## INTRODUCTION AND THESIS OUTLINE

## INTRODUCTION

In the recent years much progress has been made in cancer treatment. Besides the traditional therapies such as chemotherapy, surgery and radiotherapy, targeted therapy and immunotherapy are increasingly being used and have clearly contributed to the improved outcome of patients with cancer.

Overall, survival of patients with cancer in the Netherlands is improving [1]. However, better survival rates have not been observed equally between cancer types. A well-known explanation is phenotypic heterogeneity in tumours and their micro-environment, which has genetic and non-genetic causes [2]. Because of this, some (parts of) tumours or their metastases are intrinsically less sensitive to a certain therapy. In addition, heterogeneity in the distribution of drugs can be part of the problem. Differences in drug distribution between patients (e.g. pharmacokinetic differences), but also between organs within patients and even within regions of a single tumour or metastasis, contribute to a heterogeneous treatment effect [3-5]. Furthermore, as patients survive longer, long term side effects of the treatments become increasingly relevant [6-9].

This thesis is based on two central concepts.

First, an effective drug is only effective when it reaches the right location at the right dose. Second, a treatment can be defined as optimal when maximal efficacy is joined by minimal toxicity.

With these concepts in mind, this thesis investigates two methods using therapeutic ultrasound.

- I. **MR-HIFU hyperthermia** combined with **temperature sensitive liposomes** containing chemotherapy
- II. **Ultrasound and microbubble therapy**

Both interventions aim to optimize local drug delivery, in order to obtain a maximum therapeutic effect at the target locations, while minimizing healthy tissue damage (toxicity). To bring these therapies from studies in cells (*in vitro*) to patients, clinical trials in veterinary patients can help pave the road to clinical human translation. Obtaining detailed information on patient characteristics using imaging, but also by learning from data of previous patients, could help to further optimize targeted therapy and personalize cancer treatment.

In this introduction, the background and mechanisms behind these two therapeutic ultrasound approaches will be described briefly, as well as the patient populations we expect will benefit from these therapies. Finally, an outline of the chapters in this thesis will be provided.

## Ultrasound

Ultrasound is known for its application in imaging. During ultrasound (US) imaging, pulses of ultrasound waves (with a frequency above 20 kHz) are sent through tissue. The waves reflect on the demarcation between two types of tissues (with different acoustic impedance) and echoes are detected and converted to a grayscale image which makes distinction between tissues possible [10]. In contrast-enhanced ultrasound (CEUS), gas-containing particles (ultrasound contrast agents) are administered to obtain additional information on vascularization or delineation of body cavities. The contrast is caused by the large difference in acoustic properties between liquid (e.g. blood or lymph) and gas, and because the ultrasound pulses cause oscillation of the contrast agent [10-12].

In this thesis, we use ultrasound not just for imaging, but also to enhance local drug delivery. In this setting we use the term therapeutic ultrasound. Two examples of therapeutic ultrasound are MR-guided high intensity focused ultrasound (MR-HIFU) and ultrasound in combination with microbubbles (USMB therapy).

### Magnetic resonance-guided high intensity focused ultrasound

MR-HIFU is a truly non-invasive treatment modality, that combines magnetic resonance imaging (MRI) and high intensity focused ultrasound (HIFU) to warm up tissues or to create mechanical effects. In HIFU, transmitted ultrasound waves are focused into one specific point, which has an effect similar to focusing light with a magnifying glass to burn leaves. In the focus point the intensity will be very high and the tissue starts to warm up. Depending on the treatment goal, a tumour can be heated to 55-70°C (thermal tissue ablation) [13-15] or to 40-43 °C (mild local hyperthermia, which we investigate in this thesis) [16-18].

HIFU is commonly performed with magnetic resonance guidance: MRI is used to control which part of the patient is heated (i.e. treatment planning) and MR thermometry measures temperature simultaneously (i.e. treatment guidance) [19].

### Ultrasound and microbubble therapy

The second method of therapeutic ultrasound applied in this thesis is ultrasound and microbubble (USMB) therapy. Microbubbles are ultrasound contrast agents: gas-filled particles, 1-10 µm in diameter, with a biocompatible shell generally made of phospholipids or proteins [20, 21]. Examples of microbubbles approved for clinical CEUS are SonoVue (which contains sulphur hexafluoride (SF<sub>6</sub>) gas), Definity and Optison (both containing perfluorocarbons). In addition to its role in CEUS imaging, the combination of ultrasound and microbubbles has the potential to locally enhance the delivery of drugs. When exposed to low-intensity ultrasound, microbubbles will oscillate, which is called stable cavitation. Microbubbles exposed to higher intensities will collapse violently, called inertial cavitation. Both types of cavitation induce a number of effects, collectively known as sonopermeation, which can improve drug delivery to tumour tissue. These effects include formation of pores in cell membranes (sonoporation), enhanced endocytosis and increased vascular

permeability [22, 23]. Furthermore, both increased and decreased perfusion after USMB have been described [24].

### **Nanomedicine and lyso-thermosensitive liposomal doxorubicin**

To improve local drug delivery, MR-HIFU induced hyperthermia can be combined with (temperature-sensitive) nanomedicine. Nanomedicine aims to improve the balance between efficacy and safety of drugs by targeting drug-loaded nanometre scale particles specifically to tumours [25]. These nanomedicines include polymeric nanoparticles, liposomes, micellar nanoparticles, protein nanoparticles and inorganic and metallic nanoparticles. A small number of nanomedicines are currently used in the clinic, such as pegfilgrastim (PEGylated G-CSF protein), liposomal doxorubicin, liposomal irinotecan and nab-paclitaxel (albumin-bound paclitaxel nanoparticles) [26, 27]. Liposomes are nanoparticles which consist of a phospholipid bilayer with an aqueous core [28]. In this thesis, we propose the use of the nanomedicine lyso-thermosensitive liposomal doxorubicin (LTLD, also known as ThermoDox), containing the drug doxorubicin. The composition of the phospholipid bilayer makes the liposome temperature sensitive and suitable for heat-triggered release of doxorubicin. The cytotoxic (chemotherapy) drug doxorubicin is frequently used for the treatment of a wide range of cancers, including breast cancer. LTLD is administered intravenously. When heated to 40-42 °C, LTLD releases doxorubicin in the blood stream within seconds [29-31]. In this way, a high concentration of doxorubicin can be achieved in a heated tumour (3-25 fold higher than with conventional doxorubicin in small animals [32-34]). At normal body temperature (circa 37 °C), doxorubicin slowly leaks from the liposome, and after two hours all of the doxorubicin is released [29]. Without heating, LTLD leads to a similar biodistribution [35, 36] and antitumour efficacy [30, 33] compared to conventional doxorubicin. Several tumour heating methods have been used in combination with LTLD, also in clinical studies [37-41]. In this thesis we propose a study of magnetic resonance-guided high intensity focused ultrasound (MR-HIFU) induced hyperthermia.

### **Patient populations in this thesis**

The methods to improve drug delivery investigated in this thesis are proposed for two groups of patients. The first group consists of patients with *de novo* metastatic breast cancer (MBC) or “*de novo* stage IV”, for whom we have designed a clinical trial of LTLD plus MR-HIFU hyperthermia. Because this is the first in-human trial to evaluate this combined treatment, we considered that evaluating safety and feasibility in a study population without a curative intent was most feasible and in line with common practice in phase I trials. However, we expect that future patients with earlier stage breast cancer will benefit from the combination of LTLD plus MR-HIFU hyperthermia in the setting of neoadjuvant chemotherapy. Applying this treatment in the neoadjuvant setting could lead to more complete pathological responses, possibilities for less extensive, or even without surgery,

increase the amount of radically removed tumours and possibly decrease local recurrence rates. If safety and feasibility are sufficiently proven in patients with *de novo* MBC, we will proceed with a clinical trial in the neoadjuvant setting.

The second group contains patients with head and neck cancer, where we think USMB therapy could provide a benefit in patients with locally advanced tumours in whom radical surgery often is difficult or disfiguring. In these patients USMB could potentially facilitate radical surgery with less local morbidity and, by obtaining cancer-free margins, also reduce the risk of local recurrences. In order to bridge the gap from *in vitro* results to clinical patients we performed a study in the third population described below: veterinary patients with the feline equivalent of head and neck cancer.

### 1. *De novo metastatic breast cancer*

In the Netherlands, yearly around 14,500 patients are diagnosed with invasive breast cancer [42]. Around 5% present with *de novo* MBC: these patients have distant metastases at the time of their primary breast cancer diagnosis [43]. In the majority of patients diagnosed with metastatic (stage IV) disease, the metastases are diagnosed in the years that follow their breast cancer diagnosis, so called metachronous MBC. When patients present with *de novo* MBC, the question arises what the best approach will be in dealing with both the local breast tumour and the distant metastases. Although many studies have suggested that local treatment of the breast tumour in patients with *de novo* MBC would provide a survival benefit [44-46], recent randomized studies have refuted this [47, 48]. Usually, these patients are treated with palliative systemic treatment such as chemotherapy, endocrine therapy or targeted therapy. Because they have both local disease (in the breast) and distant metastases (elsewhere) patients with *de novo* MBC make a valuable study population to evaluate both the local and the systemic efficacy and toxicity of new therapies (such as LTLT plus MR-HIFU hyperthermia).

### 2. *Head and neck cancer*

Head and Neck Squamous Cell Carcinoma (HNSCC) affects approximately 3,000 new patients yearly in the Netherlands[49]. This group of cancers is located in the head and neck region (for example in the mouth, nose, larynx or pharynx). Most patients present with locally advanced disease [50, 51], where primary surgery is often not an option, because the tumour cannot be removed completely or because surgery would create unacceptable local damage. Combinations of chemotherapy, targeted or immunotherapy and radiotherapy are being used [52]. Despite treatment with combined modalities, up to half of the patients develop local recurrences, which are in most cases incurable [53, 54]. Moreover, treatment is associated with undesired acute and long-term toxicity [8, 9, 55]. The predominance of locally advanced disease and local recurrences emphasizes the

need for improved local therapy, while minimizing local and systemic side effects. For this reason we hypothesize that optimizing local drug delivery using therapeutic ultrasound could benefit these patients.

### 3. *Feline oral squamous cell carcinoma*

Since there are many pathophysiologic and genetic similarities between head and neck cancer in humans and in cats, feline oral squamous cell carcinoma (FOSCC) patients are a valuable model to bridge the gap between *in vitro* and small animal studies and human patients with head and neck cancer [56-58]. An additional advantage towards clinical translation is that due to the size of cats, it is possible to use the same clinical equipment used in humans, while for small animal experiments often dedicated equipment is necessary.

FOSCC is very common in aged cats, 10% of all tumours diagnosed in cats are oral tumours, of which 61.2% is squamous cell carcinoma[59]. Cats are often presented in an advanced stage of disease [60]. As in human HNSCC, cancer is often locally invasive and most cats succumb to local disease progression [58, 61].

Standard of care treatment options of oral squamous cell carcinoma in cats are similar to those in humans. Surgery is performed if possible and adjuvant radiotherapy can be added if resection is known or suspected to be incomplete. Primary radiation therapy, with palliative or curative intent, is an alternative in non-resectable disease, which can be combined with chemotherapy as a radiosensitizer [62-64]. Supportive care alone is also common and results in a median overall survival time of approximately 1.5 months. [65].

## OUTLINE OF THE THESIS

In **part 1 (chapter 1)** we discuss heterogeneity in drug distribution, which can occur on many scales, ranging from differences in pharmacokinetics and -dynamics between patients to heterogeneity within a single tumour, all potentially leading to a heterogeneous treatment effect (i.e. therapy heterogeneity). We reviewed the role of imaging to evaluate this heterogeneity in the setting of nanomedicine. These imaging techniques can be used to visualize nanoparticle distribution, drug distribution and characteristics of the tumour environment, that influence therapy heterogeneity and thus efficacy. Imaging can help to evaluate therapy effect in a (pre)clinical setting, better understand underlying mechanisms leading to heterogeneity, select patients for personalized treatment and evaluate the effect of methods that aim to address therapy heterogeneity.

In **part 2 and 3** we discuss two of these methods, with the goal to decrease therapy heterogeneity and thus to optimize drug distribution. Both methods use therapeutic ultrasound to increase local drug deposition without increasing side effects. **Part 2**

concerns the combination of MR-HIFU hyperthermia and temperature sensitive liposomes with doxorubicin used in patients with breast cancer. **Chapter 2** provides more insight into the study population of the clinical trial described in chapter 3: patients with *de novo* metastatic breast cancer. Data from the Netherlands Cancer Registry (NCR) were analysed, to compare characteristics, survival and treatment between patients with *de novo* and metachronous MBC in the period 2008-2018. **Chapter 3** describes the design of a phase I clinical trial which will investigate the combination of lyso-thermosensitive liposomal doxorubicin (LTLT, ThermoDox) and Magnetic Resonance guided High Intensity Focused Ultrasound (MR-HIFU). This trial was designed to evaluate safety, tolerability and feasibility of this combination treatment in patients with *de novo* MBC, in whom both local and systemic efficacy and toxicity of the treatment can be monitored. During palliative chemotherapy, conventional doxorubicin will be replaced by intravenous LTLT and the primary tumour in the breast will be warmed by MR-HIFU hyperthermia.

**Part 3** discusses therapeutic ultrasound and microbubbles (USMB therapy) to improve drug distribution and illustrates imaging applications of USMB. We hypothesize that USMB therapy could improve treatment for patients with head and neck cancer, as they often have local problems in the primary tumour region. Increasing drug delivery locally without increasing systemic side effects could be beneficial. This part describes the steps that we took to bring this therapy further to the clinic, from *in vitro* to a veterinary trial. In **chapter 4** we investigated the potential of a clinical ultrasound system and clinically available microbubbles to perform USMB *in vitro* and to enhance local chemotherapy effect. **Chapter 5** describes a veterinary clinical trial in cats with feline oral squamous cell carcinoma. These cats, with otherwise limited treatment options, were treated with the combination of bleomycin (chemotherapy) and ultrasound and microbubbles (USMB therapy). During the trial, perfusion of the tumour was evaluated before and after USMB therapy with contrast-enhanced ultrasound, as well as tumour progression, survival duration and owner reported quality of life of the cats. **Chapter 6** is a review concerning new developments in imaging for sentinel node biopsy in patients with head and neck cancer. Several techniques can be used to identify the lymph node with the highest change of metastasis based on lymphatic flow and proximity to the primary tumour (the sentinel node). If that lymph node does not contain metastasis, it is considered unlikely that other lymph nodes do. The procedure can help select which patient needs extensive therapy to improve survival, and in which patient this can be omitted, thereby avoiding associated side effects. One of the imaging methods discussed is contrast-enhanced lymphosonography. In this setting ultrasound and microbubbles are not used as therapy but for contrast-enhanced ultrasound imaging of lymphatic flow and accumulation in lymph nodes.

## ABSTRACT

Genetic and phenotypic tumour heterogeneity is an important cause of therapy resistance. Moreover, non-uniform spatial drug distribution in cancer treatment may cause pseudo-resistance, meaning that a treatment is ineffective because the drug does not reach its target at sufficient concentrations. Together with tumour heterogeneity, non-uniform drug distribution causes “therapy heterogeneity”: a spatially heterogeneous treatment effect. Spatial heterogeneity in drug distribution occurs on all scales ranging from interpatient differences to intratumour differences on tissue or cellular scale. Nanomedicine aims to improve the balance between efficacy and safety of drugs by targeting drug-loaded nanoparticles specifically to tumours. Spatial heterogeneity in nanoparticle and payload distribution could be an important factor that limits their efficacy in patients. Therefore, imaging spatial nanoparticle distribution and imaging the tumour environment giving rise to this distribution could help understand (lack of) clinical success of nanomedicine. Imaging the nanoparticle, drug and tumour environment can lead to improvements of new nanotherapies, increase understanding of underlying mechanisms of heterogeneous distribution, facilitate patient selection for nanotherapies and help assess the effect of treatments that aim to reduce heterogeneity in nanoparticle distribution.

In this review, we discuss three groups of imaging modalities applied in nanomedicine research: non-invasive clinical imaging methods (nuclear imaging, MRI, CT, ultrasound), optical imaging and mass spectrometry imaging. Because each imaging modality provides information at a different scale and has its own strengths and weaknesses, choosing wisely and combining modalities will lead to a wealth of information that will help bring nanomedicine forward.

## INTRODUCTION

In 2015, 17.5 million people were diagnosed with cancer globally and its incidence is increasing. Although the prognosis of most cancer types has improved, still 8.7 million people died of cancer in that year [1]. Rather than a single disease, 'cancer' comprises of a diverse collection of diseases. A high degree of heterogeneity in tumour genotype, phenotype and behaviour (including responsiveness to therapy) exists not only between tumour types, but also between tumours of the same histological type in different patients [2], between primary and metastatic tumours in the same patient, within a patient's tumour that is developing over time [3] and even within a single tumour at one moment [2, 4-10]. The genetic and non-genetic causes of tumour heterogeneity have been reviewed in detail elsewhere. This heterogeneity is an important cause of therapy resistance [3, 11-14] and in some cancer types an association between the degree of intratumoural heterogeneity and a worse prognosis has been found [15-17]. This stresses the importance of evaluating disease heterogeneity and the need for personalized treatment.

### **Therapy heterogeneity**

Therapy heterogeneity, a spatially heterogeneous treatment effect, is another important source of variability between patients and between tumours within an individual. Spatial heterogeneity in drug distribution contributes to therapy heterogeneity and can lead to pseudoresistance: the treatment does not have the desired effect, not because of cellular or genetic mechanisms of resistance, but because the drug simply does not reach all tumour cells at a high enough concentration [18-20]. Moreover, unintended accumulation of drugs in healthy tissue may lead to increased toxicity [18]. Furthermore, heterogeneity in spatial distribution of drugs can generate distinct microenvironments within the tumour, causing intra- and intertumour heterogeneity and, ultimately, influencing clinical outcome.

### **Spatial heterogeneity of nanomedicine**

Heterogeneous drug distribution occurs for drugs of all sizes. In this review we will focus on its impact in the field of nanomedicine. Nanomedicines are sub-micron size drug delivery systems, which are designed to improve the drug delivery to tumours while reducing systemic side effects [21]. Several principles for drug targeting to tumours are described in literature [22]: passive targeting (mainly relying on the enhanced permeability and retention (EPR) effect [23, 24]), active targeting (using carriers decorated with tumour-specific targeting antibodies) or triggered release (drug release from nanocarriers in response to heat, ultrasound or light) [25]. Regardless of the targeting method, nanomedicine has to overcome several physiological barriers before reaching the targeted tumour cells, which may very likely introduce therapy heterogeneity [26].

## Scales of heterogeneity

As reviewed by Garattini et al., heterogeneous drug distribution leading to therapy heterogeneity can occur on many scales [18]. On each scale different factors influence the distribution of the nanoparticle and drug.

On patient scale, the inter-patient variability of nanomedicine pharmacokinetics (PK) is influenced by many factors such as age, gender, body composition, prior treatments, and drug-drug interactions [27]. For a number of liposomal nanoparticles, it has been shown that the PK variability of nanoparticles is greater than that of the corresponding small molecule drugs [28]. Clearance of most nanoparticles occurs mainly via the mononuclear phagocyte system (MPS, also known as the reticuloendothelial system) through uptake by circulating and tissue-homing phagocytic cells, primarily in the liver and spleen [29]. One explanation for interpatient differences is that MPS function is affected by age, gender and inflammation [30]. Comorbidity affecting renal function or hepatic function could in turn diminish renal clearance or hepatobiliary excretion of certain nanoparticles. On the other hand, the presence of tumours in the liver increased the clearance of a liposomal camptothecin analogue [31]. Furthermore, due to the accelerated blood clearance (ABC) phenomenon, a second dosage of polyethylene glycol (PEG)ylated nanoparticles is cleared more rapidly, leading to additional inter and intra patient differences [32].

Also on the organ and tumour scale, many factors can contribute to heterogeneity in nanoparticle and drug distribution between different tumours in an individual patient. Accumulation of nanoparticles is tumour type and organ dependent [33]. Tumour locations with limited perfusion or specific barriers such as the blood brain barrier [34] or blood retina barrier [35] can hinder nanoparticle and drug accumulation. A large variation in EPR effect exists between tumour types, sizes and locations, most likely related to variability in tumour blood vessel architecture and function [26, 36]. Likewise, preclinical small animal tumour models generally overestimate the EPR effect compared to tumours in patients, which complicates clinical translation of nanomedicine [37]. Moreover, differences in composition of the tumour microenvironment (including immune cell infiltration, pericyte coverage of the endothelium, density of the extracellular matrix, hypoxia and interstitial fluid pressure (IFP) can lead to intertumour heterogeneity in nanoparticle accumulation and treatment effect [3, 37-40].

Finally, on tissue and cellular scale, there are numerous causes for heterogeneity in drug and nanoparticle distribution within a single tumour. These intratumour differences relate among other things to endothelial cell gaps across the vessel wall, perfusion, extracellular matrix composition and immune cell presence (e.g. tumour associated macrophages, TAM) [3, 19, 38]. Variable endothelial gaps (ranging from one to hundreds of nanometers) result in non-uniform extravasation of nanoparticles into the tumour [41]. Heterogeneity in tumour perfusion will cause non-uniform transport of nanoparticles and nutrients to different parts of the tumour and introduce local variance in oxygenation and tumour pH [19, 38].

### **Role of imaging to evaluate spatial heterogeneity of nanomedicine**

Some nanomedicine formulations are currently used in the clinic [42, 43], but overall the success of nanomedicine has been modest [44-46]. Spatial heterogeneity in distribution of nanoparticles could be an important factor limiting the efficacy in patients and therefore the acceptance of nanotherapy in the clinic. Better understanding of the extent and impact of therapy heterogeneity from cellular to patient scale may increase the success of nanomedicine in clinical practice.

Many imaging methods are available to visualize at a variety of scales the three main factors (i.e. nanoparticle distribution, drug distribution and tumour environment) that influence spatial therapy heterogeneity and thus efficacy. These methods can be used to:

1. Evaluate the effect of the therapy in a preclinical setting, to facilitate the development of new treatments.
2. Improve understanding of the underlying mechanisms that lead to heterogeneous distribution of nanoparticles and drugs.
3. Select patients and predict their treatment response for a personalized treatment plan: which patient likely benefits from a certain therapy and in which patient is adaptation of therapy necessary?
4. Evaluate the effect of methods that aim to address therapy heterogeneity, such as modulating the tumour microenvironment, hyperthermia or sonopermeation [19, 47, 48].

### **Scope**

Over the last years, several excellent review papers on imaging in nanomedicine were published focusing on imaging the biodistribution of nanoparticles [49], imaging labelled nanoparticles [50-52], the role of imaging to evaluate treatments that alter nanoparticle delivery [47], imaging nanoparticles as companion diagnostics [53, 54], or clinical applications of imaging in the field of nanomedicine [55-57]. In this review we will provide a non-exhaustive overview of imaging methods used in the field of nanomedicine, which visualize spatial distribution of nanoparticles or drugs or factors contributing to heterogeneity on different scales, i.e. patient, organ/tumour and tissue/cellular scale. For each method, we will highlight the three main aspects that can be imaged: the drug, the nanoparticle and the tumour (micro-) environment. We will focus on three groups of imaging modalities. A summary of the modalities and their strengths and limitations is presented in Table 1. First we will discuss non-invasive clinical imaging methods, because of their direct usability in clinical translation of nanomedicine. Subsequently, we will elaborate on the most commonly used preclinical modality optical imaging as it is the most frequently employed imaging modality to investigate the interplay between drug, nanoparticle and environment. Optical imaging can be a non-invasive technique in the preclinical setting, while it is invasive clinically. Finally we will discuss mass spectrometry imaging (MSI), an invasive but promising and versatile label-free method for monitoring

drug distribution and effect. Our goal is to show how imaging can provide information on all aspect that influence nanotherapy and in this way will help clinical and preclinical researchers to improve the effectiveness of nanotherapies and translate their use to cancer patients.

## NUCLEAR IMAGING: SCINTIGRAPHY/SPECT/PET

Nuclear imaging techniques, namely scintigraphy, Single-Photon Emission Computed Tomography (SPECT) and Positron Emission Tomography (PET) provide highly sensitive quantitative information about the distribution of an administered radiopharmaceutical. They are often combined with CT (SPECT/CT or PET/CT) to add anatomical information and perform attenuation correction. Since the spatial resolution is lower than that of MRI, CT and US imaging, clinical PET and SPECT are mainly informative on patient and organ scale. In the preclinical setting, high-resolution PET and SPECT techniques demonstrate expansion to the tissue scale [58], which is nicely represented by the study of Wang et al. showing the heterogeneous spatial distribution of radiolabelled multi-walled carbon nanotubes in mouse brains with high-resolution SPECT [59].

Currently, the metabolic activity measured with  $^{18}\text{F}$ -fluorodeoxyglucose (FDG-) PET/CT is widely used in the clinic for diagnosis and monitoring therapy response. Traditionally several parameters are analysed for diagnosis and prognosis, including maximum standardized uptake values (SUVmax), peak standardized uptake values (SUVpeak), metabolic tumour volume (MTV), and total lesion glycolysis (TLG). Recently, intratumoural heterogeneity of baseline  $^{18}\text{F}$ -FDG uptake measured by PET texture analysis has been introduced as new predictive and prognostic factor for neoadjuvant chemotherapy [60-63].

### **Imaging the nanoparticle**

Nuclear imaging has already gained widespread acceptance in the management of cancer using standard chemotherapeutic agents, but may also play an important role in the advancement of nanomedicine towards clinical practice. Historically, nuclear imaging is used to image the distribution of radiolabelled nanoparticles on the patient and organ/tumour scale [47, 49-51, 56, 57]. Already in 1984, Lopez et al. used scintigraphy to track the distribution of Tc-99-m labelled liposomes in cancer patients on organ scale [64]. More recently, studies have used nuclear imaging of radiolabelled nanoparticles as a companion diagnostic to predict treatment response to drug containing nanoparticles or for directly visualizing the distribution of labelled therapeutic nanoparticles [65-69]. The latter approach is nicely illustrated by a clinical study in nineteen HER2-positive metastatic breast cancer patients [69]. HER2-targeted PEG-liposomes containing doxorubicin were administered together with a  $^{64}\text{Cu}$ -labelled tracer dose of the same liposomes and their

distribution was imaged by PET/CT. This study was able to demonstrate and quantify the EPR effect in patients and found that tumour liposome concentrations were similar to those found preclinically. Heterogeneity in nanoparticle distribution on the patient and tumour scale was observed and an association was found between the amount of  $^{64}\text{Cu}$ -labelled liposome uptake in the tumour and the overall tumour response and progression free survival [69]. Recently, Miedema et al. used PET/CT to track  $^{89}\text{Zr}$ -labelled docetaxel nanoparticles in five patients with various tumour types and observed uptake of the nanoparticles in 35% of the tumours, which they attributed to the EPR effect. Heterogeneous patterns of accumulation were seen on patient and organ scale [70].

### Imaging the tumour environment

Furthermore, clinical studies with different tracers are being conducted to extend the use of nuclear imaging to gaining insight into the different aspects of tumour physiology, such as proliferation (e.g.  $^{18}\text{F}$ -fluorothymidine (FLT-PET) [71-73]), hypoxia (e.g.  $^{18}\text{F}$ -fluoromisonidazole (F-MISO)-PET [55, 74, 75]) and angiogenesis (e.g. with radiolabelled arginine-glycine-aspartic acid (RGD) peptide tracers [76] or vascular endothelial growth factor expression [76, 77]).

Other tracers visualize expression of receptors that can be targeted by drugs (e.g.  $^{18}\text{F}$ -fluoroestradiol (FES-) PET [78, 79], human epidermal growth factor receptor 2 (HER2-) PET or SPECT [80]), demonstrate suitability for targeted therapy (e.g. response prediction to tyrosine kinase inhibitors in non-small cell lung cancer [76, 81]), or image tumour specific markers (e.g. prostate specific membrane antigen (PSMA-) PET [82, 83] and radiolabelled somatostatin analogues for neuroendocrine tumours [84, 85]).

Nuclear imaging methods create the possibility to combine imaging of nanoparticle distribution with imaging of characteristics of the tumour environment. A good example of this is the ZEPHIR trial [86], which was able to characterize tumour and therapy heterogeneity on the patient and tumour scale, based on pre-treatment HER2-PET/CT with  $^{89}\text{Zr}$ -trastuzumab and FDG-PET/CT after just one treatment cycle. These two types of PET imaging were used to characterize distribution of the nanoparticle (trastuzumab in T-DM1) and the tumour environment (FDG uptake). In metastatic breast cancer patients, who all had HER2 positive disease on biopsy, the combination of early metabolic response on FDG-PET (significant reduction in FDG uptake in >50% of the tumour load) and positive  $^{89}\text{Zr}$ -trastuzumab uptake (>50% of the tumour load) on the HER2-PET could predict treatment response to the antibody-drug conjugate (ADC) trastuzumab-emtansine (T-DM1) (Fig. 1A) [86]. A preclinical immunohistochemistry study has shown that trastuzumab distribution is also very heterogeneous on the tissue scale and that a large amount of HER2 receptors are never reached by trastuzumab [87]. The ZEPHIR study demonstrates that the inherent problems of characterising the tumour environment by tissue biopsies (i.e. sampling error and overlooking intra- and intertumour heterogeneity) can be circumvented through the use of nuclear imaging.

### Imaging the drug

Depending on the nanoparticles' release characteristics, imaging nanoparticle distribution might not necessarily reflect the distribution of encapsulated drugs and thus provide an incomplete view of drug distribution. To avoid the shortcomings of imaging the nanoparticle, the chemotherapeutic drug camptothecin and a photosensitizing agent were conjugated and labelled with  $^{64}\text{Cu}$ . In this way, the distribution of the drug conjugate could be imaged even after release from the polymeric nanoparticle. This study showed that a higher amount of the  $^{64}\text{Cu}$ -labelled photosensitizing agent was delivered to the tumour when it was conjugated to camptothecin. Accordingly, nanoparticles containing the combination more efficiently inhibited tumour growth than nanoparticles containing either the photosensitizer or camptothecin [88]. Attempts have been made to distinguish the distribution of nanoparticles from the distribution of drugs with nuclear imaging. For example, Lamichhane et al. combined PET and SPECT to image [ $^{111}\text{In}$ ]-Liposomes and the encapsulated [ $^{18}\text{F}$ ]-Fluorinated Carboplatin separately on organ scale. A similar distribution was found for both drug and carrier, with the highest accumulation in the spleen and liver. (Fig. 1B) [89].

