm{g}}$ | $\mathrm{A}_{1 \mathrm{~g}}, \mathrm{~B}_{2 \mathrm{~g}}$ | $\mathrm{E}_{\mathrm{g}}$ | refs |

The spectral data of LaOCl is visualized as a contour plot in Figure 9A. Above the contour plot, the intensity plot of three characteristic vibrations, that is, $217 \mathrm{~cm}^{-1}\left(2 \mathrm{E}_{2 \mathrm{~g}}+\mathrm{A}_{\mathrm{g}}\right.$ of $\left.\mathrm{LaCl}_{3}\right)$, $341 \mathrm{~cm}^{-1}\left(\mathrm{~A}_{1 \mathrm{~g}}, \mathrm{~B}_{2 \mathrm{~g}}\right.$ of LaOCl$)$, and $440 \mathrm{~cm}^{-1}\left(\mathrm{E}_{\mathrm{g}}\right.$ of LaOCl$)$ is plotted versus time on stream. From $0-120 \mathrm{~min}$, the catalyst is chlorinated $\left(\mathrm{CH}_{4} / \mathrm{HCl} / \mathrm{O}_{2} / \mathrm{N}_{2} / \mathrm{He}\right.$ 0:20:0:1:19 in $\left.\mathrm{mL} / \mathrm{min}\right)$ at $450{ }^{\circ} \mathrm{C}$. The fresh LaOCl is rapidly converted into $\mathrm{LaCl}_{3}$ because $\mathrm{A}_{1 g} / \mathrm{B}_{2 \mathrm{~g}}$ and $\mathrm{E}_{\mathrm{g}}$ of LaOCl disappears within several minutes, while $2 \mathrm{E}_{2 \mathrm{~g}}+\mathrm{A}_{\mathrm{g}}$ of $\mathrm{LaCl}_{3}$ shows the opposite trend. The intensity of the vibrational modes corresponding to LaOCl do not change significantly after 10 min and disappear in the background. The intensity decrease of the LaOCl vibrational modes and the growth of the $\mathrm{LaCl}_{3}$ vibrational mode at 217 $\mathrm{cm}^{-1}$ occur simultaneously. A rapid increase in peak intensity is observed within the first 10 min after which the Raman vibration intensity growth levels off, as can be seen in the intensity plot. This indicates that LaOCl is almost fully converted into $\mathrm{LaCl}_{3}$ within 15 min of chlorination. From $120-210 \mathrm{~min}$, the catalyst was first heated to $500^{\circ} \mathrm{C}$ and a dechlorination step $\left(\mathrm{CH}_{4} / \mathrm{HCl} /\right.$ $\mathrm{O}_{2} / \mathrm{N}_{2} / \mathrm{He}$ 2:0:1:1:16) was performed. The dechlorination of the catalyst material was complete after 155 min because $\mathrm{A}_{1 \mathrm{~g}} / \mathrm{B}_{2 \mathrm{~g}}$ and $\mathrm{E}_{\mathrm{g}}$ of LaOCl reach their final value and $2 \mathrm{E}_{2 \mathrm{~g}}+\mathrm{A}_{\mathrm{g}}$ of $\mathrm{LaCl}_{3}$ disappears in the background. No Raman vibration at $408 \mathrm{~cm}^{-1}$, corresponding to $\mathrm{La}_{2} \mathrm{O}_{3}$, was observed. ${ }^{41,47}$ From 210-330 min, a typical oxychlorination reaction mixture $\left(\mathrm{CH}_{4} / \mathrm{HCl} / \mathrm{O}_{2} / \mathrm{N}_{2} /\right.$ He 2:2:1:1:14) was fed into the reactor at $500^{\circ} \mathrm{C}$. No observable spectral changes occur from $210-245 \mathrm{~min}$, which is most probably caused by the probed catalyst bed height. It is hypothesized that HCl is completely consumed by the top of the
catalyst bed before a steady-state consumption of HCl is reached and HCl travels further through the catalyst bed. Here, a more gradual transition between LaOCl to $\mathrm{LaCl}_{3}$ is observed, starting after 270 min . As already expected from the chlorination and dechlorination steps, the rate of chlorination exceeds the rate of dechlorination. After 330 min , vibrational modes corresponding to LaOCl and $\mathrm{LaCl}_{3}$ are both visible, indicating that the catalyst material is in between a $\mathrm{LaOCl}-\mathrm{LaCl}_{3}$ state. However, at the end of the experiment, the intensity of the LaOCl bands almost disappeared in the background (Figure S6B). At 330 min , the catalyst is composed of almost pure $\mathrm{LaCl}_{3}$ and it is expected that the remaining LaOCl would be converted to $\mathrm{LaCl}_{3}$ over prolonged reaction times. Thus, even at low HCl concentrations ( $10 \%$ ), the chlorination rate of the catalyst material exceeds the dechlorination rate.