## MAGNETIC RESONANCE IMAGING

Because of the lack of radiation, its high spatial resolution and excellent soft tissue contrast. Magnetic resonance imaging (MRI) is widely used in daily clinical practice for tumour diagnosis, characterisation and response evaluation. MRI is increasingly being investigated in image-guided therapy such as MR-guided radiotherapy (MR-LINAC) [90] and MR-guided High Intensity Focused Ultrasound (MR-HIFU) [91, 92]. Several MRI techniques have been used in nanomedicine research, to characterize the tumour environment and to image the distribution of nanoparticles or (model) drugs on organ/tumour and tissue scale [47, 49, 50, 55, 56, 93].

### Imaging the tumour environment

Tumour vascular development and density, as well as perfusion and hypoxia, are key regulators of nanoparticle distribution and nanotherapy effect. Dynamic Contrast Enhanced (DCE-) MRI has been used in clinical trials to evaluate the effect of antivascular treatment on perfusion and vascular permeability [94, 95]. Preclinically, Baker et al. used MRI and histopathology to evaluate factors of the tumour environment that contribute to therapy heterogeneity on tissue level. Distribution of trastuzumab was very heterogeneous. However, areas with little trastuzumab did not correspond with areas that were poorly vascularized [96]. More specifically related to nanomedicine, Activin receptor-like kinase 5 (ALK5) inhibition with A-83-01 was shown to increase accumulation of liposomal Gadolinium (Gd) diethylenetriaminepentaacetic acid

(DTPA) on dynamic MRI [97]. Restricted diffusion on diffusion weighted imaging (DWI) correlates with the cell density of a tumour [98, 99], while Blood Oxygenation Level Dependent (BOLD-) and Tissue Oxygenation Level-Dependent (TOLD-) MRI quantify tumour oxygenation [100, 101]. Hypoxic regions inherently have impaired transport of molecules and in addition hypoxia alters key cellular process such as energy metabolism and cellular receptor uptake and signalling, that can affect both intracellular uptake and efflux of nanomedicine [102].

### **Imaging the nanoparticle**

Iron-oxide nanoparticles have been approved as MRI contrast agent for clinical use. However, they can also function as companion diagnostic or as (imageable) drug delivery systems [103]. For example, Ramanathan et al. conducted a clinical pilot study where they used feromoxytol (FMX) iron nanoparticles (also known as superparamagnetic iron oxide particles, SPION) to predict the deposition of nanoliposomal irinotecan. They showed a correlation between FMX-MRI and tumour response [104]. This companion diagnostic approach could lead to improved patient selection and personalized treatment. Alternatively, tracking the distribution of therapeutic nanoparticles could help with response prediction and early adaptation of a treatment plan. For example Hsu et al. could track the uptake of iron oxide nanoparticles conjugated to tyrosine kinase inhibitor erlotinib at tissue scale, and observed that the particle induced tumour inhibition in non-small cell lung cancer-bearing mice (Fig. 1C) [105]. Also other MRI contrast agents such as manganese and gadolinium have been incorporated in nanoparticles to create paramagnetic nanoparticles that can be imaged with MRI [106, 107]. For instance, Nitta et al. used Gd-dendron modified liposomes to evaluate intratumoural microvasculature with MRI and found a clear difference in vessel architecture between two tumour models. In addition, increased leakage of the liposomes into the tumour tissue was observed after anti-angiogenic sunitinib treatment [108].

### **Imaging model drugs**

Moreover, MRI contrast agents have been encapsulated in nanoparticles as model drugs, to visualize and quantify drug release triggered by temperature, pH or ultrasound sensitive nanoparticles using MRI [93, 109]. Onuki et al. combined two MRI contrast agents to visualize the nanoparticle distribution as well as content release in mice on tissue scale. The mice were treated with poly(D,L-lactide-co-glycolide) nano/microspheres, encapsulated with gadolinium-DTPA, SPIONs and the chemotherapeutic drugs 5-fluorouracil. *In vivo*, release of gadolinium-DTPA was seen from 30 minutes after intravenous injection, in the same tumour regions where most of the nanospheres had accumulated [110]. Using MR contrast agents as a model drug is a convenient way to visualize *in vivo* drug release and spatial distribution at tumour and tissue scale. However, these MR contrast agents may influence the stability of nanoparticle [111] and interact

with the co-loaded drug. Furthermore, the tissue distribution of the MR contrast agent and the co-loaded drug may not correspond due to different physicochemical properties of both molecules.

## COMPUTED TOMOGRAPHY

Computed tomography (CT) imaging is very commonly used in the clinic for diagnostic purposes and response evaluation after treatment. More recently, it was shown that CT could derive tumour transport properties in patients with pancreatic cancer that correlated with gemcitabine incorporation, pathological response, and oncologic outcome [112]. Yoon et al. showed that CT texture features, as a non-invasive imaging biomarker for the identification of intratumoural heterogeneity, correlated with survival rate in gastric cancer [63].

### **Imaging the tumour environment**

The added value of CT imaging for nanomedicine through identifying tumour transport properties was already shown in the preclinical setting. Dynamic Contrast Enhanced (DCE) CT has been used in several studies to measure the intratumoural perfusion, permeability and the accumulation of CT contrast agent-containing nanoparticles in mice [49, 113-116]. Since intratumoural perfusion is associated with liposome accumulation, DCE-CT could be useful to select patients more likely to respond to treatment with liposomal drugs [117]. Correlations were found between distribution of interstitial fluid pressure, tumour perfusion and the intratumoural accumulation of iohexol-containing liposomes imaged with CT on tissue scale (Fig. 1D) [118]. Spectral CT is another promising technique to image therapy heterogeneity on tissue scale, since it can provide high-resolution imaging and quantification of various components of the tumour microenvironment by taking advantage of differences in their energy-dependent attenuation [119]. Spectral CT has already been utilized to monitor vascular and tumour response to vascular endothelial growth factor (VEGF-) inhibitors in rabbits [120] and to assess angiogenesis clinically [121]. Related to nanomedicine, both tumour vasculature and tumour retention of liposomes has been imaged simultaneously with spectral CT, by administering iodine and Gd liposomes at different intervals before CT imaging [116].

### **Imaging the nanoparticle**

In addition to imaging a contrast agent encapsulated in a nanoparticle, CT can also be utilized to image metallic nanoparticles with a high attenuation of x-rays [49, 122]. For example Mao et al. used CT to image the distribution of gold nanoparticle clusters containing doxorubicin on tissue scale and found that the nanoparticles accumulated mostly in the periphery of the tumour [123]. Because vessels in the tumour periphery are

actually on average less permeable than in the tumour core, these results suggest that EPR is not the only factor in play. Extravasation into the core might, among other factors, be hampered by tumour perfusion and the interstitial tumour matrix [26]. In another study, CT imaging showed that hollow bismuth subcarbonate nanotubes, assembled from ultrasmall nanoclusters and loaded with doxorubicin for chemoradiotherapy, had an increased circulation time and exhibited a stronger EPR effect in mice compared to non-assembled ultrasmall nanoclusters [124].

## ULTRASOUND IMAGING

Ultrasound (US) is a low-cost, radiation-free and patient-friendly clinical imaging method that is mostly used for tumour diagnosis and image-guided biopsies. The introduction of contrast-enhanced ultrasound (CEUS), i.e. using microbubbles as ultrasonographic contrast agents, has extended the application of ultrasound in many fields due to improved image quality and new information that cannot be obtained with standard US [125, 126].

### **Imaging the tumour environment**

CEUS can provide anatomical as well as functional information about the vasculature of the tumour (micro-) environment [127-131]. As an example, CEUS with poly (butyl cyanoacrylate)-based microbubbles has been used to image the degree of vascularisation on tumour scale in mice, which was correlated with the degree of EPR-mediated accumulation of a polymeric drug carrier [132]. Moreover, Rojas et al. used targeted sub-micron phase-change contrast agents (liquid perfluorocarbon droplets, that contrary to microbubbles can also provide extravascular contrast) to image angiogenic vessels and perfusion in rats [133].

Tumour environment modelling treatments to improve nanoparticle delivery have been investigated using CEUS. Changes in tumour physiology (i.e. vessel fraction and blood flow) measured by US imaging after collagenase treatment corresponded with changes in IFP, therefore US imaging can be used as an earlier marker of tumour response [134]. Fibrinolytic therapy decompressed blood vessels and improved tumour perfusion was observed with CEUS. Probably related to these physiological changes, the anticancer efficacy of nanoparticle-encapsulated paclitaxel and the penetration of liposomal doxorubicin improved by fibrinolytic therapy [135]. IFP can also be measured directly by US elastography [136].

Recent advances in US imaging such as ultrafast ultrasound and super-resolution techniques provide also information on microvascular properties [137]. Ultrafast Doppler imaging is capable of visualizing the heterogeneous tumour vasculature over time in 3-D with high sensitivity and spatial resolution (80  $\mu\text{m}$ ) [138, 139]. Super-resolution

ultrasound imaging technology allows vascular imaging at even higher spatial resolution ( $\sim 10 \mu\text{m}$ ) [140]. These techniques have already been used for detailed visualization of tumour microvascular morphology [141], characterization of tumour perfusion on tissue scale (Fig. 1E) [142] and monitoring of early tumour response to an angiogenesis inhibiting drug [143] and will soon be of great value for prediction of nanotherapy heterogeneity and response.

### **Imaging the nanoparticle**

In addition to imaging the tumour environment, the distribution of nanoparticles can be imaged by US, using echogenic nanoparticles [144] (e.g. nanobubbles [145, 146], echogenic liposomes [147], polymeric gas-containing nanoparticles [148-150] or combining ultrasound contrast agents with nanoparticles through simultaneous administration or the use of nanoparticle-coated microbubbles [151-153]. Besides the benefits associated with imaging of nanoparticle distribution, ultrasound and microbubbles can improve the therapeutic effect of a drug or nanoparticle through a number of mechanisms, summarized as 'sonopermeation' [154].

### **Imaging the drug**

Although drugs cannot be imaged directly with ultrasound, drug distribution can be visualized. To achieve this, Ektate et al. developed low-temperature sensitive echogenic liposomes, loaded with doxorubicin and perfluoropentane. Tumour hyperthermia led to increased US contrast in mice, which was correlated with increased doxorubicin delivery [147]. Min et al. used a different approach and administered doxorubicin-loaded calcium carbonate polymeric nanoparticles to tumour-bearing mice. In an acidic environment, such as a tumour, the nanoparticles released their doxorubicin load and simultaneously produced carbon dioxide nanobubbles through hydrolysis, which made ultrasound imaging of release at tumour scale possible [155].

Figure 1 [Legend on the next page]

**Figure 1. Non-invasive clinical methods to image spatial heterogeneity of nanomedicine**

**(A)** Patterns of HER2–PET/CT confronted with FDG–PET/CT, Maximum intensity projection. Lesion uptake was considered pertinent when visually higher than blood pool. **Top:** dominant part of tumour load showed tracer uptake. Lung, liver and bone involvement seen of FDG-PET: not all lung lesions are seen on HER2-PET. **Bottom:** entire tumour load lacked tracer uptake. Liver and bone involvement seen on FDG-PET are not seen on HER2PET. (Adapted with permission from [86], copyright 2016 Oxford University Press on behalf of the European Society for Medical Oncology)

**(B)** *In vivo* computed tomography (CT), positron emission tomography (PET)/CT, and SPECT/CT images of a nude mouse injected with 14 MBq of [<sup>18</sup>F]-FCP encapsulated [<sup>111</sup>In]-Liposome through tail vein injection 1 h post-administration. Coronal images. Both PET/CT and SPECT/CT images show the uptake of [<sup>18</sup>F]-FCP encapsulated in [<sup>111</sup>In]-Liposome in the liver and spleen. Both images correspond to each other in the uptake profile, demonstrating the feasibility of dual-tracer imaging from a single nano-construct. (Adapted with permission from [89], copyright 2017 MDPI)

**(C)** MR T2\* images of CL1-5-F4/NF-κB-*luc2*-xenograft-bearing mice treated with erlotinib-conjugated iron oxide nanoparticles. Voxelwise estimates of the intratumoural iron concentration derived from changes in the  $\Delta R2^*$  signal ( $P < 0.0001$ ), which correlates to the amount of intratumoural erlotinib content. **Top:** T2\* weighted MR image. **Bottom:** T2\*-weighted MR image with color-coded overlay of voxelwise estimates of intratumoural iron concentration (Adapted with permission from [105], copyright 2018 Elsevier)

**(D)** A panel of images showing point-based measurements of IFP overlaid on the intratumoural distribution of CT-liposomes in an orthotopic tumour. Images from **left to right** represent: interstitial Fluid Pressure (IFP); permeability; perfusion; interstitial volume fraction; plasma volume fraction. The coloured circles and corresponding numbers represent the region of interest (ROI) locations, ROI size used for point-based analysis, and measured IFP. Predominantly peripheral CT-liposome enhancement was observed, with some heterogeneous accumulation within the central tumour region. Metrics of perfusion were spatially heterogeneous, but tended to increase towards the tumour periphery. (Adapted with permission from [118], copyright 2015 Elsevier)

**(E)** Motion model ultrasound localization microscopy (mULM). Super-resolution ultrasound images of an A431 tumour provide detailed information on the microvascular architecture including insights into vascular connectivity and the number of vascular branching points (see arrows in magnifications). Functional information such as MB velocities (**left** image) and MB flow directions (**right** image; color-coding illustrating the direction of flow according to the coloured circle) can be determined for each individual vessel and evaluated together with the morphological characteristics. Scale bar=1mm. (Adapted with permission from [142], copyright 2018 Nature Research)

## OPTICAL IMAGING OF NANOTHERAPY HETEROGENEITY

Optical imaging modalities are used to collect a variety of information on various spatial and temporal scales [156]: from organism to molecule and from static snapshots to real-time continuous dynamic visualization [157]. These techniques are used in preclinical set-ups to provide macroscopic information at organism and organ scales (bioluminescence imaging (BLI), fluorescence imaging (FLI)) [158] or combined in tomographic set-ups to provide three-dimensional distribution profiles at organ and tissue scales (fluorescence diffuse optical tomography (fDOT), fluorescence-mediated molecular tomography (FMT)) [159, 160]. Most importantly, the possibility for high spatial and temporal resolution imaging enables tissue and (sub-)cellular scale imaging in preclinical set-ups via intravital microscopy (IVM) (confocal laser scanning microscopy (CLSM) and two-photon / multiphoton microscopy (MPM)) [161, 162]. Real-time *in vivo* optical imaging modalities are steadily substituting “old-school” *ex vivo* methodology – “dead mice tell too few tales” [163] – and, preclinically, they establish high-resolution alternatives to conventional clinical imaging modalities. In addition, supplementary *ex vivo* / *in vitro*

optical imaging techniques can provide supportive structural and functional information (immunohistochemistry (IHC) on tissue slices, electron microscopy (EM), flow cytometry imaging). Optical imaging is widely used in the development and evaluation of nanotherapies: molecular imaging helps unravel nanoparticles' complex *in vivo* fate [164, 165], while development of nanoparticles with multimodal-imaging potential [166-170] and state-of-the-art fluorescence-labelling strategies [171, 172] increase the amount and quality of information.

## WHOLE BODY FLUORESCENCE IMAGING ON ORGANISM AND ORGAN / TUMOUR SCALE

Traditionally, macroscopic optical imaging modalities are used in preclinical small animal experimental procedures as alternatives to conventional non-terminal / non-invasive whole-body imaging modalities (PET/SPECT, MRI, CT). BLI, one of the most commonly used optical imaging techniques, allows real-time detection of protein-derived native light emission (Fig. 2A). Even though the required genetic engineering (transfection of cancer cell lines, transgenic animals) makes the technique inapplicable to wild type tumours [173], BLI remains a fast and user-friendly option to evaluate nanotherapy efficacy based on the endogenous luminescence of tumours [174-180] to verify nanoparticles' diagnostic or theranostic potential [168, 181, 182], and to combine with other imaging approaches [183]. Another extensively used preclinical imaging technique is whole body fluorescence imaging (FLI), which requires the administration of fluorescent nanoparticles or molecules (Fig. 2A). Whole body FLI allows for a two dimensional organism and organ/tumour scale evaluation of nanotherapy spatial heterogeneity. Researchers use FLI to define nanoparticles' *in vivo* release profile [184], to monitor nanoparticle tumour accumulation [185-189], to determine how specific structural characteristics of nanoparticles alter their tumour accumulation [186], to examine nanoparticles theranostic potential [170, 190-192], to evaluate the performance of nanoparticles as potential single- [193-195] or multimodal [168, 170, 196, 197] imaging probes. Despite the fact that BLI and FLI can be used to delineate solid tumours and detect fluorescent nanoparticles respectively, they fail to provide three-dimensional and deep-tissue information. This disadvantage can be surpassed by integrating fluorescence-driven tomographic techniques [159]. fDOT [173] and fluorescence molecular tomography hybridized with computed tomography (FMT-CT) [198-200] in combination with Near-infrared (NIR-) decorated nanoparticles provide additional three-dimensional spatial information (Fig. 2B).

## INTRAVITAL MICROSCOPY ON TISSUE AND (SUB)CELLULAR SCALE

Recent advancements in molecular imaging revealed the dark side of the field of nanomedicine. The scepticism about the EPR effect [39], the demonstration of low targeting efficiency towards tumour cells [201], and even, surprisingly, the incrimination of nanomaterials as metastasis mediators [202] denote that nanoparticle behaviour *in vivo* is highly complex. Therefore, a deeper understanding of *in vivo* behaviour, targeting mechanisms and nanoparticles' specific engagement with cell populations (tumour, stromal, endothelial, immune cells) is essential. Extensive use of real-time imaging techniques like IVM, could potentiate our efforts to characterize the tumour microenvironment on tissue and cellular scale (Fig. 2C) and design nanotherapies with predictable and desired physicochemical and immunobiological behaviour.

### Imaging the nanoparticle

Indeed, IVM can provide information regarding nanoparticles' extravasation, diffusion, and penetration into tumours (Fig. 2C). For such purpose, orange/red fluorescence-labelled nanoparticles are most commonly injected together with large molecular weight (e.g. 2 MDa) green fluorescence-labelled dextran to delineate vessels. This two-dye strategy was applied to confirm the silica nanoparticle-based delivery of small interfering ribonucleic acid (siRNA) cancer therapeutics to orthotopic MDA-MB-231 tumours [203]. Similarly, extravasation of 100 nm long circulating liposomes into melanomas in presence / absence of Tumour Necrosis Factor (TNF) co-administration was evaluated. The IVM experiment revealed TNF-mediated vessel permeabilization that led to enhanced liposome extravasation. Unsurprisingly, the TNF-derived benefit was not observed for liposomes of larger size (400, 800 nm) [204], corroborating the realization that nanoparticles much larger than 100 nm cannot extravasate. Alongside qualitative visualization, IVM was utilized for semi-quantitative analysis comparing accumulation of nanoparticles in tumours versus healthy organs [205].

Interestingly, IVM has been used to identify differences in nanoparticle diffusion to tumour sites or nanoparticle tumour targeting, and to correlate them to different physicochemical properties, providing an excellent tool for head-to-head nanoparticle comparisons. The size-dependent diffusion of nanoparticles was studied after administration of a library of small fluorescent quantum dot nanoparticles with diameters of 12, 60 and 125 nm, revealing that 12 nm nanoparticles diffused twice as far in comparison to the largest size particles [206]. Similarly, a size effect was found when attempting to target lymph node metastases with nanoparticles: of three nanoparticles with diameters of 30, 70, and 80 nm, only the smallest reached the metastasis [207]. By comparing the studies that aimed to understand the importance of the nanoparticle size in *in vivo* behaviour, a clear pattern of deeper tissue penetration by smaller nanoparticles

is revealed. In another study low (5 mol %) PEG surface density proved to contribute to a higher targeting specificity of arginylglycylaspartic acid (RGD) nanoparticles, than high (50 mol %) surface PEG density [208]. A head-to-head comparison between the extravasation of a quantum dot and a nanotube sharing similar surface coating, surface area, and charge but different geometry (spherical vs cylindrical respectively) revealed shape-dependent and tumour-dependent extravasation patterns. Of three investigated tumour models, cylindrical single-walled carbon nanotubes were found to extravasate only markedly in a human glioblastoma tumour model, while spherical quantum dots extravasated only in a colon adenocarcinoma tumour model. Surprisingly, no extravasation of either nanoparticle was observed in an ovarian adenocarcinoma tumour model [209]. Comparably, heterogeneity in extravasation patterns between these tumour models was found for RGD-decorated and control quantum dots [210]. The importance of morphology was emphasized when plateloid-shaped microparticles were found to adhere more efficiently to tumour vasculature and exhibit a higher tumour to liver accumulation ratio than cylindroid microparticles [211].

### **Imaging the tumour environment**

In addition to addressing nanoparticle tumour targeting and accumulation profiles, IVM has been used to unravel more intricate interactions between nanoparticles and immune cells; an interesting option given the increasing appeal of cancer immunotherapy. One of the first studies providing real-time insight in the behaviour of TAM, developed magneto-fluorescent nanoparticles enabling the visualization of nanoparticle-labelled TAM on tumour/organ scale (MRI, FMT) and on tissue and cellular scale (IVM). Among other findings, TAM phagocytosed more nanoparticles than other myeloid cells, they were situated in close proximity to tumour cells and displayed low motility [212]. Since nanoparticles tend to accumulate in TAMs, the hypothesis that an increase in TAM population within the tumour microenvironment would also increase nanoparticle accumulation was tested. Application of radiation proved to increase TAM / tumour cell ratio and confirmed this hypothesis: radiation enhanced the accumulation of liposomal doxorubicin in the tumour. IVM experiments showed that the enhanced accumulation was mediated by an increase in 'vascular bursts' (bursts of extravasation of nanoparticles into the tumour tissue) for which the presence of TAM and perivascular phagocytes was required [213]. Of note, the verification that vascular bursts are a driving mechanism for enhanced accumulation of nanoparticles within a tumour, challenges the conventional EPR-effect theory about roughly homogeneously increased leakiness of tumour vasculature [214]. Another immune cell-related variable that has been tested via IVM is the nanoparticle clearance from circulation. Myeloid immune cells proved to be a significant mediator of nanoparticle clearance, as nanoparticles injected in mice pre-treated with clodronate (which causes depletion of phagocytotic cells), circulated in a significantly higher amount in the blood [215].

Given that angiogenesis is a hallmark of cancer, the attention of intravital microscopy users has been directed particularly to nanoparticle-mediated vessel wall visualization and targeting. Already in the mid '00s, a successful attempt using vascular cell adhesion molecule 1 (VCAM-1) decorated nanoparticles paved the way for future success [216]. Subsequently, the development of RGD-decorated multimodal (fluorescence and paramagnetic) quantum dots [217] or nanoemulsions [208] aimed to actively target the  $\alpha\beta 3$  integrin receptor overexpressed by angiogenic endothelium. By comparing the above studies, we see that attaching a certain targeting peptide to a nanoparticle alters the nanoparticle's *in vivo* behaviour in a similar manner regardless of the selected nanomaterial, i.e., nanoemulsions versus quantum dots. The multimodal nature of nanoparticles allows for visualization of angiogenic endothelium and neovasculature on tumour/organ scale (MRI, FLI, BLI), tissue scale (IHC and IVM), and cellular scale (IVM) [208, 217]. Of note, IVM strategies of visualizing nanoparticles and immune cells could be expanded outside the field of nanomedicine, for cancer cell imaging [218], which could be used as complementary technique in the analysis of liquid biopsies [219] and in the assessment of tumour heterogeneity [220].

The new mechanistic and molecular insights that were obtained through IVM procedures inspired researchers to develop IVM-specialized imaging agents. Biocompatible organic dots for MPM [221], magneto-fluorescent nanoparticles [222] and fluorescent nanoprobe that detect vascular permeability [223] are among representative examples of nanoparticles aiming to increase the information obtained by imaging.

## OPTICAL IMAGING OF DRUGS

Visualization of fluorescent-labelled nanoparticles and related aspects of the tumour microenvironment provide valuable information on therapy heterogeneity in nanomedicine. Imaging the administered drug itself would complete the picture. However, direct imaging of drugs remains elusive. In this respect, inherently fluorescent drugs are convenient [224, 225], and some chemotherapeutic drugs relevant to cancer research possess fluorescent properties (i.e. doxorubicin, mitoxantrone, irinotecan) [226]. The application fluorescent drugs is nicely illustrated by a study that showed colocalization of fluorescent doxorubicin with Kupffer cells outside of tumours in a liver metastasis mouse model after treatment with PEGylated liposomal doxorubicin (Fig. 2E) [225]. Another interesting study from our institution used *ex-vivo* fluorescence microscopy to quantify tumour tissue doxorubicin concentration and heterogeneity of doxorubicin distribution after treatment of mice with doxorubicin, PEGylated liposomal doxorubicin (Doxil) and temperature-sensitive doxorubicin liposomes (ThermoDox) at three different dosages. Heterogeneity in doxorubicin distribution was visualized on tissue scale and could be compared spatially to heterogeneous vessel perfusion, hypoxia and dividing cell fraction

in the tumour microenvironment [227]. However, *in vivo* imaging of inherently fluorescent drugs is hampered by their relatively low fluorescence quantum yield, which limits their detectability at therapeutic concentrations. Another approach could be the conjugation of fluorescent molecules to the drugs that are carried by nanoparticles, despite the fact that this could result into alternation of their properties. The conjugation of fluorescent dyes to macromolecular drugs has been successfully applied before [87, 96, 228]. In these studies the drugs had a significantly higher molecular weight than the conjugated fluorescent dye, which made their biodistribution properties, targeting specificity and efficacy less likely to be compromised by the dye. Fluorescently labelled therapeutic antibodies have already been administered to patients in early clinical studies [229-231].

## TISSUE OPTICAL CLEARING

Utilization of fluorescent molecules is often restricted by factors such limited imaging depth. Therefore, more sophisticated *ex vivo* techniques like the tissue optical clearing strategies [232] have been developed to surpass these limitations [233] by reversing the tissue opacity [234]. The application of such a methodology has been successfully applied to 3D cell spheres [235], tissue samples [236, 237], intact organs [238, 239] and even entire organisms [240]. Even though most of the conducted research is performed in soft tissues and organs, e.g., the brain, the tissue optical clearing strategies appear an appealing methodology for visualizing tissues in which fluorescence signal is heavily scattered, such as the dense connective tissue [241]. Tissue clearing applications provide high quality 3D information and improved mapping of the tissue environment which is useful to investigate the nanoparticle [242-244] and drug [228] distribution at tissue, organ, and organism scale. Additionally, tissue clearing has been used as a tool to study the heterogeneity of immune cell infiltration and therapeutic response in tumour models [245]. Besides its pre-clinical use, tissue clearing methodology has been applied for microscopic assessment of clinical specimens [246].

## CLINICAL TRANSLATION OF OPTICAL IMAGING

Due to the limitations in tissue penetration and size of the imageable subject, *in vivo* optical imaging is mainly constricted to preclinical applications. Clinically, optical imaging is of course widely used on *ex vivo* biopsy or surgical samples. Although this consists mostly of immune histochemistry, some work has been done to complement this with fluorescent imaging [247, 248]. To our knowledge, fluorescent imaging has not yet been applied in clinical trials using nanomedicine. However, progress has been made towards translation of the use of silica nanoparticles for intra-operative sentinel node

and tumour detection [249, 250]. In the future ex-vivo analysis of patient biopsies or surgical samples during clinical nanomedicine trials could provide detailed information on therapy heterogeneity on the tissue scale by visualizing nanoparticles, tumour microenvironment and perhaps fluorescent drugs. However, non-invasive in-vivo techniques will probably remain more appealing. Apart from nanomedicine, the clinical use of optical imaging is mostly complementary, with primary focus on intraoperative imaging [248, 251-253] and fluorescence-guided diagnosis [248, 254].

## OPTOACOUSTIC IMAGING

Optoacoustic (photoacoustic) imaging is an emerging hybrid technique that combines the benefits of US and optical techniques, i.e. deep imaging depth, high spatial resolution and high contrast [255]. In optoacoustic imaging energy emitted by a pulsed laser source is absorbed by tissue causing its thermoelastic expansion, which generates ultrasound waves that can be detected with conventional ultrasound transducers [256]. The spatial resolution and imaging depth can be adapted to the scale of the preferred application domain, ranging from cellular substructures to organs with the same type of contrast [257]. Optoacoustic signal is mainly provided by endogenous molecules, such as haemoglobin (Hb), melanin, lipids, and collagen, or exogenous contrast agents such as small-molecule dyes, gold nanoparticles and liposomes [258, 259].

Figure 2 [Legend on the next page]

**Imaging the tumour environment**

In the oncology domain the endogenous contrast is typically used to study tumour vasculature [260, 261] and oxygenation status (Hb) [262, 263] at cellular scale [264] as well as at tissue scale [265]. Whereas targeted exogenous contrast agents enable the readout of a specific biological entity or process such as Epidermal Growth Factor Receptor (EGFR) expression [266] or matrix metalloproteinase activity [267]. By using multiple wavelength illumination (i.e. Multispectral Optoacoustic Tomography (MSOT)) it is possible to differentiate the contribution of different contrast agents and analyse their concentration and distribution simultaneously. In the work of Tomaszewski et al. MSOT imaging of endogenous contrast (i.e. signals from oxy- and deoxyhaemoglobin) and exogenous contrast (signals from the FDA approved organic dye indocyanine green (ICG)) allowed for the non-invasive assessment of tumour vascular function, hypoxia, and necrosis revealing a complex, yet consistent network of relationships in the tumour vascular microenvironment [262]. Okumura et al., in turn, showed the potential of photoacoustic imaging coupled with ICG for evaluating changes in tumour vascular permeability associated with antiangiogenic therapy [268]. ICG rapidly binds to albumin in plasma, becoming a macromolecule that is not able to extravasate from vessels with intact endothelium. Reduced vessel permeability after anti-VEGF therapy, perceived as photoacoustic signal decrease in the tumour, was detected before inhibition of tumour growth indicating the potential of optoacoustic imaging as early marker of therapy response. Reporter gene products such as  $\beta$ -galactosidase [269], tyrosinase [270, 271] and fluorescent proteins [272] have also been used to produce contrast for optoacoustic imaging. Recently, Peters et al. introduced a

new approach for creating optoacoustic imaging contrast by injecting phototrophic purple bacteria into tumours, which allowed them to monitor *in vivo* spatiotemporal changes of macrophage activity [273]. The spatiotemporal distribution and activity of macrophages are very relevant for nanomedicine since macrophages are increasingly being used for targeting nanoparticles towards tumour cells [274].