The same chlorination-dechlorination-oxychlorination experiment was performed for the EuOCl material. The spectral data of EuOCl are visualized as a contour plot in Figure 9B. Above the contour plot, the intensity of three vibrations at 228 $\mathrm{cm}^{-1}\left(2 \mathrm{E}_{2 \mathrm{~g}}+\mathrm{A}_{\mathrm{g}}\right.$ of $\left.\mathrm{EuCl}_{3}\right), 357 \mathrm{~cm}^{-1}\left(\mathrm{~A}_{1 \mathrm{~g}}, \mathrm{~B}_{2 \mathrm{~g}}\right.$ of EuOCl$)$, and $489 \mathrm{~cm}^{-1}\left(\mathrm{Eg}_{\mathrm{g}}\right.$ of EuOCl$)$ is plotted versus the time on stream. In the Raman spectrum of EuOCl , two bands at $282 \mathrm{~cm}^{-1}$ ( $\lambda=540$ $\mathrm{nm})$ and $423 \mathrm{~cm}^{-1}(\lambda=544 \mathrm{~nm})$ cannot be ascribed to Raman vibrations. These peaks most likely correspond to the ${ }^{5} \mathrm{D}_{1} \rightarrow$ ${ }^{7} \mathrm{~F}_{0-2}(\lambda=525-584 \mathrm{~nm})$ emission lines of $\mathrm{Eu}^{3+} .{ }^{50,51}$ From 0120 min , a gradual decrease of all Raman vibration intensities is observed and it appears that the final state is only reached after 50 min of reaction. Considering that LaOCl was fully chlorinated to $\mathrm{LaCl}_{3}$ within 15 min , it can be stated that EuOCl is less susceptible to chlorinate into $\mathrm{LnCl}_{3}$ than LaOCl . The typical vibration of $\mathrm{EuCl}_{3}$ at $228 \mathrm{~cm}^{-1}$ also decreases in intensity because it overlaps with the more intense $282 \mathrm{~cm}^{-1}$ emission line, which decreases over time. The observed intensity of the $\mathrm{EuCl}_{3}$ vibration at the tested temperature is very weak (Figure S6D), probably due to the weakening of the $\mathrm{Eu}-\mathrm{Cl}$ bond and the loss of coordination number near $T_{\text {melt }}{ }^{44}$ Not only is the Raman signal lost upon chlorination, but the photoluminescence signal of $\mathrm{EuCl}_{3}$ is also quenched upon heating. In Figure $\mathrm{S} 7 \mathrm{~A}, \mathrm{~B}$, a temperature ramp on $\mathrm{EuOCl} / \mathrm{EuCl}_{3}$ was performed. A gradual change from the $\mathrm{EuCl}_{3}$ spectrum to the EuOCl spectrum is observed, heating from 20 to $350^{\circ} \mathrm{C}$. No difference can be observed between the reference EuOCl and the $\mathrm{EuOCl} / \mathrm{EuCl}_{3}$ spectrum (Figure S7C), even though the composition of the heated sample did not change during the temperature ramp (Figure S7D). The loss of the signal, both in the Raman and photoluminescence spectra, indicates the chlorination of EuOCl to $\mathrm{EuCl}_{3}$. Hence, the photoluminescence intensity is directly correlated to the degree of catalyst chlorination. From 120-210 min, the intensity of all Raman bands is restored during the dechlorination. Again, the Raman signal of the $2 \mathrm{E}_{2 \mathrm{~g}}+\mathrm{A}_{\mathrm{g}}$ vibration of $\mathrm{EuCl}_{3}$ at $235 \mathrm{~cm}^{-1}$ increases due to the rise of the relatively broad $282 \mathrm{~cm}^{-1}$ emission line. No formation of $\mathrm{Eu}_{2} \mathrm{O}_{3}$ was observed, as its distinct vibration at 345 $\mathrm{cm}^{-1}$ was not detected. ${ }^{52,53}$ From 210-330 min, the Raman spectra did not change during the oxychlorination step. A small variation in peak intensity was observed in the beginning of the experiment, but from the intensity plot, it is apparent that no major changes occurred. Hence, little bulk chlorination takes place. The high rate of methane chlorination, and thus surface dechlorination, results in that EuOCl does not bulk chlorinate. Evident from the reaction mechanism (Figure 5) is that the surface chlorination must occur for the reaction to take place. In combination with the fact that the activity is increased with the
increasing HCl concentration, we can conclude that the surface chlorination is rate-limiting and not the activation of $\mathrm{O}_{2}$ or $\mathrm{CH}_{4}$. An increase in the HCl concentration is therefore beneficial for the catalytic activity of EuOCl because surface chlorination occurs more readily.
3.4. Operando Photoluminescence Spectroscopy. Both activity profiles of EuOCl shown in Figure 7A show a similar behavior, as both profiles show a drop in the activity after which the activity is restored at higher temperatures. At $10 \% \mathrm{HCl}$, the onset of the drop occurs at $\sim 475{ }^{\circ} \mathrm{C}$ and the minimum is reached at $\sim 500^{\circ} \mathrm{C}$. At $80 \% \mathrm{HCl}$, the onset of the drop is delayed from 480 to $500{ }^{\circ} \mathrm{C}$ and a maximum $X_{\mathrm{CH}_{4}}$ of $42 \%$ is reached. At $550{ }^{\circ} \mathrm{C}, \mathrm{EuOCl}$ reaches the same $X_{\mathrm{CH}_{4}}$ of $\sim 38 \%$ for both conditions. As this drop is reproducible with different newly synthesized EuOCl catalysts and for the same EuOCl catalyst when the same experiment is repeated, we investigated the role of the degree of catalyst chlorination on the drop in activity. Temperature ramp experiments from 450 to $520^{\circ} \mathrm{C}$ were performed with the same catalyst, but the pretreatment step was varied. Furthermore, photoluminescence spectra of EuOCl were collected with the operando Raman probe. The collected spectra were normalized to the highest signal of the series and integrated over the entire spectral range. The relative spectral area is used as a measure for the degree of chlorination, as the chlorination of EuOCl to $\mathrm{EuCl}_{3}$ quenches the signal, as described in Section 3.3. The $X_{\mathrm{CH}_{4}}$ and relative spectral area are plotted versus the temperature. In Figure 10A, standard oxychlorination at $450{ }^{\circ} \mathrm{C}$ was applied as a pretreatment step $\left(\mathrm{CH}_{4} / \mathrm{HCl} / \mathrm{O}_{2} / \mathrm{N}_{2} / \mathrm{He}\right.$ 2:2:1:1:14). $X_{\mathrm{CH}_{4}}$ increases linearly with