### **Imaging the nanoparticle**

Nanocarriers not only serve as optoacoustic contrast agent, but can also act as vehicles for drugs. Several nanoparticles have been loaded with drugs and combined with optoacoustic imaging for non-invasive and real-time monitoring of biodistribution and pharmacokinetics [275, 276]. Herzog et al. used the MSOT approach to investigate the accumulation over time of long-circulating gold nanorods as well as intratumoural patterns of hemoglobin oxygenation to demonstrate imaging of the EPR effect (Fig. 2D). Higher nanorod accumulation was seen in the tumour model with a higher fraction of deoxygenated haemoglobin, although the underlying mechanism is still unclear [277]. The work by Song et al. illustrates nicely how MSOT is applied for whole-body visualization of the nanocarrier-based drugs distribution as well as the blood vessels in mice. They demonstrated that the distribution of platinum containing nanoparticles in tumours is highly vascularity-dependent, and could only access the peripheral region of the tumours [278]. Similarly, Kim et al. used bioconjugated gold nanocages as a contrast agent for quantitative molecular optoacoustic tomography of melanomas and surrounding blood vessels at microscopic scale *in vivo* [279]. These gold nanocages have already been used for triggered drug delivery [280]. Another interesting approach is to use pulsed laser irradiation, intrinsically part of optoacoustic instrumentation, as a stimulus for triggered drug release [281]. Here, low-intensity laser irradiation was used for photoacoustic imaging, while high-intensity laser irradiation induced the vaporization of perfluorohexane loaded in the nanoparticle and triggering the fast release of the co-loaded drug paclitaxel.

### **Imaging the drug**

In order to monitor the drugs themselves using optoacoustic imaging they should exhibit NIR-absorbing properties. Unfortunately, few if any clinically prescribed drugs have strong intrinsic absorption in the NIR. As an alternative, small molecule NIR dyes are co-loaded with drugs of interest to monitor drug release and distribution [282]. An alternative approach for monitoring drug release was recently proposed by Yang et al. [283]. They developed a multifunctional nanotheranostic platform consisting of two optoacoustic imaging probes that allowed for concurrent non-invasive real-time ratiometric optoacoustic imaging of acidic tumour pH and monitoring of pH-induced drug release in living mice.[284]

## PHOTOTHERMAL AND PHOTODYNAMIC THERAPY

Optical and optoacoustic imaging have frequently been combined with photothermal therapy (PTT [170, 187, 190, 285]) and photodynamic therapy (PDT [168, 188, 189]) so that the NIR excitation can be used for both imaging and therapy. The recent progress in this field was excellently reviewed by Zhu et al. [286]. In PDT a photosensitizer is administered, which is subsequently activated by external light. In PTT nanoparticles generate heat upon laser light excitation. Nanoparticles (e.g. gold nanoparticles) can act as photothermal agents while simultaneously delivering photosensitizing agents [287]. Clinical trials using these therapies have already been performed [288] and imaging the distribution of photodynamic and photothermal agents could help towards further clinical translation.

## MASS SPECTROMETRY IMAGING

Mass Spectrometry Imaging (MSI) is a label free, multiplex technique that is used to visualize the molecular distribution of endogenous compounds such as metabolites[289], lipids [290, 291], proteins and peptides [292-294], as well as drugs [295, 296] and drug delivery systems [297] in biological tissues. MSI therefore has the ability to collect not only drug distribution data but also endogenous compound information related to drug-induced efficacy and toxicity on tissue and cellular scale. This technique is increasingly being used in the pharmaceutical research and development pipeline and has demonstrated its utility from early stage drug discovery to preclinical development and clinical evaluation of tumour response to treatment. MSI is used for i) localizing and quantifying drug and metabolite levels (pharmacokinetics) to study efficacy [295], ii) assessing off target drug accumulation to study toxicity [298, 299], and iii) detecting endogenous biomarkers (pharmacodynamics) for predicting and evaluating treatment response [300].

In MSI spatially defined desorption/ionization methods are used to collect sequentially mass spectra from a small region (pixel) of a tissue sample. Among the multitude of surface sampling techniques, matrix-assisted laser desorption/ionisation (MALDI) uses a laser beam for desorption/ionization of tissue-representative molecules co-crystallized in a solidified matrix; while desorption electrospray ionization (DESI) makes use of an electrically charged solvent spray and in secondary ion mass spectrometry (SIMS), a beam of high energy primary ions (e.g. Ar<sup>+</sup>, Ga<sup>+</sup>, In<sup>+</sup>) is used to release secondary ions from the sample surface. In contrast to MALDI and SIMS where the sample is analysed under vacuum, DESI is non-destructive and performed at atmospheric pressure, which renders the technique more user friendly and through appropriate solvent selection, more tuneable to increase selectivity and/or sensitivity. Depending on the ionization

method used spatial resolution, sensitivity, and the molecules that can be analysed change. Mostly, MALDI is used at 10 to 20  $\mu\text{m}$  spatial resolution, whilst DESI resolution spans 50  $\mu\text{m}$  till 200  $\mu\text{m}$  and SIMS allows for sub- $\mu\text{m}$  resolution. Sensitivity wise DESI outperforms MALDI and SIMS, partly due to increased pixel size (see spatial resolution) and partly due to improved ionization efficiency. Although sensitivity is determined by e.g. physicochemical properties of the compound, typically one requires low  $\mu\text{g/g}$  concentrations in the case of DESI and approx. 20  $\mu\text{g/g}$  tissue for detection by MALDI and SIMS.

### Imaging the drug

The number of drugs that have been detected using MSI is extensive, ranging from anti-cancer drugs (e.g. paclitaxel [301], sunitinib [302], doxorubicin [303]), antibiotics (moxifloxacin [304], polymyxin [298]), beta blocker propranolol [305] and antipsychotic drug olanzapine [306]. MALDI and DESI are mainly used to study the drug distribution at tissue scale. MALDI MSI images for example showed clearly that the distribution of paclitaxel distribution is very heterogeneous and depends on the histopathological characteristics of the different tumour models investigated (figure 3A) [307]. High performance liquid chromatography (HPLC) analysis of tumour homogenates was not able to detect the heterogeneous drug distribution in tumour sections. The same group also showed that the anti-angiogenic agent bevacizumab induced changes in the tumour microenvironment (i.e. more uniform distribution of vessels and less necrosis).

Bevacizumab led to a more homogeneous distribution of paclitaxel and even though the total tumour paclitaxel concentration was lower, anti-tumour activity was greater [308]. In a comparable study, Torok et al. explored the effect of the intratumoural concentration and distribution of five receptor tyrosine kinase inhibitors on their anti-vascular and anti-tumour activities [309]. They demonstrated that limited tumour tissue drug penetration was the primary source of resistance to angiogenesis inhibitors. Both studies clearly show the impact of drug distribution on pharmacological responses and demonstrate the potential of MALDI-MSI to predict the efficacy of unlabelled small molecule drugs in malignant tissue.

Unlike whole-body autoradiography, which is the standard for quantitative assessment of drug distribution, MSI can detect the parent drug and metabolites simultaneously in a single experiment, without having to label the drug [310, 311]. For example Liu et al. imaged the time-dependent and concentration-dependent permeability and metabolism of irinotecan in tumour organoids. They discovered that the active metabolite SN-38 did not co-localize well with the parent drug irinotecan and the inactive metabolite SN-38G, which may lead to therapy heterogeneity [312]. Bruinen et al. were able to find out using MALDI and DESI that precipitation of crystal-like structures in the cortex of rabbit kidney, which were assumed to cause the renal toxicity, were mainly composed of metabolites and relatively little parent drug (figure 3B) [313].

**Table 1 Comparison of modalities to image spatial heterogeneity of nanomedicine**

Modality	Drug	Nanoparticle	Environment	Spatial resolution	
Non-invasive clinical imaging methods	PET / SPECT	Drug labelled with radioactive tracer (e.g. $^{11}\text{C}$ , $^{18}\text{F}$ and $^{123}\text{I}$ ).	NP labelled with radioactive tracer (e.g. $^{64}\text{Cu}$ and $^{89}\text{Zr}$ ).	Specific radiotracers for environmental factors such as hypoxia ( $^{18}\text{F}$ -FMISO), proliferation ( $^{18}\text{F}$ -FLT) or angiogenesis.	Clinical: ~4 mm (PET) ~10mm (SPECT) Preclinical: < 1 mm (PET/SPECT)
	MR contrast agents as model drugs (e.g. Gd- and Mn- chelate).	- Superparamagnetic NP labelled to drugs or other NP - NP incorporating, encapsulating or labelled with MR contrast agents	Particular MRI sequences that can measure perfusion, vascular permeability, diffusion or oxygenation status.	~1 mm (clinical) ~0.1 mm (preclinical)	Slow
	CT contrast agents as model drug (e.g. iodine).	Metallic NP (e.g. gold, bismuth).	Dynamic CT with contrast injection for measuring perfusion and permeability .	50-500 $\mu\text{m}$	Fast
	US contrast agents as model drug (e.g. nanobubbles).	- Micro- and nanosized echogenic NP - NP labelled with US contrast agents.	- Specific ultrasound modes for measuring flow velocity and stiffness - Contrast-enhanced ultrasound to measure perfusion	50-500 $\mu\text{m}$	Fast
Optical Imaging	BLI/FLI	- Drug labelled with fluorescent dye - Inherently fluorescent drug - Fluorescent dyes as model drug	NP co-loaded/labelled with fluorescent dye.	- Endogenous luminescence of (tumour) cell populations (BLI) - Specific (antibody-labelled) fluorescent probes to image environmental characteristics	~5 $\mu\text{m}$
	- Drug labelled with fluorescent dye - Fluorescent dyes as model drug	NP co-loaded/labelled with fluorescent dye.	Specific dyes to image environmental characteristics.	< 1 mm	Medium
	- Drug labelled with fluorescent dye - Inherently fluorescent drug - Fluorescent dyes as model drug	NP co-loaded/labelled with fluorescent dye.	Specific dyes to image environmental characteristics.	Subcellular	Fast
	Fluorescent dye as model drug (e.g. ICG, IRDye800CW).	- Co-loading/labelling with fluorescent dye (e.g. ICG) - NP as optoacoustic contrast agent (e.g. Single-walled carbon nanotubes, gold NP)	- Endogenous contrast (e.g. Hb) - Specific (antibody-labelled) fluorescent probes to image environmental characteristics	1 $\mu\text{m}$ - 1 mm	Fast
Mass Spectrometry Imaging	MSI	Label-free imaging of drugs and metabolites.	Label-free imaging of NP or NP compounds (e.g. phospholipids).	-Label-free imaging endogenous compounds (e.g. metabolites, proteins, lipids). - Imaging of tumour environmental markers (e.g. hypoxia)	1 $\mu\text{m}$ (IMC) 10-20 $\mu\text{m}$ (MALDI) 50-200 $\mu\text{m}$ (DESI) Sub- $\mu\text{m}$ (SIMS)

PET: positron emission tomography; SPECT: single photon emission computed tomography; NP: nanoparticle; F-MISO: fluoromisonidazole; FLT: fluorothymidine; CT: computed tomography; MRI: magnetic resonance imaging; US: ultrasound; BLI: bioluminescence imaging; FLI: fluorescence imaging; fDOT: fluorescence diffuse optical tomography; FMT: fluorescence-mediated

In another example, Groseclose et al. [314] reported on the nephrotoxicity of dabrafenib, an approved drug for treatment of specific tumours in adults. Pre-clinical studies showed renal pathogenesis due to obstructive nephropathy in juvenile rats. MSI allowed for spatial analysis of DAB and its metabolites and determination of the chemical composition of the renal deposits. It showed that the deposits were dabrafenib- and dabrafenib metabolite-free and they were merely composed of calcium phosphate. Hence a better risk assessment for pediatric treatment with dabrafenib was performed. So far, MALDI-MSI cannot yet match the spatial resolution of established methods for intracellular imaging such electron microscopy. However, using SIMS it is possible to map the distribution of drugs within individual cells [315]. For example, SIMS was used to localize the drug amiodarone at therapeutic dosing concentrations in four different cell types (figure 3C) [316, 317]. SIMS was also employed to study the intracellular accumulation of two drugs (p-boronophenylalanine (BPA) and sodium borocaptate (BSH)) used for boron neutron capture therapy [318]. By labelling each drug with a different boron isotope (i.e.  $^{10}\text{BPA}$  and  $^{11}\text{BSH}$ ), they were able to image the subcellular distribution of both drugs independently in the same cell. In a recent paper by Vanbellingen et al. the distribution of the B-cell lymphoma 2 (Bcl-2) inhibitor ABT-737 was studied in a treated A-172 human glioblastoma cell line [319]. They were able to visualize the drug and some endogenous markers on the (sub-)surface of the cells with high spatial ( $\sim 250$  nm) and high mass resolution ( $m/\Delta m \sim 10,000$ ), and absence in the nucleus, confirming site of action.

An alternative and novel MSI technique for imaging drug distribution at subcellular resolution, the so-called imaging mass cytometry (IMC), was introduced in the life sciences by Giessen et al. in 2014 [320]. IMC is based on laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS), and provides capability to either analyse drugs containing metal ions, like e.g. cisplatin, or use antibodies labelled with a polymer containing (rare-earth) metals (e.g. Europium, Gadolinium, Gold, Platinum). Because these metals all have distinct isotopic patterns and are absent in biological specimens, they can be quantified with high precision. Next the use of laser ablation offers the possibility to excise tissue sample of (sub-)micron size, providing an order improved spatial resolution. Using this technique Chang et al. imaged the platinum distribution at subcellular resolution ( $1 \mu\text{m}$ ) in patient-derived pancreatic cancer xenograft-bearing mice treated with cisplatin, revealing extensive binding of platinum to collagen fibres in both tumour and normal mouse tissues (Figure 3D) [321]. Theiner and coworkers also employed LA-ICP-MS to localize platinum in the kidney in mice treated with three different Pt-containing drugs. The imaging data revealed that the drugs were mostly located outside of the malignant parts of the samples. This clearly demonstrates that determining average Pt concentrations might overestimate drug uptake and cause misleading conclusions on therapy efficacy [322].

### Imaging the nanoparticle

MSI also provides the opportunity to image nanocarriers, such as lipid- and metal-based nanoparticles. Typically nanoparticles are labelled or loaded with a radioactive or fluorescent probe in order to follow the *in vivo* fate after administration. However, this requires additional chemical development and the introduction of the probe may influence the biodistribution of the nanoparticle. Recently, Zandanel et al. showed that MALDI-MSI allows for the simultaneous visualization of the polymeric nanoparticle, the encapsulated drug (doxorubicin) and its metabolite (doxorubicinol) in treated mouse liver [323]. Unfortunately, they didn't show the co-localization of the nanoparticle and the drug in the same tissue section. Fülöp et al. exploited the multiplex nature of MSI even further by determining the spatial distribution and integrity of drug-loaded liposomes in tissue with a single label-free measurement [324]. By imaging two lipids (DPPG and PEG36-DSPE) incorporated in the liposomal bi-layer they were able to visualize the liposome distribution, and in addition they could interrogate the integrity of the liposomes by looking at the co-localization of the two lipid markers (figure 3E) [324]. Furthermore, they examined the presence of remaining blood in the same tissue slice by MALDI imaging of hemoglobin, which allowed determining the localization of the liposomes with respect to the blood vessels.

Xue et al. developed an MSI method that enabled not only the visualization, but also the quantification of the *in situ* drug (doxorubicin) release from molybdenum disulphide (MoS<sub>2</sub>) nanosheets [325]. The quantification of the drug release was done calculating the intensity ratios for doxorubicin and MoS<sub>2</sub> signals. In two mouse tumour models (H22 and 4T1) they observed that the accumulation of drug-loaded MoS<sub>2</sub> nanosheets was high in the spleen and liver, but the tumour tissue accumulation was much lower. However, the highest drug release from carriers was observed in tumour tissue, which was ascribed to higher drug dissociation extent due to the acidic tumour microenvironment.

### Imaging the tumour environment

As indicated earlier, mass spectrometry offers unique capabilities for untargeted exploration of biological samples and provides simultaneous information of the distribution of the drug, the nanoparticle and endogenous compounds such as metabolites, lipids and proteins. Therefore, MSI can be used to detect biomarkers associated with disease, molecular changes due to drug treatment and tumour components limiting nanomedicine distribution and effect or augmenting off-target effects.

Figure 3 [Legend on the next page]

**Figure 3. Mass Spectrometry Imaging to image spatial heterogeneity of nanomedicine**

**(A)** Paclitaxel distribution by MALDI MSI. Necrotic areas, highlighted with dashed lines, are those where there is the lower drug signal. (Adapted with permission from [307], copyright 2016 Nature Research)

**(B)** DESI image overlay representing the spatial distribution of the drug compound ( $m/z$  378) and its most abundant metabolites ( $m/z$  380 and 394) in a tissue section of a formalin fixed frozen rabbit kidney. (Adapted with permission from [313], copyright 2016 Springer US)

**(C)** ToF SIMS 2D images of 3D data acquired in higher spatial resolution mode from HeLa cells completely consumed by the argon cluster source during analysis. The cells were incubated for 2 h with 9.7 nmol/mL amiodarone hydrochloride. Composite image where red represents ribose  $m/z$  81, blue shows the signal from the phosphatidylcholine lipid fragment ( $m/z$  184), and green shows the amiodarone signal,  $[M + H]^+$  ( $m/z$  646). (Adapted with permission from [317], copyright 2017 American Chemical Society)

**(D)** Cisplatin effects on tumour proliferation, DNA damage and cisplatin distribution in the tumour. Representative Pan-Keratin, EF5, Collagen I, 195Pt, and Histone H3 images of cisplatin-treated (40mg/kg for 24h) mice with OCIP28 patient derived xenografts. Scale bar = 100  $\mu$ m. (Adapted with permission from [321], copyright 2016 Nature Research)

**(E)** MALDI MSI images performed on brain slices of mice that were dosed with liposomes. **Four images on the left:** Half of the mice were perfused before being sacrificed (right panels) to reduce the remaining blood in the tissue. MALDI images of liposomal marker 1,2-dipalmitoyl-sn-glycero-3-phosphoglycerol (DPPG) and indocyanine green (ICG) were acquired in reflector negative ion mode, of PEG36-DSPE in reflector positive mode and of Hb  $\alpha$  chain in linear positive mode. DPPG, ICG and 1,2-distearoyl-sn-glycero-3-phosphoethanolamine conjugated with monodisperse polyethylene glycol (PEG36-DSPE) were measured with 4-Phenyl- $\alpha$ -cyanocinnamic acid amide (PhCCAA) MALDI matrix. Hb was detected after delipidation and 2,5-dihydroxybenzoic acid (sDHB) deposition on the same tissue region. **Magnifications:** MALDI-MS images of the boxed parts marked in perfused brain in pixels indicated by an arrow shows the co-localisation of the liposomal components and hemoglobin at pixel X442 Y071 and the absence of HB at pixel X449 Y074. (Adapted with permission from [324], copyright 2016 Nature Research)

Several studies report that the heterogeneous distribution of lipids and proteins could reflect the effect of therapy and/or could be used as prognostic/predictive marker for outcome. A very nice example of identifying and using endogenous proteomic profiles for distinguishing between responders and non-responders to chemotherapy for oesophageal adenocarcinoma is given by Aichler et al. [326]. Here they selected a series of proteins in pre-therapeutic biopsies, which were identified through liquid chromatography mass spectrometry (LC-MS) analysis and investigated for functional relevance in-vitro. They identified a proteomic signature that was correlated with pre-existing defects in the mitochondrial respiratory chain complexes of cancer cells and was predictive for response to neoadjuvant cisplatin chemotherapy. Yanagisawa et al. reported for the first time in 2003 the ability of MALDI-MSI to generate proteomics patterns of tumour subsets in non-small-cell lung cancer [327]. They showed that protein profiles obtained from tumour tissue samples obtained during surgery could be used to accurately classify tumours and stratify patients into groups associated to poor or good prognosis. Bauer et al. employed MALDI-MSI to identify protein markers differentially expressed in tumour biopsies from patients displaying complete pathological response (pCR) and non-complete pathological response after neoadjuvant paclitaxel/radiation treatment for breast cancer [292]. Proteomic profiling of liver tissue using MALDI-MSI was also used to compare toxicity of hollow CuS nanoparticles and hollow gold nanospheres after intravenous administration in mice [328].

Also tumour hypoxia is investigated by many groups since it is associated with tumour aggressiveness and resistance to cancer treatment. Manscini et al. used MALDI-MSI to simultaneously detect pimonidazole, a clinically used hypoxia marker, its metabolites and associated biomolecules in a single experiment [329]. They detected several endogenous species that co-localized with the hypoxic regions. Interestingly, these identified species are known to be involved in hypoxia or metabolic reprogramming in cancer, although their specific roles remain to be elucidated. Masaki et al. studied the distribution of  $^{18}\text{F}$ -fluoromisonidazole (FMISO), a widely used PET hypoxia imaging probe [330]. The mass spectrometry images showed that FMISO and its metabolites were nearly homogeneously distributed in the tumour and did not correlate with the radioactivity distribution. However, they identified a glutathione conjugate of amino-FMISO which did co-localise with the radioactive signals and was involved in FMISO accumulation in hypoxic tumour tissues.

Interestingly, most MSI studies that investigate drug distributions do not yet exploit the multiplex capabilities of MSI. Instead of using the wealth of information on endogenous molecule distributions (lipids, proteins, hemoglobin) already available in the acquired MSI image they superimpose the drug MSI images with standard H&E stained tissue images and/or various immunohistochemistry (IHC) images. As most of these IHC images are specific to a certain protein, this can be a laborious and time consuming effort. Moreover, correlating drug distribution with the distribution of these endogenous molecules would allow for non-supervised investigations to discover new factors that impair drug transport in tumour tissue and could be used as biomarker for prognosis and therapy response prediction.

## DISCUSSION/ CONCLUSION

Spatial heterogeneity in nanoparticle distribution occurs at all scales and can reduce nanotherapy efficacy. A wide range of imaging modalities help visualize nanoparticle distribution or factors contributing to heterogeneous distribution, by imaging the drug, the nanoparticle and the tumour environment.

### **Imaging scale**

When selecting imaging modalities, researchers need to take into account the desired imaging scale. Non-invasive clinical imaging methods provide three-dimensional information of the intact body on patient, organ and tumour scale, and recent developments, such as super-resolution ultrasound, have broadened their application to provide even tissue scale information. Optical imaging modalities have a superior spatial resolution, procuring images on the tissue and cellular scale, and in the preclinical setting they can provide (sometimes non-invasive) organism and organ

scale information as well. Besides that, *in vivo* applications and intravital techniques offer the possibility to visualize dynamic processes. Clinical use of optical imaging is still hampered by the limited penetration depth and therefore requires tissue sampling or intraoperative use. MSI provides information on tissue and even cellular scale. As it requires a tissue specimen it is inherently an invasive method, regardless of preclinical or clinical use. Due to this limitation, the technique is most suitable and currently most used in the preclinical setting, where an entire tumour or even the whole animal can be analysed at once. In contrast, in the clinic MSI approaches will most likely follow a workflow similar to standard histopathology. Emerging technologies allow for more accurate tissue sampling using intra-procedural multimodality imaging during biopsies [331, 332]. Whenever biopsies are used sampling error is a disadvantage (just as it is for histopathology evaluations) and the technique is therefore less suitable for imaging on organ or tumour scale. Nonetheless, implementation of MSI in clinical research (especially when tissue samples are collected anyway) is feasible and adds a wealth of molecule distribution data on tissue scale. As such, MSI is increasingly becoming an established tool in clinical and pharmaceutical studies.

### **Intrinsic versus extrinsic contrast**

Nuclear imaging methods and most optical imaging methods require labelling of nanoparticles, drugs or aspects of the tumour environment, which has some disadvantages. First, the stability of the link between a label and a nanoparticle determines its usefulness in tracking the nanoparticle, for one could be imaging the label on itself after disconnection from the nanoparticle. Second, attaching a label could change the pharmacokinetic and drug release properties of the nanoparticle leading to erroneous prediction of the distribution of an unlabelled equivalent. Third, administering a labelled version of a previously approved therapeutic nanoparticle or drug could cause additional toxicity and obtaining clinical approval is cumbersome and costly. Fourth, administration of radiolabelled theranostic nanoparticles may decrease the effect of subsequent therapeutic administration through the ABC phenomenon [333]. MSI provides a label-free alternative to obtain detailed tissue and cellular scale information on drugs, nanoparticles and the tumour microenvironment simultaneously.

### **Multimodal imaging**

The integration of imaging data collected from multimodality techniques offers a unique opportunity to combine information related to drug and nanoparticle distribution and tumour environment on multiple scales and provide synergistic advantages over the use of a single modality.

Clinical imaging modalities are generally combined to merge functional (SPECT, PET) with anatomical information (CT, MR) collected on the same scale. A range of nanoparticles for multimodality imaging have been developed [169, 196, 197, 334-336]. On tissue and

cellular scale, successful examples have shown complementarity between optical imaging and MSI techniques [337]. Fluorescence and MSI have been combined to characterize local drug release and map unlabelled therapeutic drug distribution [311]. MSI enabled monitoring of the drug and related metabolites, which were impossible to differentiate with solely fluorescence. The combination of MSI and IMC with IHC and fluorescence *in situ* hybridization (FISH), creates a new dimension to molecular pathology. Now, drug levels within tumour regions can be correlated to different degrees of vascularization of the tumour – highlighted with specific vasculature staining [338]. One of the reported limitations is the impossibility to perform all analyses on the same tissue section. As a consequence and because a tumour is such an heterogeneous system, it is highly probable that two consecutive sections have different morphology / molecular content, which is then difficult to correlate accurately.

To achieve multiscale information, optical imaging and MSI have been paired with clinical imaging [59, 169, 183, 196, 197, 339]. Using dual fluorescent and MRI probes, the high sensitivity of fluorescent imaging is complemented with MRI's ability for deep-tissue penetration and high spatial and temporal resolution [340, 341].

A challenge remains the integration of molecular information provided by 2D / *ex vivo* MSI or optical imaging with 3D / *in vivo* images, such as those generated with SPECT, PET, CT or MRI. This challenge is inherent to the fact that the images are acquired at different scales, can be subjected to different deformations, and lack common fiducial markers. A first step towards combining two-dimensional MSI with three-dimensional MRI is the ability to monitor MRI contrast agents with MSI, which was demonstrated by Tata et al. [342]. They used DESI-MSI to monitor Gadoteridol, to characterize intratumoural heterogeneity and further guide delineation of tumour margins. Coregistration of MSI with other modalities is promising to bridge the gap between the different scales [343-347]. It is worth mentioning that the route towards user-friendly automated methods that are needed to integrate these methods in a routine (clinical) workflow is still long. Nonetheless, multiscale and multi-aspect (i.e. nanoparticle, drug and environment) data is believed to open new doors to improve the characterization of spatially heterogeneous distribution and heterogeneous effect and could greatly contribute in the development of new and more effective nanotherapies.

### **Role of imaging for clinical translation**

Integration of imaging techniques in preclinical lab practice has contributed to an improved understanding of the *in vivo* behaviour of nanoparticles. Additionally, it has led to valuable information on how specific characteristics within the tumour environment can affect nanotherapy outcomes. Continued application of these imaging approaches, and especially the combination of different techniques, will further strengthen our understanding of therapy heterogeneity on organism, tissue, cellular and even subcellular scale. Meanwhile the role of imaging for monitoring PK and biodistribution

is well established in research and development stage, however in the clinical setting it is not yet adopted. Clinically, spatial heterogeneous distribution of therapeutic nanoparticles, poses the threats of under- and overtreatment. Despite the fact that many studies have shown that drug concentration does not correspond with tissue drug levels, phase I and II clinical trials mainly rely on blood samples and spatially sparse biopsies to measure PK on patient scale and biodistribution on organ scale. Imaging drugs or nanoparticles in clinical studies is still rare and often no information is acquired about spatial heterogeneity of nanomedicine on organ, tumour or tissue scale. However imaging drug/nanoparticle distribution can help predict treatment effect and therefore select which patients will benefit most and in which patients a therapy adjustment or a combination therapy that reduces heterogeneity are warranted. Combining imaging of nanoparticle and drug distribution with imaging of tumour environment characteristics or early response indicators promises to help personalize treatment further. Currently, only optical imaging is commonly used to investigate, in the preclinical setting, the interplay between environment, nanoparticle and drug. It is our hope and recommendation that non-invasive clinical imaging and MSI will play a central role in future preclinical and clinical research on the interaction of drug, nanoparticle and environment. Choosing and combining imaging modalities wisely will lay the foundation for successful future nanotherapies.

J.S.d.M and R.D, are supported by a Dutch Cancer Society (KWF) grant (UU 2015-7891) and a Vrienden UMC Utrecht project ('opereren zonder snijden').

A.M.S. is supported by a PhD stipend (90062100) and a travel grant (90284100) from the Central Norway Regional Health Authority "Helse Midt-Norge".

T.P.S. and R.J.V. acknowledge the M4I institute and financial support of the Dutch Province of Limburg through the LINK programme.

## COMPETING INTERESTS

The authors have declared that no competing interest exists.

## ABBREVIATIONS

ABC: accelerated blood clearance;  
ADC: antibody-drug conjugate;  
ALK5: Activin receptor-like kinase 5;  
BLI: bioluminescence imaging;  
BOLD: blood oxygenation level dependent;  
BPA: p-boronophenylalanine;  
BSH: sodium borocaptate;  
CEUS: contrast-enhanced ultrasound;  
CLSM: confocal laser scanning microscopy;  
CT: computed tomography;  
DCE: dynamic contrast enhanced;  
DESI: desorption electro spray ionisation;  
DPPG: 1,2-dipalmitoyl-sn-glycero-3-phosphoglycerol  
DTPA: diethylenetriaminepentaacetic acid;  
DWI: diffusion weighted imaging;  
EGFR: epidermal growth factor receptor  
EM: electron microscopy;  
EPR: enhanced permeability and retention;  
FDG: <sup>18</sup>F-fluorodeoxyglucose;  
fDOT: fluorescence diffuse optical tomography;  
FES: <sup>18</sup>F-fluoroestradiol;  
FISH: fluorescence in situ hybridization;  
FLI: fluorescence imaging;  
FLT: <sup>18</sup>F-fluorothymidine;  
F-MISO: <sup>18</sup>F-fluoromisonidazole;  
FMT-CT: fluorescence molecular tomography hybridized with computed tomography;  
FMT: fluorescence-mediated molecular tomography;  
FMX: feromoxytol;  
GFP: green fluorescent protein;  
Hb: haemoglobin;  
HER2: human epidermal growth factor receptor 2;  
HPLC: high performance liquid chromatography;  
ICG: indocyanine green;  
IFP: interstitial fluid pressure;  
IHC: immunohistochemistry;  
IVM: intravital microscopy;  
LA-ICP-MS: laser ablation inductively coupled plasma mass spectrometry;  
LC-MS: liquid chromatography mass spectrometry;

IMC: imaging mass cytometry;  
 MALDI: matrix assisted laser desorption ionisation;  
 MPM: multiphoton microscopy;  
 MPS: mononuclear phagocyte system;  
 MR-HIFU: magnetic resonance guided high intensity focused ultrasound;  
 MR-LINAC: magnetic resonance linear accelerator;  
 MRI: magnetic resonance imaging;  
 MSI: mass spectrometry imaging;  
 MSOT: multispectral optoacoustic tomography;  
 MTV: metabolic tumour volume;  
 NIR: near-infrared;  
 PDT: photodynamic therapy;  
 PEG: polyethylene glycol;  
 PEG<sub>36</sub>-DSPE: 1,2-distearoyl-sn-glycero-3-phosphoethanolamine conjugated with monodisperse polyethylene glycol;  
 PET: positron emission tomography;  
 PhCCAA: 4-Phenyl- $\alpha$ -cyanocinnamic acid amide;  
 PK: pharmacokinetics;  
 PL: photoluminescence;  
 PLGA-PEG: poly(D,L-lactic-co-glycolic acid)-*b*-polyethylene glycol;  
 PSMA: prostate specific membrane antigen;  
 PTT: photothermal therapy;  
 RGD: arginylglycylaspartic acid;  
 sDHB: 2,5-dihydroxybenzoic acid  
 siRNA: small interfering ribonucleic acid;  
 SIMS: secondary ion mass spectrometry;  
 SPECT: single-photon emission computed tomography;  
 SPION: superparamagnetic iron oxide particles;  
 SUVmax: maximum standardized uptake values;  
 SUVpeak: peak standardized uptake values;  
 TMR: tetramethylrhodamine;  
 TOF: time of flight;  
 TAM: tumour associated macrophages;  
 T-DM1: trastuzumab-emtansine;  
 TLG: total lesion glycolysis;  
 TNF: tumour necrosis factor;  
 TOLD: tissue oxygenation level dependent;  
 US: ultrasound;  
 VCAM-1: vascular cell adhesion molecule 1;  
 VEGF: vascular endothelial growth factor;

## ABSTRACT

### Purpose

The aim of this study was to compare characteristics and survival of patients with *de novo* and metachronous metastatic breast cancer.

### Methods

Data of patients with metastatic breast cancer were obtained from the Netherlands Cancer Registry. Patients were categorized as having *de novo* metastatic breast cancer (n=8,656) if they had distant metastases at initial presentation, or metachronous metastatic disease (n= 2,374) in case they developed metastases within 5 or 10 years after initial breast cancer diagnosis. Clinicopathological characteristics and treatments of these two groups were compared, after which multiple imputation was performed to account for missing data. Overall survival was compared for patients treated with systemic therapy in the metastatic setting, using Kaplan Meier curves and multivariable Cox proportional hazards models. The hazard ratio for overall survival of *de novo* versus metachronous metastases was assessed accounting for time-varying effects.

### Results

Compared to metachronous patients, patients with *de novo* metastatic breast cancer were more likely to be  $\geq 70$  years, to have invasive lobular carcinoma, clinical T3 or T4 tumours, loco-regional lymphnode metastases, HER2 positivity, bone only disease and to have received systemic therapy in the metastatic setting. They were less likely to have triple negative tumours and liver or brain metastases. Patients with *de novo* metastases survived longer (median 34.7 months) than patients with metachronous metastases (median 24.3 months) and the hazard ratio (0.75) varied over time.

### Conclusions

Differences in clinicopathological characteristics and survival between *de novo* and metachronous metastatic breast cancer highlight that these are distinct patients groups.

### Keywords

metastatic breast cancer

*de novo* stage IV

metachronous metastatic breast cancer

overall survival

prognosis

## INTRODUCTION

In the Netherlands, around 14,500 patients annually are diagnosed with invasive breast cancer [1]. Around 5% of these patients present with *de novo* distant metastases at the time of initial diagnosis [2]. Moreover, in 15-20% distant metastases are diagnosed in the years following their initial breast cancer diagnosis (metachronous metastases)[3, 4]. While systemic treatment, with a palliative intent, is the standard of care for both *de novo* and metachronous metastatic breast cancer (MBC) [5, 6], there are specific therapeutic considerations for each group. For instance, in *de novo* MBC the best approach regarding the primary tumour is still unclear. Many studies suggested an overall survival (OS) benefit of local treatment [7-9], but recent randomized studies have refuted this [10, 11]. Unlike patients with *de novo* MBC, many patients with metachronous MBC have already received (neoadjuvant or adjuvant) systemic treatment in addition to loco-regional treatment following diagnosis of the primary tumour. Recurrence following these previous systemic therapies could reflect resistance to these drugs or mean that the maximum tolerated cumulative dose of these drugs was already reached. Moreover, patients can suffer from lasting side effects and therefore be less fit for further systemic treatment. These specific considerations illustrate the importance of understanding differences between patients with *de novo* and metachronous MBC.

So far, characteristics and OS of patients with *de novo* MBC have been analysed in several cohorts [12-27] and in some studies have been compared to patients with metachronous MBC [4, 21, 28-36]. Typically, patients with *de novo* MBC have more favourable disease characteristics and longer OS compared to metachronous patients [4, 21, 28-35]. However, in younger patients ( $\leq 40$  years) the opposite appears to be true (i.e. larger tumours, more widespread metastatic disease and more brain metastasis in *de novo* MBC) [21]. Differences in gene expression profiles between *de novo* and metachronous MBC have been found, which lead to believe that these tumours possess biologically different behaviour [36]. Moreover, whereas studies consistently reported improvements in OS over time for *de novo* MBC [2, 37-39], little evidence supports such a positive trend in metachronous MBC [39], which again emphasizes the difference between these groups. While literature on *de novo* MBC is often based on nationwide registry data, data on metachronous MBC is usually based on regional cohorts [39]. Our study demonstrates nationwide data of patients with *de novo* MBC and a large cohort of patients with metachronous MBC diagnosed in 2008-2018 in the Netherlands, to compare clinicopathological characteristics, treatment and survival.

## PATIENTS AND METHODS

### Data source

The Netherlands Cancer Registry (NCR) is a nation-wide cancer registry hosted by the Netherlands Comprehensive Cancer Organisation (IKNL) and includes all patients with newly diagnosed cancer, with an estimated coverage of 96%<sup>[40]</sup>. Cancer diagnoses are notified through the nationwide Pathology Archive (PALGA) and the National Registry of Hospital Discharge Diagnoses. Trained data managers register data on diagnosis, clinicopathological characteristics and primary treatment directly from the patient files. Tumour location and morphology are coded according to the International Classification of Diseases for Oncology (ICD-O, third edition) and tumour stage is coded following the Tumor Node Metastasis (TNM) classification. Estrogen receptor (ER) and Progesterone receptor (PR) positivity of the primary tumour are set at  $\geq 10\%$  according to Dutch nationwide guidelines. Additional data on recurrences (including local, regional recurrences and distant metastases) were collected by the NCR retrospectively. Specifically, for patients with a primary diagnosis in 2003 and 2005 all recurrences up to 10 years after initial breast cancer diagnosis were identified. In addition, for half of the patients diagnosed in 2008, the first recurrence up to 5 years afterwards was identified and for patients diagnosed in the first quartile of 2012 (Q1 2012), all recurrences up to 5 years after diagnosis were recorded (**Fig. 1**). Recurrence locations were also registered following the ICD-O third edition. After diagnosis of metastases, the first systemic and/or local treatment is registered. Information on vital status was derived from the official municipal population database.

### Patient selection

All patients diagnosed with *de novo* MBC between 2008 and 2018, as well as registered patients diagnosed with distant metachronous metastases between 2008-2018 were selected from the NCR. Patients with distant metastasis within 3 months of the primary diagnosis were excluded, because they are often considered as *de novo* MBC. For the survival analyses we excluded a small group of patients ( $n = 333$ , 3.0%) with tumour morphologies other than ductal carcinoma NOS or invasive lobular carcinoma (ILC). Moreover, we excluded patients from the survival analyses who had not received systemic therapy in the metastatic setting, because untreated patients likely have severe comorbidities and inherently have a different prognosis. Moreover, knowledge about patients eligible for systemic treatment can support medical oncologists' clinical decision making.

### Data definition

Patient characteristics (age at diagnosis of metastasis, sex, performance status), primary tumour characteristics (morphology, multifocality, tumour grade, clinical T stage, receptor

and HER2 status), clinical N stage at primary diagnosis and location of metastases and treatment (local and systemic therapy after diagnosis of primary tumour and metastases) were analysed. Receptor and HER2 status of the metachronous metastases were not available. Period of metastasis diagnosis was categorized in 2008-2011, 2012-2015 and 2016-2018. Within metachronous MBC, metastasis free interval (MFI), defined as time between primary diagnosis and distant recurrence, was categorized in 3-12 months, 12-24 months, 24-60 months and MFI > 60 months. OS was analysed using time between diagnosis of distant metastasis and death or end of follow-up. If patients were alive at the end of follow-up (January 31<sup>st</sup> 2022), they were censored.

### Statistical analysis

Descriptive statistics were used to depict clinicopathological and treatment characteristics and to describe missing data. Chi-squared tests or Fisher's exact tests were used to test difference in characteristics between *de novo* and metachronous MBC. To describe OS of the groups, Kaplan Meier curves were plotted and multivariable Cox proportional hazards (PH) analyses were performed including important confounders. Because some confounders included missing data, we used multiple imputation by chained equations (MICE)[41]. Data were incomplete for any of the chosen variables in 19% of patients, therefore we considered 19 simulated datasets to have a sufficiently reliable estimation of missing values[42, 43]. The imputation model included MFI, which was used to categorize *de novo* versus metachronous MBC, and the following confounders: year of metastasis diagnosis; sex; age at metastasis diagnosis; tumour morphology; tumour multifocality; clinical T stage; clinical N stage; receptor status; metastasis location; tumour grade; performance status (assessed at primary diagnosis) and therapy variables, plus the outcome variables (vital status and the Nelson-Aalen estimator) as was recommended in literature[44-47].

The multivariable Cox PH model comparing survival of patients with *de novo* and metachronous MBC included the same variables included in the imputation model, except for tumour grade and performance status, which were considered confounders but contained too many missings. For the variable 'age at metastasis diagnosis' we used a restricted cubic spline with four knots. We also excluded therapy variables for several reasons. First, therapy choices are partly determined by the variable of interest (*de novo* versus metachronous MBC influences therapy choices) and are therefore not a confounder but an intermediary variable. Second, specifically in *de novo* MBC a RCT reported that local therapy of the primary tumour did not improve OS [10, 11], so local therapy is not a confounder either. Likelihood ratio tests of Cox PH models were used to compare OS between the groups. The PH assumption is the most important assumption underlying the Cox model [48]. The assumption was tested for each variable included in the Cox model using Schoenfeld residuals plots [49]). Confounding variables that did not meet the PH assumption were added as strata to the model. For the variable

of interest (*de novo* versus metachronous MBC), we visualised the time-varying effect of the hazards by plotting the hazard ratio (HR) against time. For this purpose, we generated a time dependent Cox model with an interaction between the variable (*de novo* vs metachronous) and a restricted cubic spline of survival time with five knots [50]. This time dependent model was based on one imputation dataset.

In addition to the described analyses we performed supplementary analyses to study patients with *de novo* and metachronous MBC separately in more detail, to test the robustness of our results and to explore hypotheses behind the differences in OS (Supplementary methods 1).

A p-value <0.05 was considered significant.

Statistical analyses were performed in Stata/SE 17.0 and R version 4.0.3.

## RESULTS

### Clinicopathological characteristics

Between 2008-2018, 8,656 patients were diagnosed with *de novo* MBC in the Netherlands. In addition, 2,374 patients were identified with metachronous MBC, of those, 639 had a primary tumour diagnosed in 2003, 1,006 in 2005, 524 in 2008 and 205 in Q1 of 2012.

**Table 1** lists patient, tumour and treatment characteristics in patients with *de novo* and metachronous MBC. Most notable differences were those in T and N stages, metastasis locations and receptor status. Patients with *de novo* MBC were more likely than metachronous to have T3 or T4 tumours and positive loco-regional lymph nodes, while the majority (68%) of metachronous MBC had N0 at time of primary diagnosis. Notably, *de novo* metastases were more commonly limited to the bone with less frequent involvement of the liver or central nervous system (CNS) than in metachronous disease. However, in young *de novo* patients ( $\leq 40$  years,  $n=489$ ) we saw more liver metastases (39%, versus 25% in *de novo* patients of all ages and 38% in young metachronous patients). CNS involvement was the same (3%) in *de novo* patients above or below 40 years of age. ER-negative/HER2-negative tumours were observed less in *de novo* MBC. Although ER positivity did not differ between *de novo* patients and the entire group of metachronous MBC, supplementary analyses showed that ER-positive (HER2 negative/unknown) tumours were more common in patients with metachronous MBC with a MFI > 60 months (83%), while patients with shorter MFI's had less ER positive tumours (39 to 65%) than patients with *de novo* MBC (67%) (supplementary table 1). Supplementary table 2 shows changes in patients with *de novo* MBC over time.

**Treatment characteristics**

Local treatment of the primary breast tumour was performed in 26% of patients with *de novo* MBC, in 43% consisting of surgery combined with radiotherapy, and in all patients with metachronous MBC at initial diagnosis. 74% of patients with metachronous metastases had received systemic treatment after primary tumour diagnosis.

Systemic therapy for metastatic disease was administered in 89% of *de novo* and in 79% of metachronous stage IV patients. Chemotherapy (without HER2 targeting agents) was administered less often to patients with *de novo* MBC (24% vs 29%) (**Table 1**). Meanwhile, *de novo* ER positive patients received endocrine treatment more often (67% vs 48%) and *de novo* HER2 positive patients received HER2 targeted therapy more often (75% vs 41%). Radiotherapy was the preferred locoregional treatment in *de novo* patients while surgery was more common in metachronous patients.

Supplementary table 2 shows changes in treatment of patients with de novo MBC over time, these changes could not reliably be compared between de novo and metachronous MBC due to the method of registration for patients with metachronous metastases (from just four primary tumour years, **Fig. 1.**).

**Fig. 1 Selection of patients with metachronous metastatic breast cancer.** Patients diagnosed with metachronous distant metastases in 2008-2018 were identified among patients diagnosed with primary tumours in 2003, 2005, 2008 and the first quartile of 2012 (Q1 2012). For patients with a primary diagnosis in 2003 and 2005 all recurrences up to 10 years after initial breast cancer diagnosis were identified. For half of the patients with a primary diagnosis in 2008 the first recurrence up to 5 years after initial diagnosis was identified. For patients diagnosed in the first quartile of 2012, all recurrences up to 5 years post diagnosis were identified. Blue circles indicate primary tumour diagnosis, green filled stars indicate a possible diagnosis of distant metastasis included in our study. Empty stars indicate a possible diagnosis of distant metastasis that was not included in our study because it was outside the study period (green) or because it was not registered (red).

**Survival in de novo versus metachronous MBC**

Among patients treated with systemic therapy in the metastatic setting, median OS in patients with metachronous MBC was 24.3 months (95% CI 22.5 – 25.5 months), compared to 34.7 months (95% CI 33.7-35.8 months) in those with *de novo* MBC (Log-rank test  $p < 0.001$ ) (**Fig. 2**). In the multivariable Cox PH analysis a difference in OS between *de novo* and metachronous MBC persisted (HR *de novo* MBC versus metachronous MBC 0.75, 95% CI 0.70-0.80, Likelihood ratio test  $p < 0.001$ ) (**Table 2**). Sensitivity analysis supported these findings when analysing complete cases and showed that within patients with metachronous MBC, patients with a longer MFI survived longer, although still not similar to patients with *de novo* MBC (Supplementary: fig 1, table 3, and table 4). **Figure 3** shows the changes in HR of patients with *de novo* versus metachronous MBC over time, while keeping all other variables constant. Although the HR varied over time, *de novo* MBC appeared to have a lower risk of death than metachronous MBC over the

entire period of follow-up. The difference is most pronounced two years after diagnosis of metastatic disease. Beyond approximately eight years the HR estimate becomes increasingly imprecise.

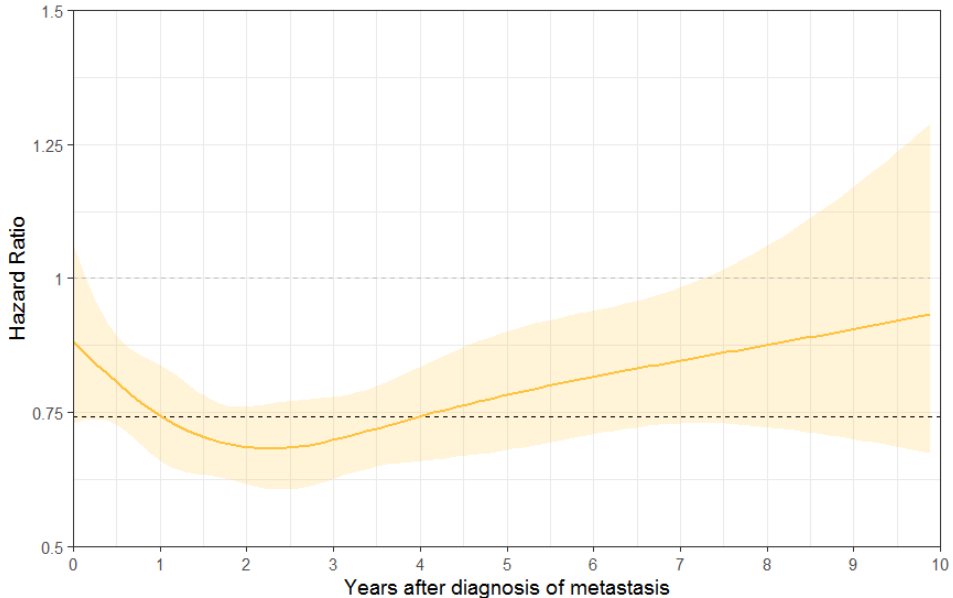

Further exploratory analysis showed that *de novo* MBC is not always associated with longer survival. In fact, patients with metachronous MBC who had not received previous (neoadjuvant or adjuvant) systemic treatment following their primary tumour diagnosis (n=461) survived longer than patients with *de novo* MBC (median OS 37.2 months, multivariable HR *de novo* MBC 1.13, 95% CI 1.01- 1.27) (Supplementary fig. 3 and table 6). Note that these were patients with favourable characteristics at primary tumour diagnosis, nearly all (97%) had T1 (75%) or T2 (22%) and 74% was ER positive and HER2 negative or unknown.

**Fig. 2 Overall survival in patients with *de novo* versus patients metachronous metastatic breast cancer (treated with systemic therapy in the metastatic setting).** The 95% confidence interval is indicated by colour around the line, number of patients at risk is noted below each year of follow-up. Overall survival is significantly longer in *de novo* MBC patients compared to metachronous MBC patients

**Table 2** Multivariable Cox proportional hazards analysis *de novo* versus metachronous MBC patients (treated with systemic therapy in metastatic setting). Multiple imputation was used before multivariable analysis. Stratification was performed for receptor status and localization of metastasis.

**Fig. 3 Overall survival in patients with *de novo* versus metachronous metastatic breast cancer (treated with systemic therapy in the metastatic setting), hazard ratio over time in multivariable analysis performed on the first multiple imputed dataset.** The 95% confidence interval is indicated by colour around each line. The difference in overall survival was not proportional over time, with a lower HR in favour of *de novo* MBC in the first years of follow-up in the multivariable model, while the HR starts to rise towards 1.0 after about 5 years. Note that the confidence interval widens after about eight years

## DISCUSSION

In this large population-based study, we compared clinicopathological features, treatment and OS between all patients with *de novo* MBC diagnosed in the Netherlands between 2008 and 2018 to a group of patients with metachronous MBC diagnosed in that same period. Our study shows that these are not only two very distinct groups but also that patients with *de novo* MBC survive longer.

A number of differences in characteristics between the groups are notable. Our data corroborate earlier reports of frequent bone and lymph node metastases and less involvement of viscera and brain in patients with *de novo* MBC [4, 30, 31]. However, in our comparison of both groups, we did not observe more ER positive tumours in *de novo* patients [28], most likely caused by the 43% of metachronous patients with a MFI >60 months, who are more often ER positive. Stage T3 and T4 and multifocal tumours were more often encountered in patients with *de novo* MBC, possibly reflecting delay in time to diagnosis. In *de novo* MBC, metastases limited to the bone were more common than in metachronous MBC resulting in increased use of endocrine treatment in this group, as was local radiotherapy on painful bone metastases [5]. The higher prevalence of triple

negative tumours, liver and CNS metastases reflect unfavourable tumour characteristics and biology in metachronous patients. For example, triple negative tumours are known to metastasize hematogenously more often.

Regarding outcome, our data support a better OS in *de novo* MBC compared to patients with metachronous MBC, partly explained by differences in disease characteristics. Even after correction for known confounding characteristics, improved survival persists in patients with *de novo* MBC. This finding is consistent with previous literature [4, 21, 28, 30, 33-35] showing that absolute differences in median OS range from 1.5 months (when comparing *de novo* to MFI > 24 months) to 20.3 months (comparing to MFI < 24 months) [31]. Without selection for MFI the reported median OS differences are similar to the 10.4 months found in our study [28, 30, 32, 33]. In our sensitivity analysis we found a similar effect of MFI on OS compared to the literature: longer MFI was associated with longer OS after diagnosis of metastases. However, even MFI > 60 months did not have better survival than *de novo* MBC, which is not a consistent observation [21, 31, 34].

There are a number of possible explanations for the longer survival observed in *de novo* MBC. The most likely hypothesis is that shorter survival of patients with metachronous MBC is related to previous (neo)adjuvant systemic therapies. Recurrence despite previous therapy could reflect 1) disadvantageous tumour-characteristics, 2) patient comorbidity / fitness and 3) primary or acquired therapy resistance. In our study, we could not quantify to what extent these factors played a role because we did not have data on the exact regimens and duration of systemic therapy nor could we account for fitness because data on performance score was only assessed at primary breast cancer diagnosis and contained too many missing values to include in the model. Nevertheless, the difference in use of systemic therapy in the metastatic setting (any systemic therapy in 89% of *de novo* and 79% of metachronous MBC and specifically targeted therapy in 75% of *de novo* and 41% of metachronous HER2 positive patients) may indicate that metachronous patients were less fit or had less treatment options for other reasons. As mentioned before, previous therapy can decrease treatment options in the metastatic setting due to acquired resistance to a drug, reaching a maximum tolerated cumulative dose or lasting side effects such as peripheral neuropathy or cardiotoxicity. Of note, due to the method of registration our data on systemic therapy could be an underestimation, as therapies administered not directly after metastasis diagnosis, but for example when symptoms did arise, may have been missed. In addition, the difference in targeted therapy among HER2 positive patients could be an overestimation because HER2 status was determined on the primary tumour and (a small percentage of) metachronous patients may have converted to HER2 negative. The same might be true for endocrine treatment, as metastases of an ER positive primary may be ER negative.

Still, we did find some evidence to corroborate the hypothesis that previous systemic therapy plays a role in the survival difference between *de novo* and metachronous MBC. In a supplementary exploratory analysis we observed a longer OS among patients with

metachronous MBC who were not systemically treated for their primary tumour. While this metachronous group had favourable characteristics at primary tumour diagnosis, the difference remained after correcting for baseline characteristics.

We also hypothesize that differences in metastatic burden could contribute to the observed differences in survival. Possibly, clinicians are inclined to perform more (and perhaps more sensitive) diagnostic imaging in a patient presenting with *de novo* MBC than in those diagnosed with recurrent disease. This would lead to detection of smaller, asymptomatic or oligo metastases in *de novo* MBC, associated with longer survival and possibly even curative treatment options. Although we have no data on number or volume of metastases, our data do support this hypothesis (Supplementary table 2) as we saw an increase in patients with *de novo* distant metastases limited to lymph nodes and increased use of anthracycline and taxane treatment (first choice in the neoadjuvant curative setting [5] and used for curative treatment of oligometastases).

In this study we extensively studied OS of patients with *de novo* and metachronous MBC using Kaplan Meier curves and Cox PH analysis. In the literature it is seldom reported whether the PH assumption was met and time-varying effects are often overlooked[51]. In our study, the variable of interest (*de novo* versus metachronous MBC) did not meet the PH assumption and therefore we additionally estimated the time-varying effects on OS. Overall, it appeared that the OS difference between *de novo* and metachronous MBC persisted over the years. The relatively small difference in OS between *de novo* and metachronous MBC in the first year could mean that a group of patients progress and die quickly despite any beneficial characteristic. Apparently, differences between *de novo* and metachronous MBC start to count after surviving longer than a year.

This study is unique as it presents a complete overview of patients with *de novo* MBC diagnosed in 2008 - 2018 in the Netherlands and the comparison to patients with metachronous MBC. The data convincingly shows that patients with *de novo* and metachronous MBC are distinct patient groups.

However, there are some limitations of our data. It would be relevant to also study metachronous patients in more detail using nationwide data. The MFI of our patients was probably not an accurate representation of all patients with metachronous MBC in 2008-2018 because the majority of metachronous patients in our cohort had their initial diagnosis in 2003 or 2005 (thus MFI at least 5 or 3 years respectively) (**Fig. 1**). Another limitation is that for patients with an initial diagnosis in 2008, distant metastases were only registered if they did not have a local or regional recurrence preceding the occurrence of metastases. Due to this registration difference, we probably missed approximately 20% of patients with metachronous MBC and an initial diagnosis in 2008 (i.e. of patients with a primary tumour in 2003/2005/Q1 2012, about 20% had a local or regional preceding their distant metastases). Additional patients were missed because recurrences from 2008 had only been registered in half of the hospitals. Nationwide data including all patients with metachronous metastases in a given period would

have allowed a more accurate comparison of the two groups. Ideally, such data would also include information on metastatic burden (e.g. oligometastases), receptor and HER2 status of the metastases and information about treatment administered in the metastatic setting in more detail and beyond those given as initial therapy.

## CONCLUSION

Dutch patients with *de novo* MBC survive longer compared to patients with metachronous metastases, also following correction for different clinicopathological characteristics. Our data show that *de novo* and metachronous MBC represent two distinct groups, the presence of a primary tumour being not the only difference.

## ETHICS AND DISSEMINATION

The datasets generated and/or analysed during the current study are not publicly available due to privacy reasons but are available from the Netherlands Cancer Registry on reasonable request.

This study was approved by the Netherlands Cancer Registry's Supervisory Committee (reference number K19.155).

## AUTHOR CONTRIBUTIONS

All authors contributed to the study conception and design. Josanne de Maar and Marianne Luyendijk contributed equally. Material preparation, data collection and analysis were performed by Josanne de Maar and Marianne Luyendijk. The first draft of the manuscript was written by Josanne de Maar and revised by Marianne Luyendijk and all authors commented on previous versions of the manuscript. All authors read and approved the final manuscript.

## FUNDING

The authors declare that no funds, grants, or other support were received during the preparation of this manuscript.

## ACKNOWLEDGEMENTS

The authors thank the registration team of the Netherlands Comprehensive Cancer Organisation (IKNL) for the collection of data for the Netherlands Cancer Registry as well as IKNL staff for scientific advice. We thank Peter Zuithoff of the Julius Center for his statistical advice in the early stages of the project and we thank Linda McPhee for her helpful writing comments.

## CONFLICTS OF INTEREST

The authors declare that they have no relevant financial or non-financial interests to disclose.

SUPPLEMENTARY MATERIALS

**Supplementary methods 1** Methods used for supplementary analyses

In addition to the above described analyses we performed supplementary analyses in order to study patients with *de novo* and metachronous MBC separately in more detail, to test the robustness of our results and to explore hypotheses behind the differences in OS.

First, differences in clinicopathological characteristics were described between patients with *de novo* MBC diagnosed in different periods, and between patients with metachronous MBC with different MFIs. Next, to study whether OS of patients with *de novo* MBC has improved over time, a multivariable Cox PH analysis among patients with *de novo* MBC was performed to compare OS in different periods of diagnosis. In this Cox model, the same variables were included, but additionally therapy variables (local treatment of the primary tumour; type of first systemic therapy in the metastatic setting; surgery of metastases and radiotherapy of metastases) were included and additional strata were added for local therapy of the primary tumour and type of first systemic therapy in the metastatic setting.

As sensitivity analysis, the multivariable Cox PH analysis comparing *de novo* and metachronous MBC was repeated on the complete cases (n= 7774), to see what the effect of multiple imputation had been. Moreover, an additional multivariable Cox PH analysis was performed to compare OS between patients with *de novo* MBC and patients with metachronous MBC with different MFIs.

In an exploratory analysis we evaluated the OS of patients with *de novo* MBC compared to patients with metachronous MBC who had not received systemic treatment for their primary breast cancer diagnosis. Objective of this analysis was to explore whether the survival difference between *de novo* and metachronous MBC might be related to previous systemic treatment in metachronous MBC.

**Supplementary fig. 1** Overall survival in patients with metastatic breast cancer (treated with systemic therapy in the metastatic setting), according to metastasis-free interval.