Figure 10. Temperature ramp experiments between 450 and $520^{\circ} \mathrm{C}$ at $1{ }^{\circ} \mathrm{C} / \mathrm{min}$ for EuOCl at the $\mathrm{CH}_{4} / \mathrm{HCl} / \mathrm{O}_{2} / \mathrm{N}_{2} / \mathrm{He}$ ratio of 2:2:1:1:14 with 2 h pretreatment of $(\mathrm{A}) \mathrm{CH}_{4} / \mathrm{HCl} / \mathrm{O}_{2} / \mathrm{N}_{2} / \mathrm{He} 2: 2: 1: 1: 14$ at 450 ${ }^{\circ} \mathrm{C}$ and (B) $\mathrm{CH}_{4} / \mathrm{HCl} / \mathrm{O}_{2} / \mathrm{N}_{2} / \mathrm{He}$ 0:4:0:1:15 at $450{ }^{\circ} \mathrm{C}$. The photoluminescence spectra were collected, normalized to the highest peak, and integrated. The relative spectral area and $X_{\mathrm{CH}_{4}}$ were plotted $v s$ the temperature.

Figure 11. (A) $X_{\mathrm{CH}_{4}}$ and $S_{\mathrm{CH}_{3} \mathrm{Cl}}, S_{\mathrm{CH}_{2} \mathrm{Cl}_{2}}, S_{\mathrm{CHCl}_{3}}, S_{\mathrm{CCl}_{4}}, S_{\mathrm{CO}}$, and $S_{\mathrm{CO}_{2}}$ plotted $v$ s time on stream and (B) operando Raman spectra plotted $v s$ time on stream between 38 and 42 h . The vertical lines in (B) are plotted individually in (C) to show the loss of Raman peak intensity of the vibrations corresponding to EuOCl .
the increasing temperature, while the opposite trend is observed for the relative spectral area. No spectral changes occurred during the temperature ramp, and only the intensity of the signal decreased with the increasing temperature. The gradual decrease in the relative area is expected, as the overall photoluminescence intensity is negatively correlated with the temperature. Subsequently, the catalyst was cooled to $450{ }^{\circ} \mathrm{C}$ and chlorinated for 2 h prior to the temperature ramp $\left(\mathrm{CH}_{4} /\right.$ $\mathrm{HCl} / \mathrm{O}_{2} / \mathrm{N}_{2} / \mathrm{He} 0: 4: 0: 1: 15$ ), as shown in Figure 10B. Now, the drop in activity is observed, starting at $500^{\circ} \mathrm{C}$, which coincides with the temperature of the drop observed in Figure 7A for EuOCl tested at $80 \% \mathrm{HCl}$. The sharp decrease in activity and the exponential growth of the relative spectral area occur simultaneously, indicating that bulk $\mathrm{EuCl}_{3}$ is rapidly converted to EuOCl , as mostly the state of the catalyst bulk is probed with photoluminescence spectroscopy. Both $X_{\mathrm{CH}_{4}}$ and the relative spectral area stabilize at $515{ }^{\circ} \mathrm{C}$, indicating that the catalyst reaches a steady state. The reaction temperature plays a crucial role in the degree of catalyst chlorination. In a scenario where excess HCl is present in the feed, bulk chlorination occurs at lower temperatures. Once the temperature is increased to $>480$ ${ }^{\circ} \mathrm{C}$, bulk chlorination becomes unfavorable, and the bulk chlorine migrates to the surface, temporarily increasing the degree of surface chlorination. Hence, an increase in the activity is observed, as chlorine is forced out of the catalyst. Once the free chlorine in the catalyst depletes, activity and selectivity are restored to the same levels as observed when no drop in activity was observed. The pretreatment step as shown in Figure 10A,B additionally reveals that the presence of methane also plays a vital role in the degree of catalyst chlorination. Figure 8B shows