**Supplementary fig. 2** Overall survival in patients with *de novo* metastatic breast cancer (treated with systemic therapy), according to period of diagnosis

**Supplementary fig. 3** Overall survival in patients with *de novo* versus metachronous metastatic breast cancer (treated with systemic therapy in the metastatic setting), these metachronous patients were not treated with systemic therapy at the time of their primary tumour

**Supplementary table 1** Descriptive statistics patients with metachronous metastatic breast cancer: comparison by metastasis-free interval

STUDY PROTOCOL OF THE I-GO STUDY, A  
PHASE I FEASIBILITY STUDY OF MAGNETIC  
RESONANCE GUIDED HIGH-INTENSITY FOCUSED  
ULTRASOUND-INDUCED HYPERTHERMIA, LYSO-  
THERMOSENSITIVE LIPOSOMAL DOXORUBICIN  
AND CYCLOPHOSPHAMIDE IN *DE NOVO* STAGE IV  
BREAST CANCER PATIENTS.

## ABSTRACT

### Introduction

In breast cancer, local tumour control is thought to be optimized by administering higher local levels of cytotoxic chemotherapy, in particular doxorubicin. However, systemic administration of higher dosages of doxorubicin is hampered by its toxic side effects. In this study, we aim to increase doxorubicin deposition in the primary breast tumour without changing systemic doxorubicin concentration and thus without interfering with systemic efficacy and toxicity. This is to be achieved by combining lyso-thermosensitive liposomal doxorubicin (LTLD, ThermoDox®, Celsion Corporation, Lawrenceville, NJ, USA) with mild local hyperthermia, induced by Magnetic Resonance guided High Intensity Focused Ultrasound (MR-HIFU). When heated above 39.5 °C, LTLD releases a high concentration of doxorubicin intravascularly within seconds. In absence of hyperthermia, LTLD leads to a similar biodistribution and antitumour efficacy compared to conventional doxorubicin.

### Methods and analysis

This is a single-arm phase I study in 12 chemotherapy-naïve patients with *de novo* stage IV HER2-negative breast cancer. Previous endocrine treatment is allowed. Study treatment consists of up to 6 cycles of LTLD at 21-day intervals, administered during MR-HIFU induced hyperthermia to the primary tumour. We will aim for 60 minutes of hyperthermia at 40-42 °C using a dedicated MR-HIFU breast system (Profound Medical, Mississauga, Canada). Afterwards, intravenous cyclophosphamide will be administered. Primary endpoints are safety, tolerability and feasibility. The secondary endpoint is efficacy, assessed by radiological response.

This approach could lead to optimal loco-regional control with less extensive or even no surgery, in *de novo* stage IV patients and in stage II/III patients allocated to receive neo-adjuvant chemotherapy.

### Ethics and dissemination

This study has obtained ethical approval by the Medical Research Ethics Committee Utrecht (Protocol NL67422.041.18, METC number 18-702). Informed consent will be obtained from all patients before study participation. Results will be published in an academic peer-reviewed journal.

### Trial registration number

NCT03749850, EudraCT 2015-005582-23.

Synchronous stage IV breast cancer  
Metastatic breast cancer

**Strengths and limitations**

- This first in human clinical trial investigates the combination of Lyso-Thermosensitive Liposomal Doxorubicin and Magnetic Resonance guided High Intensity Focused Ultrasound induced hyperthermia in breast cancer patients.
- A dedicated MR-HIFU breast system with real-time MR temperature feedback will be used for safe non-invasive local hyperthermia treatment of breast tumours.
- Because the study population consists of patients with *de novo* stage IV breast cancer, both local and systemic response to the treatment can be monitored.
- A survival benefit of treating the primary tumour in patients with metastatic breast cancer has not been proven, therefore study participants will participate altruistically in the interest of future patients.
- This approach could lead to improved local control during palliative chemotherapy in *de novo* stage IV breast cancer or neoadjuvant chemotherapy in stage II/III disease, with less extensive or even no surgery.

## INTRODUCTION

Both neo-adjuvant and adjuvant chemotherapy of breast cancer aim to improve survival by eradicating microscopic distant metastases. In addition, neo-adjuvant treatment offers the opportunity to observe the biological behaviour of the primary tumour and increase the likelihood of less extensive radical (breast conserving) surgery. Given the fact that pathological complete response (pCR) is achieved at best in 68% of patients [1], efforts should be focused on improving primary tumour response. This may be achieved by increasing the dose of chemotherapy at the site of the tumour. In pre-clinical data, a higher concentration of chemotherapy in the tumour is correlated with increased tumour response, in particular for doxorubicin, one of the most frequently applied cytostatics in breast cancer treatment [2-4]. Clinically this was confirmed by studies using other chemotherapeutics, i.e. 5-fluorouracil and docetaxel. Higher tumour uptake of radioactive labelled 5-fluorouracil or docetaxel chemotherapy on PET was shown to correlate respectively with longer survival in patients with liver metastasis of colorectal carcinoma [5] and with better tumour response in lung cancer patients [6]. In a study comparing different dose schedules of the adjuvant AC regimen, the highest dosages (60mg/m<sup>2</sup> doxorubicin and 600mg/m<sup>2</sup> cyclophosphamide) were most effective, and this is currently the standard of care [7]. However, the administration of higher doses of doxorubicin is hampered by its systemic side effects. A randomized study evaluating even higher doxorubicin dosages (60mg/m<sup>2</sup> versus 75mg/m<sup>2</sup> and 90 mg/m<sup>2</sup>) did not find a difference in disease-free or overall survival. However, the higher dose levels did lead to significantly more dose reductions and delays, which could explain why the efficacy did not increase further [8]. In the i-GO study we aim to increase doxorubicin levels in the primary tumour, without interfering with systemic efficacy and toxicity, by combining lyso-thermosensitive liposomal doxorubicin (LTLD, ThermoDox®; Celsion Corporation, Lawrenceville, NJ, USA) with mild local hyperthermia, induced by Magnetic Resonance guided High Intensity Focused Ultrasound (MR-HIFU). This will be followed by the intravenous administration of a second cytostatic agent, cyclophosphamide. The combined administration of doxorubicin and cyclophosphamide (AC) is a well-known regimen in the standard of care treatment in both the (neo-) adjuvant setting as in the treatment of metastatic breast cancer.

The i-GO study will be a phase I feasibility study in stage IV breast cancer patients who present with distant metastases and a primary tumour in situ (*de novo* stage IV patients). Several studies have suggested that by obtaining loco-regional control in metastatic breast cancer, overall survival in advanced disease would be improved [9-11] However, randomized controlled trials have contradicted this [12, 13] A recent presentation at ASCO 2020 [14] confirmed that local treatment in addition to systemic therapy did not improve survival. As such, besides a personal preference of the patient and the possibility of preventing local morbidity, study participation will not have a benefit compared to the standard of care. However, based on pharmacokinetic studies (details outlined in Supplementary materials

1) we do expect at least an equally effective treatment. Study participants will participate altruistically in the interest of future patients in the neoadjuvant setting. In the future, the combination of LTLD, MR-HIFU hyperthermia, and cyclophosphamide may lead to improved local control during neoadjuvant chemotherapy in stage II/III disease, with less extensive or even no surgery.

### Lyso-thermosensitive liposomal doxorubicin

LTLD is a temperature-sensitive liposomal encapsulation of doxorubicin. Doxorubicin is a cytotoxic (chemotherapy) agent that is approved and frequently used for the treatment of a wide range of cancers, including breast cancer. When heated to 40-42 °C, LTLD releases the encapsulated doxorubicin intravascularly within seconds [15-17]. (Figure 1.) In small animal tumour models, LTLD combined with hyperthermia results in a 3-25 fold higher tumour concentration than conventional doxorubicin [2, 18-22] and increased antitumour efficacy [2, 16, 18]. In the absence of hyperthermia, doxorubicin leaks slowly from the liposome, and after two hours all of the doxorubicin is released [15]. Furthermore, LTLD without hyperthermia leads to a similar biodistribution [19, 20] and antitumour efficacy [16, 18] compared to conventional doxorubicin.

**Figure 1** The concept of LTLD combined with MR-HIFU hyperthermia for local drug delivery in the primary breast tumour. The patient is lying in prone position on the dedicated MR-HIFU breast system under procedural sedation and analgesia, with the breast hanging in the water-filled cup. HIFU-induced hyperthermia is administered to the tumour for 60 minutes. Real-time MR thermometry (screen on the right) allows for precise control of the target temperature of 40-42 °C in the tumour. After intravenous infusion, LTLD circulates through the vasculature and releases a small amount of doxorubicin at 37°C. However, when LTLD reaches the heated tumour it releases a high amount of doxorubicin intravascularly within seconds. We hypothesize that the combination of LTLD and MR-HIFU hyperthermia will increase the tumour concentration of doxorubicin without interfering with systemic treatment efficacy and toxicity.

### **Magnetic resonance-guided high intensity focused ultrasound**

MR-HIFU is a truly non-invasive treatment modality, that combines magnetic resonance imaging (MRI) and high intensity focused ultrasound to perform image-guided thermal tissue ablation (55-70 °C) [23-25] or mild local hyperthermia (40-43 °C) [26-28]. Unlike other heating methods, using microwaves, radiofrequency or non-focused ultrasound, HIFU allows for non-invasive localized heating of deep-seated tumours [29]. In addition to treatment planning based on anatomical MRI, MR-guidance can provide temperature feedback and control during hyperthermia treatment, through real-time MR thermometry. For this study we will use a dedicated MR-HIFU breast system: the Sonalleve MR-HIFU breast tumour therapy system (hereafter referred to as 'MR-HIFU breast system', Profound Medical, Mississauga, Canada), integrated with a clinical 1.5 Tesla MR scanner (Achieva, Philips Healthcare, Best, The Netherlands). This system has a lateral sonication approach, which enables specific heating of the breast tumour, while reducing the risk of heating the skin or other organs to a minimum [30]. A phase I study in our hospital with MR-HIFU ablation of breast tumours showed that the MR-HIFU breast system allows for safe, accurate and precise thermal ablation [31, 32].

### **Previous clinical studies**

This will be the first-in-human study to evaluate LTLD with MR-HIFU hyperthermia in breast cancer patients. LTLD has been studied previously in combination with superficial hyperthermia in patients with chest wall recurrences of breast cancer [33]. This phase I/II study showed that LTLD at 40 mg/m<sup>2</sup> with superficial hyperthermia was safe and the 48% overall response (14/29, 95% CI:30–66%) was promising in this heavily pre-treated population. A large randomized phase III study in 701 patients with hepatocellular carcinoma compared LTLD at 50 mg/m<sup>2</sup> with radiofrequency ablation (RFA) to RFA alone (the HEAT study) [34, 35]. In that study the primary endpoint of 33% improvement in progression free survival was not met. However, a post-hoc analysis in the subgroup of 285 patients with solitary lesions that were treated with ≥45 min of RFA showed a significant overall survival benefit for the combination treatment (Hazard Ratio for Overall Survival 0.63 (95% CI, 0.41–0.96; P < 0.05), in favour of RFA+LTLD with ≥45 minutes heating). Systemic adverse events increased in the RFA+LTLD arm (83% vs 35% with RFA alone) as expected, with a similar profile to that of conventional doxorubicin [35].

Furthermore, the combination of LTLD and ultrasound guided HIFU hyperthermia has been evaluated in a phase I proof-of-concept study in ten patients with incurable primary or metastatic liver tumours (the TARDOX study) [36, 37]. Adverse events did not differ from those associated with doxorubicin alone and in the group of patients that underwent invasive thermometry sufficient mean tumour temperatures were measured. In seven out of ten patients, the intratumoural doxorubicin concentration doubled after HIFU, although a within-patient comparison was not possible for all patients. We aim to take advantage of the same principle to treat the primary tumour in patients presenting with metastatic

breast cancer. Monitoring the treatment by MR thermometry may further enhance safety, efficacy and feasibility. Using multiple cycles of LTLD + MR-HIFU hyperthermia is expected to increase treatment efficacy and mimics the standard of care treatment.

## METHODS AND ANALYSIS

This single-arm phase I feasibility study aims to determine the safety, tolerability and feasibility of the combination of LTLD, MR-HIFU induced mild local hyperthermia, and cyclophosphamide, for the enhanced local treatment of the primary tumour in patients presenting with metastatic breast cancer. All eligible participants will receive up to 6 cycles of LTLD at 21-day intervals, administered during MR-HIFU induced hyperthermia to the primary tumour and cyclophosphamide administered afterwards.

### Patient population

We will include 6 or 12 adult female patients with *de novo* stage IV (distant metastases at the time of diagnosis, with the primary tumour in situ) HER2-negative breast cancer, who have not received previous chemotherapy for their disease. Previous endocrine treatment in those with hormone-receptor positive disease is allowed. The small samples size was chosen because this is the first study evaluating the combination of MR-HIFU hyperthermia, LTLD and cyclophosphamide. No formal sample size calculation was performed. Potentially eligible patients will be referred to the department of Medical Oncology at the University Medical Center Utrecht, The Netherlands. In order to achieving adequate participant enrolment, medical oncologists in hospitals in the Netherlands will be asked to refer potentially eligible and interested patients.

### Inclusion criteria

Patients must meet all of the following inclusion criteria:

- Histologically confirmed adenocarcinoma of the breast and planned for palliative chemotherapy with doxorubicin and cyclophosphamide.
- Biopsy-proven stage T1-2AnyNM1 at diagnosis of breast cancer.
- Measurable disease according to either RECIST 1.1 or PERCIST 1.0 at baseline.
- Non-pregnant, non-lactating female at least 18 years of age. If the patient is of child-bearing age, she must have a negative serum pregnancy test prior to enrolment and must agree to practice an acceptable form of birth control while on study.
- The tumour is located within the reach of the HIFU beam (based on pre-treatment dynamic contrast-enhanced (DCE-) MRI findings).
- The distance of the tumour from the skin, nipple, and pectoral wall is at least 1.0

- cm (based on pre-treatment DCE-MRI findings).
- The target breast is expected to fit in the cup of the MR-HIFU breast system (based on pre-treatment MRI findings).
- The patient is able to provide written informed consent and willing to comply with protocol requirements.

### Exclusion criteria

Patients will be excluded if any of the following conditions are observed:

- HER2-positive disease or classic invasive lobular carcinoma (ILC).
- A treatment plan with curative intent is available.
- Any prior chemotherapy treatment for invasive breast cancer (previous anti-hormonal therapy is allowed).
- Any prior therapy with anthracyclines.
- The patient weighs  $\geq 90$  kg (restriction of the HIFU table top).
- Any concomitant malignancy or previous malignancy in the last 5 years, except basal cell or squamous cell cancer of the skin or in situ carcinoma of the cervix. Subjects with a prior contralateral breast malignancy more than 5 years ago can be included if they did not receive any chemotherapy.
- Any previous malignancy in the unilateral breast (even if more than 5 years ago)
- Prior sensitivity (including rash, dyspnoea, wheezing, urticarial, or other symptoms) attributed to any liposomal-encapsulated drug.
- Baseline laboratory values:
 

Absolute Neutrophil Count (ANC)	< $1.5 \times 10^9/L$
Platelets	< $75 \times 10^9/L$
Haemoglobin	< 5.6 mmol/L (transfusion is allowed)
Total Bilirubin	> 1.5 times upper limit of normal
Alanine Transaminase (ALAT) and Aspartate Transaminase (ASAT)	> 2.5 times upper limit of normal
	>5 times upper limit of normal in case of liver metastases
- Estimated Glomerular Filtration Rate < 30 ml/min/1.73m<sup>2</sup>
- World Health Organization Performance Status (WHO-PS) >2.
- Left Ventricular Ejection Fraction <50% (validated by baseline scan).
- History of: acute coronary syndrome in the last year, cerebral vascular accident in the last year, abnormal cardiac stress testing within the last six months, symptomatic coronary artery disease, uncontrolled hypertension or cardiomyopathy, cardiac valvular surgery or open-heart surgery in the last year or known structural heart disease.
- Any condition which may interfere with the hyperthermia portion of the trial such as: functioning cardiac pacemaker; metal plates, rods or prosthesis of the chest

wall, breast prosthesis in the treated breast, severe numbness and/or tingling of the chest wall or breast, skin grafts and/or flaps on the breast or chest wall, scar tissue or surgical clips in the HIFU beam path.

- Active infection.
- Body temperature > 38.0 degrees Celsius on the day of a MR-HIFU treatment.
- Concurrent use of any of the following prohibited medications within a reasonable wash-out time: protease inhibitors, cyclosporine, carbamazepine, phenytoin, valproic acid, paclitaxel, trastuzumab and other liposomal drugs (Abelect™, Ambisome™, Nyotran™, etc.) or lipid-complexed drugs. Caution will be exercised with medications, dietary components and herbal supplements that affect CYP2A4, CYP2D6 or P-gp or have been described to interact with doxorubicin in other ways.
- Contraindications to MR imaging (e.g., pacemaker in situ, severe claustrophobia, metal implants incompatible with the MRI-scan, body size incompatible with MR bore).
- Contraindications to gadolinium-based contrast agents and the tumour is not sufficiently visible on MRI without contrast (including prior allergic reaction to gadolinium-based contrast agent, and/or renal failure).
- Contraindications to sedation and analgesia with Propofol and Remifentanyl, including history of Chronic Obstructive Pulmonary Disease (COPD) that results in the inability to perform a physical activity corresponding with a Metabolic Equivalent (MET(57)) of 4; dependence on artificial ventilation at home; sleep apnoea or an American Society of Anaesthesiologists (ASA) classification  $\geq 4$ .
- Inability to lie in prone position.
- A medical or psychiatric condition or other circumstances which would significantly decrease the chances of understanding the informed consent process, obtaining reliable data, achieving study objectives, or completing the study treatment and/or examinations.

### Endpoints

Primary endpoints are safety, tolerability and feasibility. These will be evaluated by the following assessments.

Safety and tolerability:

- Incidence and severity of Adverse Events and Severe Adverse Events
- Incidence of Dose Limiting Toxicity (DLT, systemic and loco-regional)
- Necessity for dose adjustments, delay and early cessation
- Incidence and severity of post-procedural pain
- Patient reported tolerability (questionnaires)
- Cardiotoxicity: Left Ventricular Ejection Fraction measurement and

electrocardiogram abnormalities.

Feasibility:

- The number of cycles in which hyperthermia treatment was sufficient: at least 30 minutes at the target temperature of 40-42 °C.
- The number of completed cycles with MR-HIFU induced hyperthermia, LTLT and cyclophosphamide
- Quality of MR thermometry data acquired during the MR-HIFU treatment
- Spatiotemporal temperature distribution in the tumour
- Total duration of the study procedures on a treatment day.

Secondary endpoints consist of efficacy parameters:

- Assessment of distant radiological objective response rates
- Assessment of local radiological objective response rates

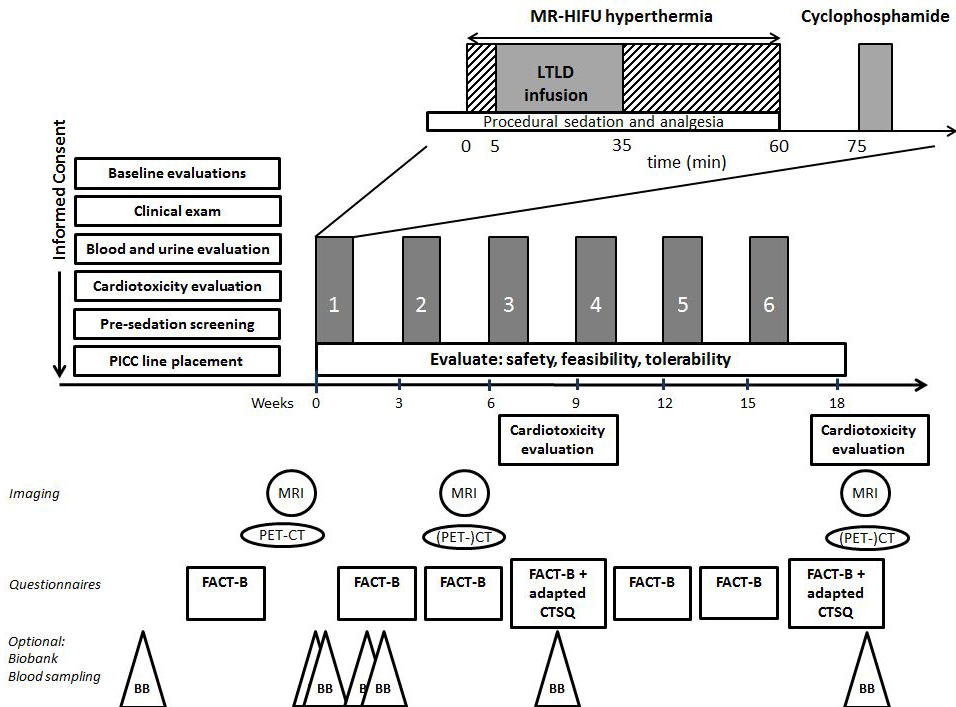

### Study procedures

The study design (Figure 2) was based on the AC regimen, a well-known chemotherapeutic regimen that consists of doxorubicin and cyclophosphamide. This regimen is used in the (neo-)adjuvant setting as well as in the first-line chemotherapy treatment of metastatic breast cancer. Standard of care for our study population consists of 6 cycles at 21-days intervals. In this study we will replace doxorubicin in this regimen with the combination of LTLT and MR-HIFU induced hyperthermia.

All participants will receive procedural sedation and analgesia with propofol and remifentanyl to limit patient movement during the treatment and to establish a regular breathing pattern that will facilitate respiratory gated MR thermometry [38]. To prevent any hypersensitivity reactions to LTLT, the participants will also receive a premedication regimen of steroids, H1- and H2- histamine antagonists. Anti-emetics will be administered according to standard-of-care hospital guidelines for the AC regimen.

MR-HIFU hyperthermia will be performed on the MR-HIFU breast system, with the patient in prone position. We will aim for 60 minutes of hyperthermia at 40-42 °C to the breast tumour, in four blocks of 15 minutes. After each block the MR thermometry is restarted to minimize the possible influence of magnetic field drift or patient displacement. When MR thermometry indicates that the target temperature is reached, 50 mg/m<sup>2</sup> of LTLT will be administered intravenously over 30 minutes, via a peripherally inserted central catheter (PICC), while the patient is on the MR-HIFU breast system. Temperature will be monitored by respiratory navigator-gated MR thermometry, using the proton resonance frequency shift method [39, 40]. In case the target temperature is not reached, conventional doxorubicin (60 mg/m<sup>2</sup>) will be administered instead of LTLT. Shortly after MR-HIFU, 600 mg/m<sup>2</sup> of cyclophosphamide will be administered intravenously according to standard of care in the AC regimen.

**Figure 2** Study procedures. The standard of care palliative AC regimen consists of 6 cycles of doxorubicin and cyclophosphamide at 21-days intervals. In this study we will replace doxorubicin with the combination of LTLD and MR-HIFU induced hyperthermia, in up to six cycles. After informed consent, the baseline procedures will be performed as mentioned. During the cycles, the primary endpoints of safety (adverse events), feasibility and tolerability will be monitored, including cardiotoxicity evaluation and questionnaires on specified time points as indicated in the bottom of the figure. Imaging to determine local (MRI) and systemic ((PET)/CT) response will be performed at baseline, after cycle two and after cycle six. Optionally, the patient can consent to additional blood sampling for future research, which will be stored in the Biobank.

Participants will receive up to six treatment cycles. Feasibility will be evaluated after each MR-HIFU treatment and during the course of the cycles. Safety and tolerability will be assessed three hours after MR-HIFU treatment, during telephone contact on day +1 and +7 and during a hospital visit on day +14 and +21 of each cycle, by monitoring of adverse events, laboratory measurements and evaluation of pain. Cardiotoxicity evaluations (LVEF and ECG) will be performed at baseline, after cycle 3 and after cycle 6. The participants will be asked to fill out the Dutch version of the Functional Assessment of Cancer Therapy – Breast (FACT-B, version 4, FACIT)[41] at baseline and after each treatment cycle, combined with a selection of questions adapted from the Dutch version of the Cancer Therapy Satisfaction Questionnaire (CTSQ, Pfizer 2007, modified with permission from Pfizer)[42, 43] in cycles 3 and 6. Before starting the next cycle, any toxicities will be evaluated and if necessary, dose reductions will be made. DLT will be categorized in systemic or loco-regional toxicity (Table 1). Thus, we aim to distinguish systemic chemotherapy effects from

local effects of MR-HIFU hyperthermia and/or the high local doxorubicin concentration. Planned dose adjustments for these categories have been established (Supplementary materials 2). In case of a systemic DLT the LTLD dosage will be decreased, while for loco-regional DLT the duration of hyperthermia will be decreased. Cyclophosphamide dose will not be reduced. No dose increases will be performed. Depending on the severity and nature of the toxicity, study treatment can be delayed or even ceased. In case of solely loco-regional DLT, technical issues or other feasibility issues that restrict the use of MR-HIFU treatment, the participant will receive the standard of care AC regimen. If hyperthermia is insufficient (i.e. the target temperature of 40-42 °C is not reached or was only maintained for less than 30 minutes) in two separate cycles, the treatment is not considered feasible for that patient and study participation will end.

**Table 1** Definitions of Dose Limiting Toxicity

<b>Dose limiting systemic toxicity</b>	
A	<i>Hematologic DLT</i> defined as Grade 3 anaemia, Grade 4 thrombocytopenia, febrile neutropenia, or Grade 4 neutropenia $\geq$ 7 days in duration.
B	<i>Non-hematologic DLT (non-loco-regional)</i> defined as Grade 3 or greater toxicity with the exceptions of alopecia, fatigue, nausea or vomiting and loco-regional effects. Including Cardiotoxicity DLT, defined as: <ul style="list-style-type: none"> <li>• Grade 3 or greater cardiac disorders OR</li> <li>• a decline in LVEF of <math>&gt;</math> 15% while the LVEF remains <math>&gt;</math> 40% OR</li> <li>• a decline to an LVEF of <math>\leq</math> 40%.</li> </ul>
<b>Dose limiting loco-regional toxicity</b>	
C	<i>Loco-regional DLT</i> defined as post-procedural effects (e.g. pain or skin effects) on the treated breast warranting dose adjustment or delay.

For the secondary endpoint of efficacy, MRI of the breast will be performed using a 3 Tesla MRI scanner with a dedicated breast coil, at baseline and after cycle 2 and 6 to determine local radiological objective response. In addition, MRI of the breast will be performed during each MR-HIFU treatment. However, the receiver coil in the MR-HIFU breast system is not suited for clinical imaging. In case a complete radiological response of the breast tumour is obtained after less than 6 cycles, the patient will continue with the conventional AC regimen.  $^{18}\text{F}$ -fluorodeoxyglucose (FDG-) Positron Emission Tomography combined with Computed Tomography (PET/CT) of the thorax and abdomen will be performed at baseline and CT or PET/CT after cycle 2 and cycle 6, to determine the distant objective response according to RECIST 1.1 [44] or PERCIST 1.0 [45]. PET/CT will be performed for response evaluation in patients with only PERCIST-measurable disease, such as patients with only bone metastases. If a patient shows distant progression of disease, study participation will end and the patient will be treated according to the standard of care. Additional specific

reasons for study withdrawal are dose limiting toxicity that warrants a delay in treatment administration for longer than 14 days or a recurrence of dose limiting toxicity after dose reduction of LTLT (Supplementary materials 2).

The participants will be followed for adverse events from the time of signing informed consent until the end of study visit after six cycles of chemotherapy. Afterwards patients will receive standard of care treatment.

If the patient consents to the biobank study, additional blood samples will be taken from the PICC-line at seven time points (Figure 2) when the patient is already at the hospital. These blood samples will be collected in the UMC Utrecht Biobank for future research. Moreover, in case tissue samples of the breast tumour and/or metastases were obtained in standard care before inclusion or following study participation, we will ask for consent to perform additional analyses on these samples.

### **Concomitant care and prohibited interventions**

All supportive measures consistent with optimal medical care will be employed, including transfusion of blood and blood products, and treatment with antibiotics, antiemetics, antidiarrheals, and analgesics, as appropriate.

Certain concomitant medications, a number of herbal supplements, food stuffs and nutritions are restricted during the study (Supplementary materials 3). Patients cannot use creams, ointments or lotions on the breast on the MR-HIFU treatment day, to avoid additional risks during the procedure. Patients cannot use methods or treatments that increase the body temperature or skin temperature during the study period (e.g. sauna, hot-water baths, warmth massages), because this could result in increased release of doxorubicin in the warmed areas, possibly causing extra adverse events.

### **Interim analysis**

An interim analysis of safety and efficacy will determine whether accrual will continue after six participants (Supplementary materials 4). Safety will be evaluated once the first six patients complete two treatment cycles. If safety is sufficiently proven or is deemed inadequate, the trial will end after six participants. Otherwise accrual will continue until twelve patients have been treated, if necessary after dose adjustments. All patients who have signed informed consent will be evaluated for the primary endpoints of safety, feasibility and tolerability. Patients who have been withdrawn from the study because MR-HIFU induced hyperthermia was insufficient in two separate treatment cycles and who did not experience a DLT, will be replaced by another participant for in the interim safety evaluation. If this happens to four patients, the study will be terminated, because of insufficient feasibility.

Systemic efficacy will be evaluated once the first six patients have received the CT scan after cycle 2. If four or more of the first six participants show distant disease progression at that time the trial will be stopped, as this suggests that efficacy against disease outside the

heated treatment field is inadequate. This early stopping rule was based on a phase III trial with liposomal doxorubicin in metastatic breast cancer [46] where 77.5% of the subjects were free of disease progression at two months post-randomization (the 95% confidence interval of 2/6 patients does not contain 0.775).

An independent, qualified monitor will monitor the study procedures. An external Data Safety Monitoring Board (DSMB) will review accumulating safety data at regular intervals throughout the study, perform the interim safety and efficacy analyses and monitor trial data integrity (DSMB charter in Supplementary materials 5).

### Data analysis

Descriptive statistics will be used to describe the incidence and severity of adverse events (National Cancer Institute Common Terminology Criteria for Adverse Events version 5.0), the patient reported outcomes in the questionnaires and feasibility parameters including the number of completed study treatment cycles, duration of study procedures and spatiotemporal temperature distribution during MR-HIFU treatment. For the secondary endpoint of efficacy, distant and local radiological objective response rates (RECIST 1.1) will be described.

## DISCUSSION

This is the first clinical trial that investigates the combination of LTLT and MR-HIFU induced hyperthermia in breast cancer. In a small number of patients we will focus primarily on safety, tolerability and feasibility of this procedure. We hypothesize that the combination of LTLT and MR-HIFU hyperthermia leads to improved treatment of the primary tumour, without changing the systemic doxorubicin concentration and thus without interfering with systemic efficacy and toxicity. A future randomized study with a control group receiving the standard of care AC regimen would be needed to prove this. Including patients with *de novo* stage IV breast cancer provides the unique possibility to monitor both local and systemic disease simultaneously. While in this setting a survival benefit of treating the primary tumour has not been proven, the study treatment (if proven safe and feasible) could in the future improve outcomes in the neoadjuvant setting.

We aim to replace doxorubicin by LTLT plus MR-HIFU hyperthermia in all six cycles of the AC regimen, because we expect this to maximize the local treatment effect. In each cycle, the feasibility to achieve tumour hyperthermia at 40-42 °C for 30 minutes will be verified with MR thermometry. If hyperthermia treatment is repeatedly insufficient, or if (after any number of cycles) radiological complete response is already obtained, patients will continue on the standard-of-care AC regimen. The number of MR-HIFU hyperthermia plus LTLT cycles that our patients are willing and able to complete could be less than six, which would be an important feasibility finding.

Our goal is to maintain an equivalent systemic efficacy compared to the standard-of-care AC regimen using 60 mg/m<sup>2</sup> conventional doxorubicin. Pharmacokinetic studies showed that the area-under the curve (AUC<sub>0-∞</sub>) of free/unencapsulated doxorubicin in plasma of patients receiving LTLD 50 mg/m<sup>2</sup> with local hyperthermia or RFA [33, 47, 48] was higher than the AUC<sub>0-∞</sub> of conventional doxorubicin 60 mg/m<sup>2</sup> [49-51]. To be able to compare the AUCs we converted the AUC<sub>0-∞</sub> of the metabolite doxorubicinol that was measured in the LTLD studies to the AUC<sub>0-∞</sub> of doxorubicin [52-54] (Additional explanation in Supplementary materials 1). The 50 mg/m<sup>2</sup> LTLD dose was also recommended for and well-tolerated in the phase III trial in combination with RFA [35]. Due to local toxicity, the recommended dose for LTLD combined with local superficial hyperthermia for chest wall recurrences was decreased to 40 mg/m<sup>2</sup> [47]. In our study local (skin) toxicity is not expected because a margin of at least 1.0 cm is preserved from the tumour to the skin, therefore the LTLD dose of 50 mg/m<sup>2</sup> was chosen. Real time MR thermometry and the lateral configuration of the MR-HIFU breast system will help mitigate this risk. If however local DLT do occur, the duration of hyperthermia will be decreased while maintaining the LTLD dosage to avoid decreasing systemic efficacy. We will only decrease LTLD dosage in case of systemic DLT. If despite these measures, systemic efficacy seems inadequate, the trial will be halted prematurely based on the interim analysis for efficacy.

Because this is a small phase I feasibility study, the results will only provide a rough indication of local efficacy based on radiological response. To diminish the burden on participants, we will not perform tissue biopsies or breast surgery and therefore cannot describe the number of pathological complete responses or measure the concentration of doxorubicin in the tumour. Proof-of-concept that hyperthermia increases the tumour doxorubicin concentration has already been established in the Tardox study, although doxorubicin concentrations were not compared between heated and unheated tumours.

With this phase I clinical trial, we aim to show that LTLD combined with MR-HIFU induced hyperthermia on a dedicated MR-HIFU breast system can safely replace doxorubicin in the AC regimen. We hypothesize that this combination will result in improved response of the primary tumour without compromising the systemic efficacy on metastatic sites or increasing systemic toxicity. If feasibility and tolerability are adequate, this approach could in the future lead to optimal loco-regional control with less extensive or even no surgery, in stage II or III breast cancer patients allocated to receive neo-adjuvant chemotherapy. Finally, it could also be suitable for other doxorubicin sensitive tumour types that benefit from enhanced local treatment, such as soft tissue sarcoma.

### **Ethics and dissemination**

This study has obtained ethical approval by the Medical Research Ethics Committee of the UMC Utrecht (METC Utrecht) on May 29<sup>th</sup> 2019 (Protocol NL67422.041.18, METC number 18-702). This paper is based on protocol version 6, dated August 28<sup>th</sup> 2020. Substantial

protocol amendments will also be evaluated by METC Utrecht and communicated to relevant parties by the investigators. Informed consent will be obtained from all patients by an authorized representative of the Principal Investigator before study participation (Informed consent form in Supplementary materials 6). The results of this study will be disseminated by publication in an academic peer-reviewed journal.

### **Roles and responsibilities**

This is an investigator-driven single-centre clinical trial, with the UMC Utrecht as sponsor and trial site. The UMC Utrecht is responsible for the study design, data collection, data management, analysis, interpretation of data, writing and submission of the report for publication. The Principal Investigator will report (serious) adverse (device) events to the METC Utrecht, to the Central Committee on Research Involving Human Subjects (CCMO), and to Celsion Corporation and Profound Medical according to national guidelines. UMC Utrecht has liability insurance which provides cover for damage to research subjects through injury or death caused by the study. Celsion Corporation (manufacturer of the investigational medicinal product) and Profound Medical (manufacturer of the investigational medical device) will provide technical support during the trial and have provided input on the study protocol. Both manufacturers will be allowed to review and comment on draft publications prior to submission. The investigators at the UMC Utrecht will have ultimate authority over the publication. An external Data Safety Monitoring Board (two clinicians and one statistician) has been established and an independent qualified monitor (Julius Clinical) has been appointed to perform intensive monitoring.

### **Data management**

The handling of personal data will comply with the General Data Protection Regulation (GDPR, in Dutch known as AVG). After informed consent is signed, each patient receives a unique subject number. A subject identification code list will be used to link the data to the subject. The key to this pseudonymization code will be available only to the investigators and employees of the research team.

Research data that are relevant for the study will be collected by the investigators on electronic Case Report Forms (eCRFs) in Research Online, in compliance with the Good Clinical Practice (GCP) guidelines for electronic data collection. An audit trail will be available. The completed eCRFs will be reviewed, signed and dated by the Principal Investigator or Co-investigator. Scans, results and registrations of medical imaging will be collected on the Research Imaging Architecture (RIA), which is secured by password-protection and stores pseudonymized images. Data from the MR-HIFU device such as log files and MR images obtained during the MR-HIFU treatment that cannot be stored on the Research Imaging Architecture will be stored in a secured UMC Utrecht bulk-storage folder. Celsion and Profound will not receive any patient's identifiable (personal) information. UMC Utrecht shall provide pseudonymized data regarding the occurrence and severity of adverse

device effects to Profound Medical and regarding the occurrence and severity of adverse events to Celsion Corporation. This cannot be refused by the patient and is obligatory for study participation. If the patient consents (optional), additional pseudonymized data on the study treatment, will also be provided to Profound Medical and Celsion Corporation. Research data will be stored for 15 years after the end of study. Biomaterial is stored in the Central biobank (blood) or at the UMC Utrecht pathology department (tissue samples).

### **Patient and public involvement**

Patient experiences have been the starting point for the grant proposal to the Dutch Cancer Foundation and patients were involved in the design of the study and the choice of outcome measures. Patients will not be actively involved in recruitment or dissemination of study results, however information regarding the study can be found by individual patients on the UMC Utrecht website and [clinicaltrials.gov](https://clinicaltrials.gov).

### **Trial status**

Patient recruitment was initiated on March 10<sup>th</sup> 2020. Due to the COVID-19 outbreak, the study has been temporarily discontinued, but the study is now open for enrollment.

### **Authors' contributions**

JdM, BS, MB, SL, CM, EW and RD were all involved in the design of the study and in writing the manuscript.

PvD, HV and AW critically reviewed the design of the study providing additional comments and suggestions.

### **Funding statement**

This work was supported by the Dutch Cancer Foundation (project no. UU 2015-7891), Center for Translational Molecular Medicine (CTMM) in the projects VOLTAVALO (project no. 09P-106) and HIFU-chem (project no. 03O-301) and by "Friends of the UMC Utrecht".

## ACKNOWLEDGEMENTS

We thank Roelien Kronemeijer of the trial bureau medical oncology and Heleen Klein Wolterink-Blok, research nurse medical oncology, for their work leading up to the Medical Research Ethics Committee approval of the study and the start of patient recruitment.

We thank Prof. Gert Storm for his work in the preceding HIFU-CHEM project that has contributed to the current project.

We thank Christiaan van Kesteren for his help with the design of Figure 1.

We thank Celsion Corporation for their support relating the use and safety of ThermoDox and their input during the design of the study.

Finally, we thank Profound Medical for their support relating the use and safety of the MR-HIFU breast system in their role as legal manufacturer of this investigational medical device.

## COMPETING INTERESTS STATEMENT

The authors have no competing interest to declare.

## LIST OF ABBREVIATIONS

AC	Doxorubicin (A) and cyclophosphamide (C)
AF	Alkaline Phosphatase
ALAT	Alanine Transaminase
ANC	Absolute Neutrophil Count
ASAT	Aspartate Transaminase
AUC <sub>0-∞</sub>	Area Under the Curve 0-infinity
CCMO	Central Committee on Research Involving Human Subjects
CTSQ	Cancer Therapy Satisfaction Questionnaire
DCE	Dynamic contrast-enhanced
DLT	Dose Limiting Toxicity
DSMB	Data Safety Monitoring Board
eCRF	electronic Case Report Forms
FACT-B	Functional Assessment of Cancer Therapy – Breast
GCP	Good Clinical Practice
GDPR	General Data Protection Regulation
LTLD	Lyso-Thermosensitive Liposomal Doxorubicin
MR-HIFU	Magnetic Resonance guided High Intensity Focused Ultrasound
MRI	Magnetic Resonance Imaging
(FDG-) PET/CT	<sup>18</sup> F-Fluorodeoxyglucose Positron Emission Tomography combined with Computed Tomography
PICC	Peripherally inserted central catheter
RFA	Radiofrequency ablation
RIA	Research Imaging Architecture

## ABSTRACT

Chemotherapy efficacy is often reduced by insufficient drug uptake in tumor cells. The combination of ultrasound and microbubbles (USMB) has been shown to improve drug delivery and to enhance the efficacy of several drugs *in vitro* and *in vivo*, through effects collectively known as sonopermeation. However, clinical translation of USMB therapy is hampered by the large variety of (non-clinical) US set-ups and US parameters that are used in these studies, which are not easily translated to clinical practice. In order to facilitate clinical translation, the aim of this study was to prove that USMB therapy using a clinical ultrasound system (Philips iU22) in combination with clinically approved microbubbles (SonoVue) leads to efficient *in vitro* sonopermeation. To this end, we measured the efficacy of USMB therapy for different US probes (S5-1, C5-1 and C9-4) and US parameters in FaDu cells. The US probe with the lowest central frequency (i.e. 1.6 MHz for S5-1) showed the highest USMB-induced intracellular uptake of the fluorescent dye SYTOX™ Green (SG). These SG uptake levels were comparable to or even higher than those obtained with a custom-built US system with optimized US parameters. Moreover, USMB therapy with both the clinical and the custom-built US system increased the cytotoxicity of the hydrophilic drug bleomycin. Our results demonstrate that a clinical US system can be used to perform USMB therapy as efficiently as a single-element transducer set-up with optimized US parameters. Therefore, future trials could be based on these clinical US systems, including validated US parameters, in order to accelerate successful translation of USMB therapy.

USMB, sonoporation, sonopermeation, ultrasound, microbubbles, chemotherapy, drug delivery, imaging

## INTRODUCTION

Chemotherapy is typically used as systemic treatment to destroy metastatic cancer cells that have spread away from the primary tumor. However, local action of chemotherapy is also of importance throughout the spectrum of oncological therapy. First, surgically unresectable tumors can be made operable with neoadjuvant chemotherapy [1, 2]. Secondly, neoadjuvant chemotherapy can lead to less extensive surgery and reduce the risk of local recurrences [3, 4]. Third, chemotherapy can enhance the local effect of radiotherapy during chemoradiation [5-7]. Finally, local response to palliative chemotherapy can decrease morbidity [8-10]. Unfortunately, there is substantial heterogeneity in the local response to systemic treatment within and across cancer types. A plausible explanation for suboptimal response is the heterogeneous and/or insufficient delivery of drugs to tumor cells caused by biophysical barriers of the tumor tissue [11, 12].

The combination of ultrasound and microbubbles (USMB) has been shown to overcome these biophysical barriers and increase local tumor uptake of several drugs resulting in enhanced efficacy [13-15]. Microbubbles are micron sized (1-10  $\mu\text{m}$  in diameter) gas-filled particles with a biocompatible shell that are widely used as vascular contrast agents for ultrasound imaging [16, 17]. In addition, the interaction of US waves and microbubbles has the potential to enhance the delivery of drugs. Microbubbles exposed to low-intensity US fields will oscillate (i.e. stable cavitation), while microbubbles exposed to higher intensities will collapse violently (i.e. inertial cavitation). Both types of cavitation lead to a number of bio-effects collectively known as sonopermeation, such as the formation of pores in cell membranes (sonoporation), enhanced endocytosis and increased vascular permeability, that improve the deposition of drugs in tumor tissue [14, 18].

In particular, hydrophilic drugs such as bleomycin and cisplatin, that have difficulties crossing the cell membrane, may benefit from local USMB therapy, leading to increased delivery of such drugs *in vitro* [19-32] and increased anti-tumor response *in vivo* [19, 23-25, 28, 29, 31]. The first clinical trials using the combination of chemotherapy and USMB have been conducted. In a phase 1 clinical trial, USMB with clinically available microbubble SonoVue was combined with gemcitabine in ten inoperable pancreatic cancer patients. Trial participants could tolerate significantly more treatment cycles and the median overall survival was longer compared to historical controls treated with gemcitabine alone [33, 34]. Another phase 1 trial in eleven patients with hepatic metastases and one patient with pancreatic cancer concluded that treatment with physician's choice chemotherapy (most commonly FOLFIRI, i.e. folinic acid, fluorouracil and irinotecan) plus USMB with SonoVue was safe [35]. Several follow-up phase 1 / 2 studies are currently recruiting or being prepared (Clinicaltrials.gov NCT04146441, NCT04821284, NCT03477019 and NCT03458975). A phase 3 trial investigates the addition of USMB to neoadjuvant chemotherapy in breast cancer (Clinicaltrials.gov NCT03385200, current status unknown).

Despite these promising developments, translation of USMB therapy from *in vitro* and small animal studies to the clinic is still limited. One major obstacle for clinical translation of USMB therapy is the lack of a clinically approved US system with settings optimized to perform USMB therapy. A large variety of (non-clinical) US set-ups and US parameters have been used for *in vitro* and *in vivo* studies [36]. While these studies have provided invaluable insights on the underlying mechanisms of USMB therapy and provided *in vivo* proof of concept, their methods and results cannot be easily transferred to clinical studies because the US equipment is not, and will not likely be, approved for clinical use. In this study we take a different approach to facilitate the clinical translation of USMB therapy by investigating the potential of an existing clinical ultrasound system (Philips iU22) in combination with clinically available microbubbles (SonoVue) to perform USMB therapy. To this end, we use *in vitro* experiments to evaluate the effect of USMB therapy on the intracellular uptake of a model drug (SYTOX™ Green) and the efficacy of the hydrophilic chemotherapeutic drug bleomycin.

## MATERIALS AND METHODS

### Chemicals and reagents

All cells were cultured in high glucose Dulbecco's modified eagle medium (DMEM) supplemented with 10% fetal bovine serum (FBS) and 1% non-essential amino acids (NEAA).

Dulbecco's Phosphate Buffered Saline (PBS), modified, without calcium, chloride and magnesium chloride was used as solvent and for washing steps.

PBS, DMEM, FBS, NEAA and trypsin / ethylenediaminetetraacetic acid (EDTA) were purchased from Sigma-Aldrich (St. Louis, USA).

Bleomycin sulfate (Bleomedac® powder for solution for injection, GmbH, Wedel, Germany) was dissolved in sterile 0.9% NaCl to reach a final concentration of 10µg/mL, which corresponds to at least 15IU (Ph. Eur) per mL. Bleomycin is hydrophilic (LogP-7.5) and has a molecular weight of 1415.6 g/mol<sup>1</sup>.

SYTOX™ Green is a cell-impermeant fluorescent nuclear acid stain with excitation/emission wavelength of 504/523 nm. Its impermeability and >500-fold fluorescence enhancement after binding to nuclear acids makes it suitable to visualize USMB therapy efficacy. DRAQ5™ fluorescent probe is a cell-permeant fluorescent dye (excitation 647 nm, emission 681nm) that was used to counterstain the DNA content of all cells. AlamarBlue™ reagent was used for the cell viability assay. The eBioscience™ Annexin V Apoptosis Detection Kit APC, containing both fluorescently labelled Annexin V and Propidium Iodide (PI), was used for the apoptosis assay. SYTOX™ Green, DRAQ5™,

1 <https://pubchem.ncbi.nlm.nih.gov/compound/Bleomycin#section=CAS> [Accessed August 31<sup>st</sup>, 2021]

AlamarBlue™ and eBioscience™ Annexin V Apoptosis Detection Kit APC were purchased from ThermoFisher Scientific (Waltham, Massachusetts, USA).

### Cell culture

A human pharyngeal squamous cell carcinoma cell-line (FaDu) (ATCC® HTB-43™, LGC Standards GmbH, Wedel, Germany) was cultured in high glucose DMEM supplemented with 10% FBS and 1% NEAA. FaDu cells were cultured in a humidified incubator at 37 °C and 5% CO<sub>2</sub>. They were split 2-3 times per week at a confluency of around 80%, until a maximum passage number of 20. One day before each experiment, FaDu cells collected using trypsin/EDTA and seeded in a 35 mm diameter lumox® culture dish (Sarstedt AG& Co. KG, Nümbrecht, Germany).

### Ultrasound systems and microbubbles

SonoVue (Bracco International B.V., Amsterdam, the Netherlands) was prepared according to the manufacturer's instructions, producing sulfurhexafluoride-filled phospholipid microbubbles with a mean bubble diameter of ~2.5 μm and a concentration of 1-5\*10<sup>8</sup> microbubbles/mL in sterile 0.9% NaCl. Microbubbles were kept at 4°C in between use, resuspended before every use and used within 2 hours after preparation.

We used a clinical ultrasound system (iU22 Ultrasound system, Philips Medical Systems Nederland B.V, Best, the Netherlands) combined with the following probes: S5-1, C5-1 and C9-4. USMB therapy was done in Pulsed Wave (PW) Doppler mode. The transmission frequency of each transducer was set by the system and cannot be changed. The Pulse Repetition Period (PRP) was set to the longest period for each transducer by setting the scale parameter to the minimum. The acoustic pressure was varied by changing the mechanical index (MI). The number of cycles per pulse was varied by changing the sample volume (SV), while the MI (pressure) was kept constant.

The acoustic field of each transducer in PW Doppler mode as well as the acoustic pressure for each setting was measured using a 0.2 mm needle hydrophone (Precision acoustics Ltd., Dorset, UK) in degassed water.

As reference, we used a custom-built US set-up that was previously used for USMB therapy [37]. This US set-up consisted of a single-element transducer operated at 1.5 MHz, 150 cycles per pulse, pulse repetition frequency of 1.0 kHz and Peak negative pressures ( $P_{neg}$ ) of 0.39, 0.56 and 0.72 MPa.

### Microbubble response

The acoustic bubble response to the specific acoustic pulses used in the experiment was characterized by attenuation measurements. A sample holder (acoustical path length of 8 mm) with two acoustically transparent windows was positioned such that its center coincided with the focal point of two single-element transducers. The transmit transducer (Olympus V304,  $f = 2.25$  MHz,  $F = 1.88$  inch,  $D = 1$  inch) was calibrated using a

fibre-optic hydrophone (Precision Acoustics). The receiving transducer (Olympus V307,  $f = 5$  MHz,  $F = 1.93$  inch,  $D = 1$  inch, was aligned such that the received signal (without microbubbles) was at a maximum.

Eight differently shaped US pulses were used, four with a rectangular envelop (as used in the single-element set-up) and four with a Gaussian envelop (to recreate the pulses of the US imager probe), with 11, 23, 46 and 150 cycles. These pulses were generated by a waveform generator (Tabor 8026) and amplified (vectawave, VBA100-200) before transmission. The receiving transducer and the waveform generator were connected to a digital oscilloscope (picoSCOPE 5444d) such that both the transmitted and received signal were recorded. The waveform generator as well as the oscilloscope were triggered (BNC, 575) simultaneously.

Each US pulse was repeated 5 times, with a pulse repetition frequency (PRF) of 6.7 kHz, for 5 different Peak negative pressures (150 kPa to 750 kPa with 150 kPa steps), such that one measurement consisted of 200 pulses. During the measurements the sample in the holder was continuously refreshed by a gravity-driven flow. Measurements were done at the frequencies used throughout the rest of the paper, namely 1.6 MHz, 2.25 MHz and 4 MHz. All measurements were performed with diluted (1000x) SonoVue and without microbubbles for reference.

Attenuation coefficients were calculated by comparing the transmission through the SonoVue solution to that through distilled water:

where  $\alpha$  is the attenuation coefficient in dB/cm,  $L$  is the acoustical path length through the sample in cm, and  $A_1$  and  $A_2$  are the amplitudes of the frequency spectra of the SonoVue and reference signal, respectively, at the transmit frequency  $f$ .

### USMB therapy experimental set-up

In order to apply USMB therapy to cells cultured in lumox<sup>®</sup> dishes we used TwentiCells, which were designed and manufactured at Twente University (**Figure 1**). The TwentiCell consists of a 3D-printed lumox<sup>®</sup> dish holder and a screw-on ring to seal the lumox<sup>®</sup> dish with a polyolefin (25  $\mu$ m thick), creating a water-tight compartment. The holder contains an in-let and out-let to fill the compartment with drugs/microbubbles in solution and remove unwanted air, respectively. The parts were assembled before each experiment and UV-sterilized before inserting the lumox<sup>®</sup> dish containing the cells to avoid infection. Acoustic transparency of the TwentiCells and inserted lumox<sup>®</sup> dishes is close to 100% (data not shown).

For the USMB therapy the TwentiCell was immersed in degassed water ( $T = 37^\circ\text{C}$ ) and fixed above the transducer in a custom-built frame. The distance between the surface of the clinical ultrasound probes and the lumox<sup>®</sup> dish membrane was 3.0 cm and the PW Doppler Sample Volume was centered on this position (**Figure 1 (C)**). In the single-element transducer set-up the lumox<sup>®</sup> dish membrane was positioned in the focal zone

of the transducer, i.e. 8.0 cm above the transducer surface (**Figure 1 (D)**).

**Figure 1.** Experimental US set-up for *in vitro* experiments. **(A)** Cross section of 3D-printed TwentiCell **(B)** Schematic drawing and photos of TwentiCell (I) including upside-down inserted lumox® dish (II) in custom-build frame (IV). A 5 mL syringe (III) is used to insert the medium and to remove air. **(C)** TwentiCell immersed in degassed water, in a custom-build frame, with clinical US probe 3.0 cm below the cells or **(D)** with single element transducer 8.0 cm below the cells. In both set-ups at least 5 cm of water was above the cells.

### SYTOX™ Green experiments

One day after seeding  $3.0 \cdot 10^5$  FaDu cells in lumox® dishes, the medium was removed and a mixture of 2  $\mu$ L SYTOX™ Green (SG, 5 mM solution in DMSO), 180  $\mu$ L SonoVue and 4.8 mL medium was added to the TwentiCell. For USMB-untreated samples, a lumox® dish with regular lid was used and the volumes were adjusted to 0.5  $\mu$ L SG, 45  $\mu$ L 0.9%

NaCl and 1.2mL medium. The TwentiCells were incubated (37 °C and 5% CO<sub>2</sub>) for 15 minutes with the cell containing surface upwards, in order for the microbubbles to float towards the cells. Next, the TwentiCell was placed in the waterbath (cell containing surface remaining upwards), exposed to ultrasound for 15 seconds and put back in the incubator. The US-untreated samples were not removed from the incubator. 30 minutes after USMB treatment, the SG-containing medium was removed and clean medium was added. Afterwards, the cells were washed with PBS, fixated with paraformaldehyde (4% in PBS) and stained with 1 mL DRAQ5 (5 μM in PBS) at 37°C for about 20 minutes. The lumox® membrane was covered with solidifying mounting medium FluorSave™ (Merck Millipore, Burlington, Massachusetts, USA) and a glass cover slip, and kept in the dark at 4°C until fluorescence imaging. These experiments were performed with the single element transducer as well as the clinical US system.

### Bleomycin experiments

One day after seeding  $1.5 \cdot 10^5$  FaDu cells in lumox® dishes, the medium was removed and a mixture of 498 μL bleomycin solution or 0.9% NaCl, 180μL SonoVue and 4.302 mL medium was added to the TwentiCell. For US-untreated samples, a lumox® dish with regular lid was used and the volumes were adjusted to 125 μL bleomycin solution or 0.9% NaCl, 45μL 0.9% NaCl and 1.075 mL medium. The TwentiCells were incubated (37 °C and 5% CO<sub>2</sub>) for 15 minutes with the cell containing surface upwards. Next, the TwentiCell was placed in the waterbath (cell containing surface remaining upwards), exposed to ultrasound for 15 seconds and put back in the incubator. The US-untreated samples were not removed from the incubator.

To determine the IC<sub>50</sub> and IC<sub>25</sub> of bleomycin with or without USMB, the final bleomycin concentrations were 0, 0.1, 0.5, 1, 5, 10, 50, 100 and 500 μg/mL and the single-element transducer set-up was used. The apoptosis assay was performed at a single bleomycin concentration (10 μg/mL) using the single-element set-up as well as the clinical US system.

Two hours after USMB therapy, the bleomycin or 0.9% NaCl containing medium was removed, the cells were washed with PBS and clean medium was added. The cells were then incubated at 37°C, 5% CO<sub>2</sub> until 48 hours after adding the bleomycin, microbubbles and/or 0.9% NaCl.

### Fluorescence microscopy

Fluorescence imaging for the SG experiments was performed on a Confocal Zeiss LSM 700 microscope. SG was imaged with excitation 488 nm and emission >500 nm. DRAQ5 was imaged with excitation 639nm and emission > 640 nm. All microscope settings, including laser power, gain, pinhole size and digital offset, were kept constant during all experiments. Images were obtained with 10 times enlargement with a frame size of 512x512 and a square tile size of 640.17 μm<sup>2</sup>. For each lumox® dish, a square of 10 by

10 tiles was imaged with a 10% overlap, starting in the visual center of the SG signal. The tiles were stitched immediately after acquisition. In each tile a Z-stack of 3 levels was created to compensate for height variances of the cells over the tiles.

To quantify the USMB efficacy for different US-settings we performed automated cell segmentation of SG-positive and DRAQ5-positive cells using (Fiji Is Just) ImageJ 2.0.0-rc-69. First, a standard-deviation Z-projection was created for the SG and DRAQ5 images. To segment the SG-positive cells global thresholding was applied, with a fixed threshold for all samples, whereas for segmenting the DRAQ5-positive cells a local threshold was applied (i.e. mean method with a radius of 5). Next, the noise in the binary masks after thresholding was removed with a median filter and the watershed algorithm was applied to split clustered objects. Objects with a size  $\geq 20$  pixel units were counted as cells, regardless of circularity.

The number of SG and DRAQ5-positive cells were analyzed in a region of interest (ROI) of 600x600 pixels, centered on the position with the highest SG signal after blurring the SG image with a 2-D Gaussian smoothing kernel with standard deviation of 200 in Matlab (R2019a). When there was no noteworthy SG signal, the ROI was positioned in center of the 10x10 square. Objects on the edges of the ROI were not counted.

### Viability assay

The effect of bleomycin with or without USMB therapy on cell viability was determined with an AlamarBlue assay. 48 hours after adding medium with or without bleomycin and microbubbles to the Twentycell, a solution of 1mL medium and 100 $\mu$  AlamarBlue reagent (500  $\mu$ M solution in PBS) was added to each lumox<sup>®</sup> and incubated (37 °C and 5% CO<sub>2</sub>). After two hours, the mixture was removed from each lumox<sup>®</sup> and pipetted into a well plate.

The fluorescence intensity in the well plate was measured using the FLUOstar OPTIMA (BMG LABTECH) plate reader, with excitation and emission wavelengths of 550-10 and 600-610 nm and a gain of 1500. The cell viability of a sample was calculated as percentage fluorescent signal relative to that of untreated control samples, after subtraction of the fluorescent signal of a negative control without cells.

To determine  $IC_{50}/IC_{25}$  in each group (with or without USMB), the cell viability percentages were calculated with reference to their own controls, i.e. no exposure to bleomycin but with or without USMB depending on the group. The  $IC_{50}$  was then defined as the concentration resulting in 50% inhibition of cell viability, likewise, the  $IC_{25}$  was the concentration resulting in 25% inhibition of cell viability. The method to determine  $IC_{50}/IC_{25}$  is described in 2.11.

### Apoptosis assay

In addition to the viability assay, an apoptosis assay was performed to determine the effect of USMB on bleomycin efficacy. The apoptosis and viability assays were performed

in separate experiments. 48 hours after adding medium with or without bleomycin and with or without microbubbles to the Twentycell, the medium and detached cells were collected from each lumox<sup>®</sup> dish. The remaining cells were detached from the lumox<sup>®</sup> membrane with trypsin/EDTA and added to the rest of the medium. Residual EDTA was removed by centrifugation and washing with PBS. The cells were resuspended in binding buffer with a concentration of  $\sim 1 \times 10^6$  cells/mL and then stained and incubated for 15 minutes with Annexin V. The cells were washed, resuspended in binding buffer, stained with Propidium Iodide (PI) and then kept on ice protected from light.

Within 4 hours, the samples were analyzed by flow cytometry using the BD FACSCanto<sup>™</sup> II Cell Analyzer, for PI (488nm) and Annexin V (633nm). Compensation was performed with samples stained with only PI and only Annexin V. The FACS data was analyzed using FlowJo 10.7.1. The four quadrants (live, early apoptotic, late apoptotic, and necrotic cells) were distinguished based on a control sample containing 50% necrotic and 50% live cells.