that the HCl oxidation rate at $450^{\circ} \mathrm{C}$ and $10 \% \mathrm{HCl}$ is low, and dechlorination of the catalyst via HCl oxidation is thus a slow process. Furthermore, the HCl oxidation rate is limited by the HCl concentration in the feed, as the rate could be significantly enhanced when excess HCl was fed (Figure 8C). In Figure 10, we showcase that with and without the presence of methane in the feed, the catalyst is either in a dechlorinated or in a chlorinated state, respectively. We can therefore conclude that the state of the catalyst is determined by both the reaction temperature and the $\mathrm{HCl} / \mathrm{CH}_{4}$ ratio in the feed.
3.5. Stability of EuOCI. Finally, EuOCl was tested for its stability under oxychlorination conditions at $450{ }^{\circ} \mathrm{C}$. Over a period of 48 h , the catalyst was exposed to increasing HCl concentrations with constant $\mathrm{CH}_{4}$ and $\mathrm{O}_{2}$ concentration and total flow. The $X_{\mathrm{CH}_{4}}$ product yields and reaction selectivity are plotted in Figure 11A. At the start, a drop in $X_{\mathrm{CH}_{4}}$ and yields of $\mathrm{CH}_{3} \mathrm{Cl}$ and CO are visible. This effect is most probably caused by the decrease in the surface area of the catalyst because no prechlorination step was performed. ${ }^{22}$ After 2 h of reaction, the $\mathrm{CH}_{3} \mathrm{Cl}$ yield stabilizes, while the CO yield gradually decreases. This is also visible from the selectivity plot shown in Figure 11A where $S_{\mathrm{CO}}$ decreases from 44 to $37 \%$, while $S_{\mathrm{CH}_{3} \mathrm{Cl}}$ increases with the same percentage and $S_{\mathrm{CH}_{2} \mathrm{Cl}_{2}}$ remains the same. Subsequently, the HCl concentration was increased to $20 \%$ without increasing the total flow. An immediate jump in $\mathrm{CH}_{3} \mathrm{Cl}(+2.2 \%)$, $\mathrm{CH}_{2} \mathrm{Cl}_{2}(+0.6 \%)$, and $\mathrm{CO}(+0.8 \%)$ yield occurs due to the increased chlorination rate of the catalyst surface. However, now, the $\mathrm{CH}_{3} \mathrm{Cl}$ yield drops over time ( $-0.8 \%$ ), while the CO yield remains constant.

Again, a jump in yield is observed when increasing the HCl concentration to $40 \%$ for $\mathrm{CH}_{3} \mathrm{Cl}(+2 \%), \mathrm{CH}_{2} \mathrm{Cl}_{2}(+1.1 \%)$, and $\mathrm{CO}(+1 \%)$. The selectivity of all the products remains fairly constant over the duration of 10 h . The yields of the reaction products decrease slightly. Up to this point, the catalyst material behaves in the same fashion. However, when the HCl concentration is further increased from 40 to $60 \%$, a different catalytic behavior is observed.