### Statistical analysis

Statistical analysis was performed in GraphPad Prism 8.3.0. For the fluorescence microscopy data and cell viability data we used the Kruskal Wallis test and a Dunn's test for multiple comparisons. The absolute  $IC_{50}$  for bleomycin with and without USMB was determined with a nonlinear least-squares regression of the bleomycin concentration versus the response (cell viability percentage) with the Hill's slope fixed at -1.0 and the top and bottom of the fitted curve restrained to 100 and 0 %, respectively. To compare the  $IC_{50}$ 's of both groups we used the extra sum of squares F-test. Because the  $IC_{50}$ 's had a very broad confidence interval we also calculated the  $IC_{25}$  for both groups with the same method. A p-value < 0.05 was considered to indicate a statistically significant difference.

## RESULTS

### Acoustic characterization of clinical US system

The acoustic output of the clinical ultrasound system as well as the US beam profile were characterized for the probes S5-1, C5-1 and C9-4. The acoustic output as function of different US settings is summarized in **Table 1**. With increasing SV, the number of cycles per pulse increased. The maximum MI (and therefore pressure) increased with decreasing SV. **Figure 2** shows the characteristics of the S5-1 probe. **Supplementary figures 1-3** show these characteristics for the other clinical US probes and the single-element transducer. In PW mode the S5-1 probe emits a US pulse with a Gaussian shaped envelope with a center frequency of 1.6 MHz and an increasing number of cycles when SV is increased (**Figure 2(A and B)**). The pressure field maps in PW mode (**Figure**

**2(C)** show that the ultrasound energy is limited to a beam with dimensions of 5.0 mm by 6.3 mm (Full width at half maximum) at the middle of the sample volume. **Figure 2(D)** demonstrates the difference in signal intensity in the Twenticell (red rectangle) before and after USMB therapy (15 sec sonication at MI 0.6, SV 20mm), due to microbubble disruption.

**Table 1.** US parameters and corresponding measurements on clinical US system

### Bubble response to US

**Figure 3** shows the attenuation coefficient for SonoVue for different pulse envelop shapes and lengths as a function of acoustic pressure and frequency.

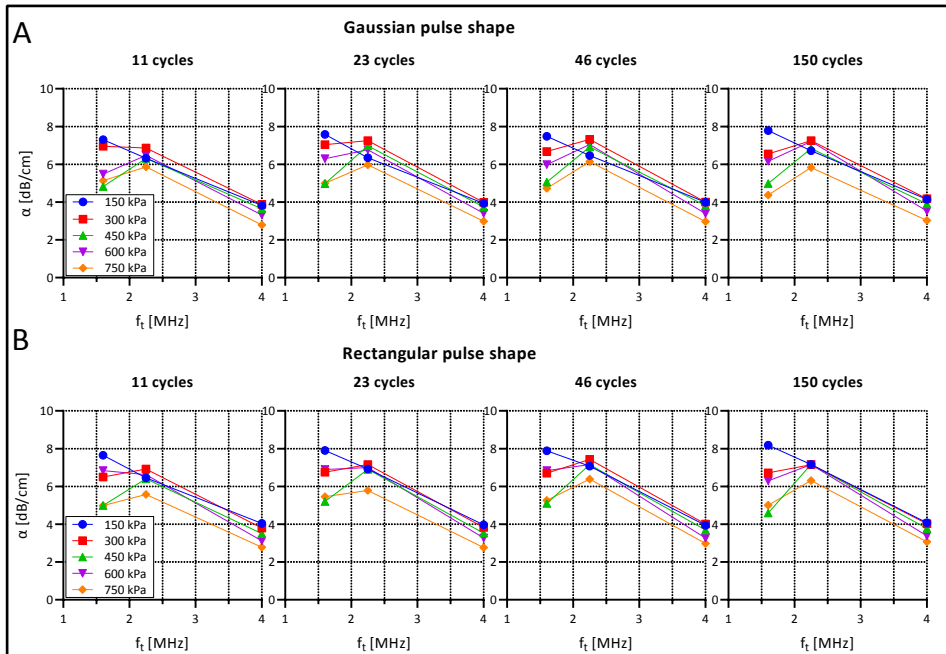

The attenuation curve shows a maximum at 1.6 and 2.25 MHz indicating a maximum attenuation for the frequencies that are closest to resonance frequency of SonoVue.

The attenuation coefficient decreased, mainly at 1.6 MHz, as the excitation pressure was increased from 150 kPa to 750 kPa. This observation is not consistent with previous experimental measurements of pressure-dependent attenuation coefficients [38, 39]. As we have observed no visible trace of bubble destruction based on the repeated pulses, the refreshment rate of the bubble solution appears to be sufficient, and we ascribe this effect to radiation forces and bubble clustering. As such, this effect may be even more prominent at the higher concentrations used for the cell experiments.

When comparing rectangular versus Gaussian envelop shapes no differences were observed in attenuation coefficient. Furthermore, the number of cycles per pulse did not influence the attenuation coefficient.

**Figure 2.** Characteristics of S5-1 probe (A) Shape of emitted ultrasound pulses in PW mode for different pulse length. (B) Frequency spectrum of SV 20 mm pulse. (C) Pressure field maps in PW mode. (D) B-mode images of TwentiCell (red rectangle) containing microbubbles, before and after USMB therapy (15 seconds at MI 0.6, SV 20mm). SV: sample volume; f: frequency; a.u.: arbitrary units;  $P_{neg}$ : Peak negative pressure; USMB: ultrasound and microbubbles.

**Figure 3.** Attenuation coefficient  $\alpha$  for SonoVue for different pulse shapes and lengths as a function of acoustic pressure and frequency. **(A)** Gaussian pulse envelop (as used in PW Doppler mode on clinical US system). **(B)** Rectangular pulse envelop (as used in single-element set-up).  $\alpha$ : attenuation coefficient;  $f_t$ : transmit frequency.

### Effect of transducer and ultrasound settings on USMB efficiency

The USMB efficacy for each transducer as function of acoustic pressure is shown in **Figure 4(A)**. The percentage of SG positive cells increased significantly with the addition of USMB treatment using the S5-1 (1.6 MHz) or C5-1 (2.25 MHz) probes and was comparable (C5-1) or even higher (S5-1) than with the single element transducer (**Figure 4(A)**). In contrast, no relevant SG uptake was observed using the C9-4 probe (4.0 MHz). For the S5-1 probe a similar percentage of SG positive cells (i.e.  $\sim 30\%$ ) was observed for all pressures above 0.30 MPa. In contrast, the C5-1 probe and the single element transducer showed a pressure-dependent increase of SG positive cells, reaching  $\sim 30\%$  and  $15\%$  at the highest pressures, respectively.

The effect of pulse length for the S5-1 and C5-1 is shown in **Figure 4(B)**. For the S5-1 probe at maximum pressure (0.59 MPa), a similar percentage of SG positive cells (i.e.  $38\%$ ) was observed independent of pulse length. For the S5-1 probe at a lower pressure (0.38 MPa) only a higher number of cycles per pulse (SV 20 and 10mm) caused a significant increase in SG positive cells compared to USMB untreated samples. For the C5-1 probe at maximum pressure (0.59 MPa), the percentage SG positive cells increased with increasing pulse length.

**Figure 4(C)** shows representative fluorescence images of the ROI after USMB therapy

with S5-1 probe at MI 0.6 and SV 20mm, stained with SG and DRAQ5.

**Figure 4.** Effect of transducer and ultrasound settings on USMB efficiency measured by percentage SG positive cells in ROI. **(A)** Effect of pressure on USMB efficiency with (from left to right) clinical US system with S5-1, C5-1 or C9-4 probe and custom-build US set-up with single-element transducer. **(B)** Effect of pulse length on USMB efficiency of clinical US system with (from left to right) S5-1 probe at maximum pressure (MI 0.6, P<sub>neg</sub> 0.59 MPa), S5-1 probe at MI 0.4 (P<sub>neg</sub> 0.38 MPa) and C5-1 probe at maximum pressure (MI 0.8, P<sub>neg</sub> 0.59 MPa). SG uptake in 35.1% of cells. ns: not significant; SG: SYTOX™ Green; USMB: ultrasound and microbubbles.

**Effect of USMB on bleomycin efficacy**

To confirm that USMB therapy improved the efficacy of bleomycin, the IC<sub>50</sub> and IC<sub>25</sub> of bleomycin were determined, with or without USMB with the single-element transducer **(Figure 5(A))**. The absolute IC<sub>50</sub> of bleomycin decreased from 791.8µg/L (95% CI 578.8 - 1125) to 173.2µg/mL (95% CI 96.06 - 333.0) when combined with USMB (P<sub>neg</sub> = 0.56 MPa). The USMB-induced difference in IC<sub>50</sub> was statistically significant (p < 0.0001). The IC<sub>25</sub> decreased significantly from 263.9 µg/mL (95% CI 192.9 - 374.8) to 57.73 µg/mL

(95% CI 32.02 - 111.0) ( $p < 0.0001$ ). Note that both curves have their own reference of 100% cell viability without bleomycin (i.e. with or without USMB), which guarantees that the observed differences in  $IC_{25}$  and  $IC_{50}$  are not a direct cytotoxic effect of USMB alone, but due to enhanced intracellular delivery of bleomycin causing more cell death at the same concentration. The effect of USMB treatment in the absence of bleomycin is illustrated in **Figure 5(B)**. Cell viability did not significantly decrease with increasing acoustic pressure.

The apoptosis assay confirmed the decreasing cell viability with addition of USMB to bleomycin. **Figure 5(C)** shows the mean distribution of cells over the quadrants after USMB with the single-element transducer. Representative dot plots of flow cytometry analysis from experiments with two or three samples per group are shown in **Figure 5(D)**. Increased apoptosis was observed 48 hours after bleomycin plus USMB ( $P_{neg}$  0.56 MPa), compared to untreated samples or samples treated with either bleomycin alone or USMB alone.

#### Effect of USMB with clinical US system on bleomycin efficacy

**Figure 6** demonstrates that the cytotoxicity of bleomycin could also be increased by USMB therapy using the clinical US system with the S5-1 probe. The combination of bleomycin (10  $\mu\text{g}/\text{mL}$ ) and USMB with significantly decreased the cell viability compared to untreated samples at the three pressures used, while either bleomycin alone or USMB alone had little effect (**Figure 6(A)**). Addition of USMB at  $P_{neg}$  0.59 MPa (MI 0.6) to bleomycin, also significantly decreased the cell viability from 94 to 47% compared to samples treated with bleomycin alone. At the lower pressures we also observed a decrease in cell viability when USMB was added to bleomycin (from 94% to 57% at  $P_{neg}$  0.46 MPa and to 54% at  $P_{neg}$  0.38 MPa), however these changes were not significant.

The results of the apoptosis assay again confirmed the decrease in cell viability with the combination of bleomycin and USMB. **Figure 6(B)** shows the mean distribution of cells over the quadrants after USMB with the clinical US system and S5-1 probe. Representative dot plots of flow cytometry analysis from experiments with two or three samples per group are shown in **Figure 6(C)**. Besides increased apoptosis, similar to what was seen with the single element transducer, also increased necrosis (11.4 % versus 8% with bleomycin alone) was observed after bleomycin plus USMB with the clinical US system.

**Figure 5.** Cell viability after bleomycin +/- USMB using the custom-build US set-up with single element transducer. **(A)** Nonlinear least-squares regression of bleomycin concentration versus cell viability percentage (relative to samples without bleomycin), with (red circles) and without (blue triangles) USMB at  $P_{neg}$  0.56 MPa. Symbols and bars indicate mean and SD ( $n \geq 3$ ). **(B)** Cell viability with (red, circles) or without (blue, triangles) USMB alone at three pressures, symbols indicate individual measurements and bars indicate mean and SD ( $n \geq 6$ ). **(C)** Flow cytometry analysis of Propidium Iodide and Annexin V staining 48 hours after bleomycin 10 µg/mL or NaCl 0.9% with or without USMB at  $P_{neg}$  0.56 MPa. Pie charts represent the mean of the samples with  $n=2$  or (for bleomycin + USMB samples)  $n=3$ . **(D)** Representative dot plots of flow cytometry analysis shown in **(C)**. More apoptosis was observed after bleomycin + USMB. Bleo: bleomycin;  $P_{neg}$ : Peak negative pressure; USMB: ultrasound and microbubbles.

**Figure 6.** Cell viability after bleomycin +/- USMB using the clinical US system with S5-1 probe **(A)** Bleomycin 10  $\mu\text{g}/\text{mL}$  or NaCl 0.9% with (red, circles) and without (blue, triangles) USMB at three pressures (MI 0.6, 0.5 and 0.4). Symbols indicate individual measurements and bars indicate mean and SD ( $n \geq 3$ ). \*  $p < 0.05$  \*\*  $p < 0.01$  **(B)** Flow cytometry analysis of Propidium Iodide and Annexin V staining 48 hours after bleomycin 10  $\mu\text{g}/\text{mL}$  or NaCl 0.9% with or without USMB at  $P_{\text{neg}}$  0.59 MPa (MI 0.6), pie charts represent the mean of the samples with  $n=2$  or (for bleomycin + USMB samples)  $n=3$ . **(C)** Representative dot plots of flow cytometry analysis shown in **(B)**. More apoptosis and necrosis was observed after bleomycin + USMB. Bleo: bleomycin; MI: Mechanical Index;  $P_{\text{neg}}$ : Peak negative pressure; USMB: ultrasound and microbubbles.

## DISCUSSION

In preclinical studies, USMB therapy has overcome biophysical barriers that cause heterogeneous and/or insufficient drug delivery to tumor cells, thereby increasing intracellular uptake and enhancing the efficacy of several drugs. Although the first clinical studies have been published, clinical translation of USMB therapy is still limited. We hypothesize that clinically available US systems with fixed and validated parameters will accelerate clinical translation. To pave the road forwards, we characterized several clinical probes and US-parameters and showed that effective USMB therapy can be performed *in vitro* with a non-modified clinical US system and EMA/FDA approved microbubbles.

After evaluation of three clinical US probes and a set of parameters, the US probe with the lowest center frequency (i.e. 1.6 MHz for S5-1) showed the highest USMB efficiency as measured by SG uptake. This was consistent with literature showing that a frequency close to the resonance frequency of SonoVue (i.e. 1.6–3.1 MHz depending on the bubble size [40]) was the most efficient [36, 41]. Moreover, at lower pressures a larger number of cycles per pulse was beneficial. This was also seen in previous studies, although some conflicting results have been reported and intermediate pulse lengths might be optimal [36, 42-45]. The SG uptake levels that we achieved with the clinical US system were comparable, or even higher depending on the transducer and US-settings, to those obtained with a custom-built US set-up with a single-element transducer and optimized US parameters [37]. A possible explanation for these higher uptake levels would be that the gradually increasing pressure in the Gaussian pulse shape of the PW Doppler mode leads to a more efficient bubble response than the block shaped pulse of the single-element transducer. However, we found no evidence in our microbubble attenuation experiments to support this. Since the experimental set-up and handling were equal for both set-ups and the frequencies of S5-1 probe (1.6 MHz) and the transducer of the custom-build set-up (1.5 MHz) were very similar we conclude that the improved USMB efficiency using the S5-1 and C5-1 probes must be due to other factors that we did not investigate (e.g. PRF, non-linear US propagation and beam shape). Future experiments including cavitation measurements might further elude the underlying mechanisms.

In this study we used the PW Doppler mode for USMB therapy, in contrast to previous clinical studies that used B-mode and contrast mode, or color power angiography doppler (Clinicaltrials.gov NCT03385200, personal communication). The first clinical trial used B-mode, with settings optimized to achieve a linear acoustic signal, the maximum possible duty cycle (1%), center frequency of 1.9 MHz and MI 0.4 (measured pressure 0.27 MPa  $P_{neg}$ ) [33, 34]. The second clinical trial did not provide details about specific ultrasound settings used, apart from the MI that varied between 0.4 and 1.0 [35]. Although not clinically applied, PW Doppler on a clinical US system has been evaluated in a mouse study for blood-brain barrier disruption using a variation of clinically available

US parameters (e.g., frequency 5.0-8.0 MHz) [46]. As demonstrated by the pressure fields (**Figure 2(B)** and **Supplementary figures 1 and 2**), PW Doppler mode creates a very small (5.0 mm by 6.3 mm for S5-1) USMB therapy focus, much smaller than the treatment area described in the previous phase 1 clinical trial (i.e.  $69 * >100 * 1.0 \text{ mm}^3$ ) [33]. Therefore, PW Doppler mode is well suited for precisely targeted treatment. In addition, the use of a clinical US imager provides the opportunity to perform imaging and therapy consecutively, thus performing image-guided therapy.

This is to our best knowledge the first *in vitro* study that evaluates the effect of USMB therapy using a clinical US system and approved SonoVue microbubbles, while performing extensive evaluation of multiple transducers and US settings available in PW Doppler mode. Previously, *in vitro* studies have used Optison microbubbles for USMB therapy with clinical US systems in spectral Doppler, 2-D scan mode or harmonic imaging (Octave) mode at a frequency of 1.5 of 3.5 MHz [47, 48]. Compared to our findings, these methods resulted in a lower USMB efficacy (below 10%), which could indicate that PW Doppler mode is more effective. Other *in vitro* studies have used a diagnostic US system to evaluate microbubble response, while therapeutic USMB was omitted or administered with a non-clinical transducer [45, 49, 50]. USMB therapy would benefit from simultaneous (real-time) cavitation monitoring with a single transducer of a clinical US system. This solution would allow for monitoring of bioeffects [51-54], while using standardized US settings. Currently, simultaneous USMB therapy and cavitation monitoring is not yet available on clinical US systems, although our work and the work by Keller et al. show it is technically feasible [50]. Meanwhile, our approach leads to a standardization of US parameters used and may be immediately used in clinics.

Next to correct determination and extensive reporting of the US exposure conditions used [55], which has been performed for clinical US systems, and performing cavitation monitoring during treatment, the use of mono-disperse microbubbles will further reduce the disparity of experimental results. Currently, commercial, clinically approved microbubbles are polydisperse. However, recent papers show that monodisperse microbubbles have a more uniform acoustic response and an increased imaging sensitivity [56, 57], which will also improve the reproducibility and controllability of USMB therapy.

We hypothesized that USMB therapy with a clinical US system and approved microbubbles could improve the local efficacy of chemotherapy. Both the Alamar Blue assay and the flow cytometry analysis showed that *in vitro* USMB therapy with both the clinical and the custom-built US system clearly increased the cytotoxicity of the hydrophilic drug bleomycin. However, our absolute  $IC_{50}$  values have to be interpreted with caution. The nonlinear regression model included only one concentration above the  $IC_{50}$  for the cells treated with USMB, and none for the cells treated without USMB. This led to a large confidence interval in the  $IC_{50}$  estimations. Unfortunately, due to a worldwide shortage of bleomycin [58] it was not feasible to increase the concentration further, in order to

achieve an effect closer to 100% cell death. For this reason, we additionally calculated the  $IC_{25}$  of each group and compared those. These data confirmed the increased cytotoxicity of bleomycin with the addition of USMB therapy.

While in clinical practice bleomycin is only used in a few tumor types, these results could be extended to a wide range of treatments with other hydrophilic chemotherapeutics. For example, based on previous *in vitro* results of Lammertink et al. future patients receiving chemotherapy or chemoradiation containing cisplatin could benefit from the addition of local USMB therapy [30]. Furthermore, USMB therapy could be used to enhance the effect of therapeutic antibodies or nanoparticles [25, 59-62]. Finally, clinical studies evaluating the potential of USMB therapy in addition to radiotherapy in the absence of drugs are ongoing [63] (Clinicaltrials.gov NCT04431674, NCT04431648).

The custom-made TwentiCells used in our experiments are an attractive alternative to for example CLINiCells and provide the opportunity to perform USMB experiments with a large number of independently sonicated samples, while using small volumes of medium, drugs and microbubbles. In addition, the TwentiCells hardly interfere with the applied ultrasound field, a common limitation of *in vitro* US set-ups [64, 65]. To obtain reliable and reproducible results we standardized the procedures throughout our experiments as much as possible. This is essential, as many parameters (e.g. position of cells with respect to transducer, time between preparation and use of microbubbles, time between addition of microbubbles and sonication [45, 66]) can affect outcome of USMB therapy.

To conclude, we have shown that a non-modified clinical US system in combination with clinically approved microbubbles can be used to perform highly effective USMB therapy *in vitro*. The next step towards clinical translation is to apply these methods *in vivo*. Future trials should determine the safety and efficacy of our methods and US parameters in patients.

## AUTHOR CONTRIBUTIONS

JM, CB, CM, and RD conceived and designed the analysis. JM, CR, and RD collected the data. BE, HV, GL, and RD contributed data or analysis tools. JM, BE, and RD performed the analysis. JM and RD wrote the manuscript. CR, BE, HV, GL, CB, and CM revised and approved the submitted version.

## FUNDING

The contribution of CR to this research was funded by the European Union's Horizon 2020 research and innovation program under the Marie Skłodowska-Curie grant agreement No. 722717.

## ACKNOWLEDGEMENTS

- The researchers and technicians of the department of Pharmaceutics, Utrecht University, for the opportunity to use their laboratory facilities and for their support
- Kim van der Wurff - Jacobs for her assistance with the flow cytometry experiments.
- Corlinda ten Brink from Cell Microscopy Core, Department of Cell Biology, Center for Molecular Medicine, UMC Utrecht, for use of the LSM700 and technical support.
- Sandra Bruggink for her work on the bleomycin  $IC_{50}$  experiments during her internship.

## CONFLICTS OF INTEREST

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

## ABSTRACT

To investigate the feasibility and tolerability of ultrasound and microbubbles (USMB) enhanced chemotherapy delivery in patients with head and neck cancer, we performed a veterinary trial in feline companion animals with oral squamous cell carcinomas. Five cats without treatment options besides supportive care were treated with a combination of bleomycin and USMB therapy three times with 1 week intervals, using the Pulse Wave Doppler mode on a clinical ultrasound system and EMA/FDA approved microbubbles. They were evaluated for adverse events, quality of life, tumour response and survival. Furthermore, tumour perfusion was monitored before and after USMB therapy using contrast-enhanced ultrasound (CEUS). USMB treatments were feasible and well tolerated. Among the four cats treated with optimized US settings, three had stable disease at first, but showed disease progression 5 or 11 weeks after first treatment. One cat had progressive disease one week after the first treatment session, maintaining a stable disease thereafter. Eventually, all cats showed progressive disease, but each survived longer than the reported median overall survival time of 44 days. CEUS performed immediately before and after USMB therapy suggested an increase in tumour perfusion based on an increase in median area under the curve (AUC) in 5 out of 9 evaluated treatment sessions. In this small hypothesis-generating study USMB plus chemotherapy was feasible and well-tolerated in a feline companion animal model and showed potential for enhancing tumour perfusion in order to increase drug delivery. This could be a step forwards toward clinical translation of USMB therapy to human patients with head and neck cancer or other tumours with a clinical need for locally enhanced treatment.

USMB, bleomycin, contrast-enhanced ultrasound, veterinary medicine, companion animals, feline, oral squamous cell carcinoma, head and neck cancer

## INTRODUCTION

Head and neck squamous cell carcinoma (HNSCC) is diagnosed in approximately 900,000 patients yearly worldwide, 5% of all cancer diagnoses [1]. Most patients present with locally advanced disease [2, 3], and because primary surgery is often not possible or is expected to result in unacceptable morbidity, they are often treated with combination therapies including radiotherapy, chemotherapy and targeted therapy [4]. Even so, up to half of the patients develop (often incurable) local recurrences [5, 6] and treatment is associated with acute and long-term toxicity [7-9]. Primary chemoradiotherapy with cisplatin as a radiosensitizer is often used in locally advanced HNSCC. Higher cumulative cisplatin dose is associated with better local control and to some extent longer overall survival [7, 10], but due to local and systemic toxicities 30-50% of patients cannot complete all planned cycles of cisplatin [7, 11]. This emphasizes the need for improved local tumour delivery of cisplatin, without increasing the chemotherapy dose in healthy tissues. To this end, a method to increase local drug delivery without increasing systemic toxicity could lead to improved outcomes of (chemo)radiotherapy.

We hypothesize that this goal could be achieved by means of ultrasound and microbubbles (USMB) therapy. Microbubbles are micron-sized gas-filled bubbles used for contrast-enhanced ultrasound (CEUS) imaging [12, 13]. When exposed to ultrasound, stable or inertial cavitation of microbubbles can occur, creating a number of biological effects collectively termed sonopermeation [14, 15]. USMB therapy has been shown to improve drug delivery for various molecules *in vitro* and *in vivo* [15]. In particular, addition of USMB therapy improved the effect of chemotherapy or chemoradiotherapy with cisplatin on HNSCC cells *in vitro* [16]. However, pre-clinical studies often use custom-made setups and a large variety of US parameters, which cannot easily be translated to the clinic. Thus far, USMB therapy has not been studied in human head and neck cancer patients. Most (ongoing) clinical studies of USMB therapy have focused on brain applications, using dedicated systems not applicable to other organs [17-19]. Meanwhile, studies outside the brain are limited to small numbers of patients with pancreatic cancer, liver metastases and breast cancer, which all used different ultrasound settings [20-23]. Using clinically available US systems and settings (preferably uniform US settings across clinical studies) combined with FDA/EMA approved microbubbles can help make this technique more accessible.

In order to bridge the gap between human HNSCC patients and *in vitro* and small animal studies, we performed a veterinary feasibility trial. Cats are a suitable model because they are big enough to use clinical ultrasound equipment, and because many pathophysiological and genetic similarities exist between humans and cats [24-26]. Furthermore, feline oral squamous cell carcinoma (FOSCC) is very common in aged cats [27]. Like human patients, cats often present with advanced stage disease [28] and often succumb to local disease progression, rather than metastatic disease [26, 29]. Standard of care treatment options are similar to the human setting: when surgery is not an option, primary radiotherapy can

be combined with chemotherapy as a radiosensitizer [30-32]. Supportive care (antibiotics and/or anti-inflammatory drugs) results in a median overall survival of approximately 44 days [33]. The platinum-based drug cisplatin, often used in human patients, creates unacceptable toxicity in cats when systemically administered [34]. Instead, bleomycin is a well-tolerated cytostatic drug in cats, but has limited efficacy because efficacy is dependent on intracellular uptake, which is complicated by the hydrophilic nature and dependence on protein receptors to enter the cell [35, 36]. To improve the efficacy of bleomycin, electroporation can be used, also known as electropermeabilization: making cell membranes reversibly permeable by application of an electrical current [37, 38]. In a feline study the combination of bleomycin plus electroporation resulted in an overall response of 89%, compared to 33% with bleomycin alone [39] but it causes unpleasant muscle contractions and possibly an increased risk for cardiac arrhythmias [39, 40]. After electroporation of large bulky tumours, patients could be more susceptible to adverse events such as tumour lysis syndrome, thromboembolism, disseminated intravascular coagulation, delayed wound healing and local necrosis [38]. These adverse effects have not been described for USMB therapy. A safety study performing USMB therapy on the livers of eight pigs with a clinical US system did not result in any clinical adverse events or histopathological damage to the liver [41]. Meanwhile, CEUS imaging has been studied in hundreds of cats, without significant adverse effects [42-47]. *In vitro*, USMB therapy was shown to enhance local bleomycin effect using a clinical US system with standard settings and clinically available microbubbles [48].

The combination of bleomycin with USMB therapy using a clinically available US system and microbubbles could provide a low-toxicity low-burden additional treatment option for these cats as well as a step towards clinical translation to human head and neck cancer patients. The primary objectives of this veterinary study were to evaluate tolerability and feasibility of bleomycin plus USMB therapy while using a clinical US system and microbubbles, while secondary objectives were to assess tumour response, survival and effect of USMB therapy on tumour perfusion.

## METHODS

### Subjects

Five cats with spontaneously arisen FOSCC were eligible for inclusion in our single-arm prospective study. They had at least cytologically proven squamous cell carcinoma, without other suitable treatment options except for palliative care and informed consent was provided by the pet owner. Exclusion criteria were life-threatening comorbidities leading to a life expectancy of less than 1 month, contraindications for anaesthesia and known hypersensitivity to bleomycin or any of the excipients of SonoVue (Bracco).

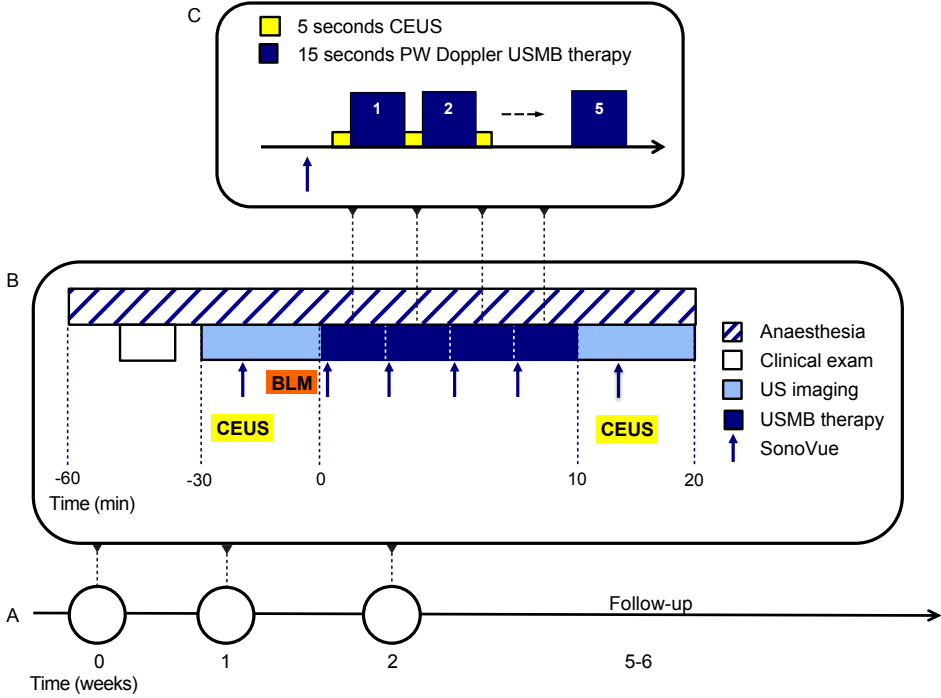

## USMB treatment

Each cat was treated three times, once per week (see **Figure 1** for timeline of treatment procedures). US imaging and treatment were performed using an EPIQ5 or EPIQ7 imager with a C9-2 transducer (Philips) complemented by a L18-5 transducer solely for US imaging. A tissue mimicking gel was used to obtain enough distance between probe and cat for the region of interest to be outside the near field of the transducer. The treatment was performed under general anaesthesia, while continuously monitoring vital signs. USMB therapy was started 7 minutes after intravenous (i.v.) injection of bleomycin (10.000 IU/m<sup>2</sup>). Microbubbles (SonoVue, Bracco, conc. 1-5 x 10<sup>8</sup> bubbles/mL, dosage 0.1 mL/kg body weight per bolus injection) followed by a 1.5mL saline flush were administered through an i.v. catheter of at least 22 gauge. When the microbubbles appeared in the tumour (based on CEUS imaging), treatment of the oral tumour was started in Pulse Wave (PW) Doppler mode. PW Doppler for 15 seconds was alternated with CEUS imaging for five seconds (to allow for complete reperfusion of the tumour with fresh microbubbles) and repeated five times per MB injection, as by that time no more MBs were visible on CEUS images. This process was repeated three times to a total of four microbubble injections for therapy. During USMB therapy the probe was hand-held by a veterinary radiologist and the Sample Volume of the PW Doppler was slowly moved to treat the entire tumour. Before a new microbubble injection, transducer orientation was changed to treat a different cross-section of the tumour. Optimized PW Doppler settings for USMB therapy and CEUS parameters used in cats 2-5 are shown in **Table 1**. These procedures have been optimized during treatment of cat 1 and the first treatment session of cat 2.