Right from the moment that the HCl concentration was further increased, the CO yield drops gradually ( $-1.1 \%$ ), while the CM yields do not show any downward trend. $S_{\mathrm{CO}}$ is reduced from 26 to $20 \%$, a relative decrease of $23 \%$. Under these conditions, we observe a low $\mathrm{CHCl}_{3}$ yield of $0.4 \%$, which correlates to a $\mathrm{S}_{\mathrm{CHCl}_{3}}$ of $2.4 \%$. Near the end, the production of $\mathrm{CH}_{3} \mathrm{Cl}$ increases slightly after which it starts to drop when the HCl concentration is further increased to $80 \%$.

Just before the feed ratio is adjusted to $80 \% \mathrm{HCl}$, we observe a change of the catalyst property, as analyzed with operando Raman spectroscopy. The operando Raman spectra in the spectral range of $180-500 \mathrm{~cm}^{-1}$ are plotted versus the time on stream in Figure 11B. Furthermore, some individual operando Raman spectra are plotted of moments before and after changing the feed ratio to $80 \% \mathrm{HCl}$ in Figure 11C. After 38 h time on stream, the Raman spectra start to change and the overall intensity decreases, which are indicative of the transition from EuOCl to $\mathrm{EuCl}_{3}$.

The full chlorination of the catalyst material has severe effects on the catalytic behavior. While the selectivity of the reaction does not seem to be affected by the changing catalyst properties, the catalyst deactivates. The decreasing CO yield trend is continued, but the $\mathrm{CH}_{3} \mathrm{Cl}$ yield is negatively affected over time. From previous experiments, we proved that EuOCl was difficult to chlorinate, especially under oxychlorination conditions. We now show that bulk transformation of EuOCl to $\mathrm{EuCl}_{3}$ occurs under very high HCl concentrations $(\geq 60 \%)$ over prolonged reaction times. Moreover, bulk chlorination is unwanted because a decrease in the product yield was observed. A balanced HCl concentration in the feed mixture is therefore crucial to enhance the surface chlorination rate but also to prevent bulk chlorination. An HCl concentration between 40 and $60 \%$ appears to be optimal, in terms of catalyst stability and catalytic performance.

## 4. CONCLUSIONS

We have investigated a series of lanthanide oxide chlorides (i.e., LnOCl with $\mathrm{Ln}=\mathrm{La}, \mathrm{Pr}, \mathrm{Nd}, \mathrm{Sm}, \mathrm{Eu}, \mathrm{Gd}, \mathrm{Tb}, \mathrm{Dy}$, or Ho ) and $\mathrm{Er}-$ and Yb -based catalyst materials, which turned to be all active in the catalytic oxychlorination of $\mathrm{CH}_{4}$. Based on their catalytic activity, the following ranking can be made as follows: $\mathrm{Eu}>\mathrm{Tb}>$ $\mathrm{Gd} \sim \mathrm{Ho} \sim \mathrm{Er}>\mathrm{Dy}>\mathrm{Sm}>\mathrm{Pr} \approx \mathrm{Nd} \approx \mathrm{La} \approx \mathrm{Yb}$. Furthermore, from all the catalyst materials under investigation, EuOCl exhibited the highest activity and the best selectivity toward $\mathrm{CH}_{3} \mathrm{Cl}$. The catalytic performance of EuOCl could be further increased by altering the HCl concentration, as an excess of HCl doubled the activity and lowered the CO selectivity. Exceptionally high conversion levels ( $\sim 40 \%$ ) could be reached, while maintaining a low $\mathrm{CO}_{x}$ selectivity ( $<15 \%$ ). Operando Raman spectroscopy revealed that the surface chlorination of the catalyst surface is rate-limiting, and hence, the activity of both the MOC and the HCl oxidation is boosted when an excess HCl is present. Operando photoluminescence spectroscopy of $\mathrm{Eu}^{3+}$ revealed that the bulk of EuOCl was subjected to major changes,
and the state of the catalyst is determined by the $\mathrm{CH}_{4} / \mathrm{HCl}$ ratio. However, if high HCl concentrations are applied at low $X_{\mathrm{CH}_{4}}$ over prolonged reaction times, EuOCl does chlorinate fully and the catalyst activity is lowered. The tunable activity and selectivity by altering the HCl concentration in the feed and the reaction make EuOCl a very interesting candidate as a catalytic material for a viable $\mathrm{CH}_{4}$ oxychlorination process.