**Table 1** Optimized Pulsed Wave Doppler settings for USMB therapy and CEUS parameters used in cats 2-5

Parameter	Indication / setting on EPIQ5 or EPIQ7	Value
Optimized Pulse Wave (PW) Doppler settings for ultrasound and microbubble (USMB) therapy		
Frequency	C9-2 probe in PW mode	2.9 MHz
Pulse length	Sample volume: 7.5 mm (maximum)	21 cycles per pulse
Pulse Repetition Frequency	Scale:-4 – 4 cm/sec (minimum)	0.4 kHz
Mechanical index	Relative intensity:- 10 dB *	MI 0.3-0.4 at target depth
Contrast enhanced ultrasound (CEUS) settings		
Mechanical Index (MI)	MI in CEUS mode <0.1	CEUS MI = 0.06
Gain	Gain slightly above the noise floor in absence of microbubbles and kept constant	Gain = 45%
Dynamic range (compression)		Dynamic range = 50
Focus position	Focus positioned at the target or a bit deeper (2/3 of image depth)	Adjusted per treatment session and moved during USMB therapy
Time Gain compensation (TGC)	All switches in central position	All switches in central position
Persistence		Off

\* In cat 4 relative intensity was increased to -7dB to account for enhanced attenuation due to extensive bone invasion and fibrous tissue formation of bone.

**Figure 1** Ultrasound and microbubbles (USMB) treatment procedures. A: each cat is treated three times, once per week. B: Each treatment session is performed under general anaesthesia and starts with a clinical exam. Ultrasound imaging and contrast-enhanced ultrasound imaging (CEUS) are performed before and after USMB therapy. 7 minutes after intravenous injection (i.v.) of bleomycin (BLM), USMB therapy is started by i.v. bolus injection of SonoVue microbubbles. C: when the microbubbles appear on the CEUS image, 15 seconds of Pulsed Wave (PW) Doppler are alternated by 5 seconds of CEUS imaging. This is repeated five times per microbubble injection, for a total of four microbubble injections.

**Other study procedures**

Primary endpoints were tolerability and feasibility, assessed at baseline and 1, 2 and 5 weeks after the first USMB therapy. Tolerability was assessed by reporting adverse events, clinical performance score and quality of life. Adverse events were reported by VCOG Common Terminology Criteria for Adverse Events version 1.1, clinical performance (CPS, 0-5 [49]) was monitored and quality of life (QoL) was assessed using a 16-item owner-completed questionnaire, translated to Dutch with permission from Adelphi UK and Zoetis [50]. Feasibility was assessed by the amount of time needed for study procedures and the ability to complete study treatments per cat. Secondary endpoints were clinical response (including tumour response and survival) and the effect of USMB therapy on tumour perfusion. Tumour response was evaluated by calliper measurements at baseline and 1, 2 and 5 weeks after the first USMB therapy. Overall survival was registered from first USMB therapy until death. To evaluate the effect of USMB on tumour perfusion, CEUS was performed immediately before and after USMB treatment using a mechanical arm

to position the US probe and with the same volume of MBs used for USMB therapy. All equipment settings (MI = 0.06, gain = 45%, TGC at central position, dynamic range = 50, persistence set to Off, see **Table 1** for more details) were kept consistent for all cats and between CEUS measurements before and after USMB therapy.

### Quantitative CEUS evaluation

Time-intensity curve analysis was performed on contrast loops before and after USMB treatment to evaluate changes in tumour perfusion using in-house developed Matlab software. Image data post-processing consisted of 5 steps. First, the DICOM images, transferred from the ultrasound imager, were loaded using the standard Matlab DICOM reader and the colour images were converted into greyscale. Second, the onset of the contrast enhancement was determined. Third, from the images obtained before the onset of contrast enhancement, an averaged image (background image) was calculated and this background image was subtracted from the original images. Fourth, the temporal data was smoothed using a moving-average filter. Finally, peak intensity (PI: maximum signal intensity, also known as peak enhancement), time-to-peak (TTP: time between first arrival of contrast and reaching maximum intensity) and area under the curve (AUC: area under the time versus signal intensity curve) maps were calculated for each pixel [51]. Using a region of interest (ROI) with the same size before and after USMB therapy, the parameters were visualized with a colour scale and plotted in histograms to compare results pre and post USMB therapy. Pixels with high signal intensity already before onset of the contrast enhancement (e.g. regions containing bone) were excluded for analysis. The percentage of pixels reaching >25% of the peak intensity in that ROI were compared between before and after USMB with a paired samples Wilcoxon test. A two-sided p-value < 0.05 was considered significant. Median values of the AUC in the ROI are compared after discarding AUC values  $\leq 0$ .

## RESULTS

### Baseline characteristics

We included five feline patients with tumours located in different oral regions.

**Table 2** describes relevant patient and tumour characteristics. All cats were domestic shorthairs over 10 years of age, with T2 or T3 tumours [52], two cats had known lymph node metastases and one cat had pulmonary metastases. All cats received supportive care with antibiotics and pain medication, two cats required assisted feeding (oesophageal feeding tube). Two cats received concomitant treatment for hyperthyroidism (thiamazole or carbimazole).

**Table 2** Relevant patient and tumour characteristics, including survival

Patient	1	2	3	4	5
Sex	male	male	male	female	male
Age at inclusion (years)	11	11	18	15	14
Body weight at inclusion (kg)	2.8	7.2	3.4	2.8	6.7
TNM stage [52]	T2N1M0	T2bN0M1 (lungs)	T2bN0M0	T3bN0Mx	cT3N1Mx
Tumour location	tongue, frenulum, and sublingual soft tissue	right maxilla	lip and cheek extending into corner of mouth and caudal maxilla	rostrally in the mouth, infiltrated into mandibula	tongue base and floor of mouth
Supportive care measures	Antibiotics Analgesics (NSAIDs, tramadol) Tube feeding	Antibiotics Analgesics (NSAIDs)	Antibiotics Analgesics (NSAIDs, gabapentin)	Antibiotics Analgesics (NSAIDs, gabapentin)	Antibiotics Analgesics (NSAIDs, buprenorphine) Tube feeding
Concomitant drugs	Treatment for hyperthyroidism (carbimazole) initiated during study	Treatment for hyperthyroidism (carbimazole) initiated during study	-	-	-
Survival (days)	46	85	64	56	57
Death	euthanasia	euthanasia	euthanasia	euthanasia	natural death

### Bleomycin plus USMB therapy was tolerable without serious adverse events

The USMB treatments were well tolerated. All cats experienced adverse events, but these were not severe, mainly grade 1 or 2 (**Table 3** lists all adverse events). In addition, adverse events were considered related to anaesthesia (e.g. constipation, fatigue, hypotension, hypothermia, lethargy and vomiting), comorbidity (untreated hyperthyroidism) or progressive tumour growth (e.g. anorexia, generalized weakness, fatigue haemorrhage from the tumour, pain, ptyalism, skin ulceration, soft tissue necrosis and weight loss). One cat had localized alopecia and erythema related to an i.v. catheter. Another cat experienced a mild sinus tachycardia during the treatment session, which could be related to USMB therapy or anaesthesia but resolved spontaneously. Clinical performance score (CPS) did not change from 0 (“fully active”) in cat 1-3. In cat 2 it temporarily decreased one point in week 1 but then recovered to “fully active” and in cat 5 it decreased from 1 (“slight tiredness/dyspnoea after severe exertion”) to 3 (“Spontaneous tiredness or dyspnoea without exertion, lies often on the floor.”) after 5 weeks. **Figure 2** shows QoL scores. QoL remained stable in cats 1-3, and decreased gradually in cat 5, most likely due to tumour progression. In cat 4, QoL decreased temporarily after 1 week, due to pain and inability to eat. Supportive treatment was intensified (antibiotics restarted, pain medication increased) and the next USMB treatment was postponed for 1 week. In this week the cat’s condition and QoL improved. Since QoL

recovered quickly, infection at the tumour site was considered the most likely cause.

**Figure 2** Quality of life per cat during the study, assessed by a 16-item owner-completed measure of feline quality of life, translated to Dutch with permission from Adelphi UK and Zoetis. Higher scores indicate better quality of life. A: healthy behaviour score, B: clinical signs score, C: total score, which is the mean of healthy behaviour and clinical signs.

### Three treatment sessions of bleomycin plus USMB therapy were feasible

The study treatment was considered feasible, as all five pet owners completed all planned study visits including three USMB treatment sessions and a follow-up visit. In the four cats with optimized procedures, mean time in hospital ranged from 153 minutes in cat 4 to 207 minutes in cat 3 and mean time spent on US imaging plus therapy ranged from 44 minutes in cat 2 to 66 minutes in cat 3 (**Figure 3**).

**Figure 3** Feasibility of USMB treatment, assessed by duration of study procedures. For each procedure, the mean of three treatment days was calculated. In cat 1, treatment procedures had not yet been optimized.

### Modest clinical response

For cat 1 USMB therapy procedures had not yet been optimized, therefore its clinical response parameters are not reported here. Upon clinical examination three cats had stable disease during the three treatment sessions, but disease progression was observed at five weeks (cats 3 and 5) or 11 weeks after the first treatment session (cat 2). Cat 4 had

progressive disease one week after the first treatment session (possibly due to tumour infection), but remained stable at follow-up. Eventually, all cats had progressive disease (**Figure 4**). Three cats were euthanized respectively 85, 64 and 56 days after their first treatment session, the fourth cat died spontaneously after 57 days (**Table 2**).

**Figure 4** Estimation of tumour volumes (length \* width \* depth, percentage of baseline) in cats treated with optimized USMB settings, based on calliper measurements of the tumour prior to that day's study treatment. Cats 2, 3 and 5 had stable disease during the three treatment sessions, but showed disease progression five weeks (cats 3 and 5) or 11 weeks after first treatment (cat 2, not shown here). In cat 5, reliable tumour measurement was not possible five weeks after treatment due to tumour necrosis, but clear disease progression was noted. Cat 4 had progressive disease one week after the first treatment (possibly due to tumour infection), but remained stable at follow-up.

#### Indication of increased tumour perfusion assessed by contrast-enhanced ultrasound

CEUS imaging before and after USMB treatment was available for cat 2 (two treatment sessions), cat 3 (three treatment sessions) cat 4 (one treatment session) and cat 5 (three treatment sessions). During the first treatment session of cat 2 the US probe was unintentionally moved during CEUS acquisition and during the second and third treatment sessions of cat 4 the US system with contrast license was unavailable. **Figure 5** shows representative parametric maps in cat 3 and **Supplementary Figures 1, 2 and 3** show an overview of all cats. Based on visual interpretation of the data, peak intensity (PI) increased in six out of nine treatment sessions, decreased in two and did not change in one (**Supplementary figure 1**), while for time-to-peak (TTP) the changes were small and there was no clear trend (**Supplementary figure 2**). The median AUC in the ROI decreased in four out of nine treatment sessions (mean decrease 23.5%, range -4 to -45%) while it increased in five out of nine treatment sessions (median increase 118%, range 10 to 1039%) (**Supplementary figure 3**). These findings were supported by the percentage of pixels in the ROI reaching >25% of the peak intensity (PI). Taking nine evaluated treatment sessions together, this percentage was significantly higher after USMB therapy compared to baseline (**Figure 6**, Wilcoxon matched-pairs signed rank test  $p = 0.0391$ ).

**Figure 5** Contrast enhanced ultrasound (CEUS) parametric maps of cat 3 before (first column) and after (second column) USMB therapy for visual comparison. For each of the three treatment sessions from top to bottom the following parameters are depicted: selection of region of interest (ROI), peak intensity (PI), time-to-peak (TTP), area under the curve (AUC). Pixels with high signal intensity before administration of microbubbles (e.g. regions containing bone) were set to zero and delineated with white dotted lines. In the third column these parameters are compared in histograms between before (white) and after (blue) USMB. Note that the range of the y-axes differs between different treatment sessions. ROIs pre and post USMB are identical in size within one treatment

session and matched in position as much as possible. CEUS parameters were kept constant between treatment sessions, except in treatment session 2 of cat 3 when gain inadvertently changed from 45% (before USMB) to 49% (after USMB).

**Figure 6** Peak Intensity (PI) on CEUS in the tumour before (left) and after (right) USMB therapy. Representative maps of cat 3 in three treatment sessions (S1-3). Pixels with high signal intensity before administration of microbubbles (e.g. regions containing bone) were set to zero and delineated with red dotted lines. Percentage of pixels reaching >25% of the peak intensity (white pixels) in the ROI was significantly higher after USMB therapy compared to baseline. \* = Wilcoxon matched-pairs signed rank test  $p = 0.0391$

## DISCUSSION

We conducted a clinical feasibility study in a small cohort of non-laboratory cats, evaluating the combination of bleomycin chemotherapy and USMB therapy in cats with oral squamous cell carcinoma.

The USMB treatment sessions were feasible and well tolerated. Due to our patient selection process, all tumours were accessible to USMB therapy. Adverse events were considered related to anaesthesia, comorbidity or progressive tumour growth. We did not observe severe adverse events such as tumour lysis syndrome and disseminated intravascular coagulation, which have been described with electroporation [38]. Muscle contractions and arrhythmias are not expected to occur with USMB due to the difference in technique (ultrasound versus electrical pulses) and while vascular disruption caused by electroporation leads to acute tumour necrosis, USMB therapy may have a more gradual and tolerable anti-tumour effect. The relatively mild adverse effects of USMB therapy could reflect that it is a more tolerable and feasible option than electroporation and that there is room for treatment intensification (i.e. more treatment sessions or higher dosages of chemotherapy).

Unfortunately, all cats eventually had progressive disease based on clinical tumour

measurements. However, while the median overall survival is (historically) around 44 days with supportive care alone [33], survival in our study (albeit small and without a control group) was somewhat longer (46- 85 days). A number of hypotheses could explain why tumour responses and overall survival did not improve more substantially. First, the cavitation-induced permeabilization of cancer cells to enhance the intracellular uptake of bleomycin, which we previously demonstrated *in vitro* [48], may not have worked as well *in vivo* in our veterinary study. Unfortunately, we could not measure sonopermeation efficacy directly, i.e. by quantifying bleomycin uptake in tumours, nor indirectly, by monitoring microbubble cavitation activity during the procedure. Future application of simultaneous USMB therapy and cavitation detection could confirm our assumption and lead to further optimization of US settings. Based on previous literature this is feasible using a clinical US system, but it requires modifying predefined factory settings, which could lengthen the process towards clinical approval [53]. Second, USMB therapy will only cause sonopermeation in cells in the close proximity of microbubbles [54], i.e. endothelial cells and perhaps a few layers of tumour cells. Moreover, CEUS imaging showed that microbubbles did not spread throughout the entire tumour, which further diminishes the efficacy of sonopermeation. Third, the US parameters we used (which are standard settings for PW Doppler on the clinical US system) are likely to be suboptimal. Our previous *in vitro* results demonstrated that PW Doppler using an unmodified clinical ultrasound probe with the lowest centre frequency (S5-1 with a frequency of 1.6MHz), and the maximum number of cycles per pulse (46) resulted in the most efficient cell permeabilization [48]. While it was not feasible to use the exact same settings in this veterinary study (the S5-1 probe provided insufficient anatomical detail for target identification in the cat) we were able to closely mimic them. Optimization steps were performed during the first treatment sessions. In the first treatment session of cat 1, a lower MB dosage and the S5-1 probe were used. In all treatment sessions of cat 1 and the first treatment session of cat 2 a higher mechanical index was applied (relative intensity 0 dB, MI =1.0 - 1.2). However, decreased perfusion was noted on CEUS after USMB therapy in the first treatment session of cat 2 and therefore the relative intensity was decreased to -10 dB (i.e. MI = 0.3 - 0.4). With this drop of MI, we expect that we moved from an inertial cavitation to a stable cavitation regime. On the other hand, customized settings, such as used by Keller et al. in a healthy porcine model, may provide even better results [41]. Fourth, if sonopermeation did occur successfully, (part of) these tumours may have not been intrinsically sensitive to bleomycin, meaning that bleomycin could not kill the cell even after entering it [55]. Finally, it is possible that more bleomycin plus USMB treatment sessions are needed to obtain a durable clinical response. It would be interesting to continue study treatment until tumour progression or unacceptable toxicity in a future study. Although clinical response in our small study was modest, our findings on increased tumour perfusion after USMB treatment were promising. Most notably, we saw an increase in median AUC in 5 out of 9 treatment sessions and a significant increase in percentage of

pixels with an intensity above 25% of the PI in the ROI. Increased AUC is a typical feature of increased perfusion, which indicates increased microvascular blood volume (MBV: the proportion of tissue volume existing of blood) [56, 57]. Increased perfusion should also lead to shorter TTP, but this was not observed in our study. Improving MBV will benefit the exchange of oxygen, nutrients and drugs [58]. Note that these findings have to be interpreted with caution, as the number of evaluable treatment sessions is small and the position of the transducer (i.e. anatomical location) for CEUS ROIs before and after USMB were matched to our best effort but were never identical. More so, similar transducer positions for CEUS in different treatment sessions of the same cat are even harder to obtain. Nevertheless, previous studies have also shown that USMB therapy can affect tissue perfusion and thereby reduce tumour hypoxia. Both increased and decreased perfusion have been described, and more research is needed to determine exactly which ultrasound parameters induce either effect. Decreased perfusion seems to be related to vascular damage and platelet activation, while increased perfusion is associated with vessel dilation and (on longer term) induction of angiogenesis [59]. Improving tumour perfusion is also of interest for (chemo)radiotherapy in HNSCC since clinical response to chemoradiotherapy is negatively affected by tumour hypoxia [60], caused by structural abnormalities in the tumour vasculature [61, 62]. Consequently, increased tumour perfusion could decrease hypoxia and thereby improve outcomes. Because the effect of bleomycin is mainly limited by intracellular uptake, rather than by perfusion, only a small survival benefit can be expected in our study as a result of increased tumour perfusion. In contrast, combining USMB therapy with drugs known to be perfusion-limited could lead to improved outcome in future studies.

5

Due to the similarities between humans and cats in size and tumour characteristics, a feline veterinary trial provides a great opportunity to study feasibility of USMB therapy using an unmodified clinical US system and clinically available microbubbles. Our optimized USMB therapy procedure can easily be translated to human patients. In the future, we expect that USMB therapy, if proven safe and feasible in human patients with head and neck cancer, could be added to standard of care chemo(radio)therapy to improve local drug delivery (e.g. of cisplatin and/or cetuximab) or to standard of care radiotherapy (to enhance tumour perfusion and consequently reduce hypoxia). Finally, adding USMB therapy to chemoradiotherapy could in the future lead to adapted treatment regimens with similar efficacy while reducing systemic toxicity. Early clinical trials using USMB in combination with chemotherapy in patients with various tumour types have already shown promising results or are still ongoing [20-23] (ClinicalTrials.gov Identifiers: NCT04146441, NCT04821284, NCT03477019 and NCT03458975, NCT03385200), as well as clinical studies on USMB therapy with radiotherapy in the absence of a drug (Clinicaltrials.gov NCT04431674, NCT04431648). Since we used a clinical US system and EMA/FDA approved microbubbles in this study, the step to a clinical trial in human head and neck cancer patients can be taken in the near future. While customized USMB therapy settings might

lead to even better results in the long term, the approval process could take longer and we expect that the use of PW Doppler without adaptations will accelerate the road to clinical benefit.

## CONCLUSIONS

Our veterinary feasibility trial shows that the combination of bleomycin and ultrasound and microbubbles therapy, using an unmodified clinical ultrasound system and FDA/EMA approved microbubbles, is a feasible and well-tolerable treatment in cats with oral squamous cell carcinoma. Besides a modest clinical response, we found indications of enhanced tumour perfusion after USMB therapy. This could be a step forwards toward clinical translation of USMB therapy to human patients with head and neck cancer or other tumours with a clinical need for locally enhanced treatment.

## ACKNOWLEDGEMENTS

We thank Laurien Feenstra and Francine van der Steen for their help with collecting clinical data of the cats, Charis Rousou and Mirjam de Visser for their practical support during treatment sessions and Remco de Bree and Lot Devriese for the clinical discussions.

## ANIMAL RIGHTS

The research protocol was approved by the Animal Welfare Body Utrecht

## CONFLICTS OF INTEREST DISCLOSURE

## ABSTRACT

Sentinel lymph node biopsy (SLNB) is a diagnostic staging procedure that aims to identify the first draining lymph node(s) from the primary tumor, the sentinel lymph nodes (SLN), as their histopathological status reflects the histopathological status of the rest of the nodal basin. The routine SLNB procedure consists of peritumoral injections with a technetium-99m [ $^{99m}\text{Tc}$ ]-labelled radiotracer followed by lymphoscintigraphy and SPECT-CT imaging. Based on these imaging results, the identified SLNs are marked for surgical extirpation and are subjected to histopathological assessment. The routine SLNB procedure has proven to reliably stage the clinically negative neck in early-stage oral squamous cell carcinoma (OSCC). However, an infamous limitation arises in situations where SLNs are located in close vicinity of the tracer injection site. In these cases, the hotspot of the injection site can hide adjacent SLNs and hamper the discrimination between tracer injection site and SLNs (shine-through phenomenon). Therefore, technical developments are needed to bring the diagnostic accuracy of SLNB for early-stage OSCC to a higher level. This review evaluates novel SLNB imaging techniques for early-stage OSCC: MR lymphography, CT lymphography, PET lymphoscintigraphy and contrast-enhanced lymphosonography. Furthermore, their reported diagnostic accuracy is described and their relative merits, disadvantages and potential applications are outlined.

### Keywords

Squamous cell carcinoma of head and neck; mouth neoplasms; lymphatic metastases; sentinel lymph node biopsy; diagnostic imaging; lymphatics; tracer

### Simple Summary

In early-stage (cT1-2N0) oral cancer, occult lymph node metastases are present in 20–30% of patients. Accordingly, accurate staging of the clinically negative cervical nodal basin is warranted in these patients. Sentinel lymph node biopsy has proven to reliably stage the clinically negative cervical nodal basin in early-stage oral cancer. However, due to the limited resolution of conventional sentinel lymph node imaging, occult lymph node metastasis may be missed in particular circumstances. Therefore, technical developments are necessary to bring the diagnostic accuracy of sentinel lymph node biopsy, in early-stage oral cancer, to a higher level. This review evaluates novel sentinel lymph node imaging techniques for early-stage oral cancer, such as MR lymphography, CT lymphography, PET lymphoscintigraphy and contrast-enhanced lymphosonography. Their reported diagnostic accuracy is described and their relative merits, disadvantages and potential applications are outlined.

## INTRODUCTION

In early-stage (cT1-2N0) oral squamous cell carcinoma (OSCC), occult lymph node metastases are present in 20–30% of patients, even when the status of the regional lymph nodes has been evaluated using combinations of advanced clinical diagnostic imaging modalities (i.e., ultrasound guided fine-needle aspiration (USgFNA), magnetic resonance imaging (MRI) and/or computed tomography (CT)) [1–3]. As watchful-waiting in these patients has been associated with a poor prognosis, especially when compared to those in whom the clinically negative neck was electively treated [1], two strategies for the clinically negative neck in early-stage OSCC are available: elective neck dissection (END) and sentinel lymph node biopsy (SLNB) [3–6]. Although END is the strategy of choice in the majority of medical centers globally [5], which has the benefit of being a single-stage procedure, SLNB is a less invasive procedure for the 70–80% of patients without metastatic neck involvement and has overall lower morbidity rates, better quality-of-life and lower health-care costs as compared to END [7–10].

The concept of SLNB is based on the premise that lymph flow from the primary tumor travels sequentially to the sentinel lymph node (SLN) and then on to the other regional lymph nodes. Hence, the SLN is the lymph node that has the highest risk of harboring metastasis [11].

The SLNB procedure aims to identify these first draining lymph node(s), as their histopathological status reflects the histopathological status of the rest of the nodal basin. Complementary nodal treatment (e.g., surgery, radiotherapy) should be performed in case of metastatic involvement of SLN(s). A negative SLNB, however, would justify a wait-and-scan policy [12].

In short, the routine SLNB procedure consists of preoperative peritumoral injections with a technetium-99m [ $^{99m}\text{Tc}$ ;  $\gamma$ -emitter]-labelled radiotracer followed by planar dynamic and static lymphoscintigraphy including SPECT-CT (single photon emission computed tomography-computed tomography) imaging. Based on preoperative lymphoscintigraphy, the position of the SLN(s) is marked on the skin. The marked SLNs are surgically removed, using a portable  $\gamma$ -probe for intraoperative localization of SLNs. Subsequently, the harvested SLNs are subjected to meticulous histopathological assessment using step-serial-sectioning and immunohistochemistry [12–15].

SLNB has proven to reliably stage the clinically negative neck in early-stage OSCC with a pooled sensitivity and negative predictive value (NPV) of 87% and 94%, respectively [16]. However, an infamous limitation of the routine SLNB procedure arises in situations where SLNs are located in close vicinity of the tracer injection site. In these cases, the hotspot of the injection site can hide adjacent SLNs, which consequently hampers the discrimination between tracer injection site and SLNs (shine-through phenomenon; Figure 1). This shine-through phenomenon is particularly evident in patients with floor-of-mouth OSCC and sublingual, submental and submandibular SLNs, resulting in a

significantly lower accuracy of SLNB in floor-of-mouth tumors (sensitivity 63%; NPV 90%) compared to other oral cavity subsites (sensitivity 86%; NPV 95%) [4,17–21].

**Figure 1.** Shine-through phenomenon in 72-year-old patient with a cT1N0 floor-of-mouth carcinoma. **(A,C)** Coronal and axial SPECT-CT images: radiation flare of the tracer injection site over shines a sentinel lymph node located in cervical lymph node level Ib (white circle). **(B,D)** Coronal and axial low-dose CT images of same patient: (sentinel) lymph node located in cervical lymph node level Ib that could not be differentiated from the hotspot originating from tracer injection site on SPECT-CT (white circle). **(E)** Schematic illustration of shine-through phenomenon. **(A–D)** Informed consent has been obtained from this patient. **(E)** ©University Medical Center Groningen.

Therefore, technical developments are needed to bring the diagnostic accuracy of SLNB for all subsites of OSCC to the same high level. This review evaluates new developments in preoperative SLN imaging techniques for early-stage OSCC: MR lymphography, CT lymphography, PET lymphoscintigraphy and contrast-enhanced lymphosonography. Furthermore, this review describes their diagnostic accuracy as reported in literature and outlines their relative merits, disadvantages and potential applications.

## RESULTS

A systematic literature search for new developments in preoperative SLN imaging techniques for early-stage OSCC resulted in a total of 452 PubMed indexed articles, of which 40 were considered relevant. Cross-reference led to 1 additional relevant study with healthy volunteers. Of these 41 articles, 27 were reviews ( $n = 1$ ), animal or preclinical

studies ( $n = 26$ ). In particular, 20 animal or preclinical studies used similar methods for SLN identification (i.e., imaging modality, tracer) as corresponding clinical studies. Table 1 shows the range of reported diagnostic accuracy, in terms of sensitivity and NPV, and rate of patients in which SLNs were identified using the reviewed techniques. Figure 2 illustrates how both preoperative detection and intraoperative localization of SLNs was achieved, using the reviewed techniques, as described in literature.

**Figure 2.** Overview of the reviewed preoperative SLN imaging techniques (column 1), the administered tracers for the corresponding techniques (column 2) and their intraoperative SLN localization techniques (column 3) as described in literature. SLNB; sentinel lymph node biopsy, LSG; lymphoscintigraphy, SPECT-CT; single photon emission computed tomography-computed tomography, MR; magnetic resonance, CT; computed tomography, PET; positron emission tomography, ICG; indocyanine green, USgFNA; ultrasound guided fine needle aspiration.

**Table 1.** Reported diagnostic accuracy and detection rate of sentinel lymph nodes per technique.

Technique	Source	Tracer	Number of studies	Sensitivity	NPV	SLN identification in (%) of patients
Conventional lymphoscintigraphy & SPECT-CT	$\gamma$ -ray	$\gamma$ -emitting [ $^{99m}\text{Tc}$ ]-labelled radiotracer (e.g., [ $^{99m}\text{Tc}$ ]-nanocolloid)	$n = 66$	87% <sup>[16]</sup>	94% <sup>[16]</sup>	–
MR Lymphography (Gd <sup>3+</sup> )	Radio-wave	Paramagnetic (Gd <sup>3+</sup> ) contrast agent (e.g., gadobutrol)	$n = 1$	91% <sup>[26]</sup>	93% <sup>[26]</sup>	100% <sup>[26]</sup>

## Magnetic Resonance Lymphography

Magnetic resonance (MR) lymphography with peritumoral administration of a paramagnetic gadolinium [Gd<sup>3+</sup>]-based contrast agent has been recently introduced in breast and cervical cancer, as an alternative method for preoperative visualization of SLNs and lymphatics [22–24]. These studies showed that paramagnetic gadolinium [Gd<sup>3+</sup>]-based contrast agents, conventionally administered intravenously for contrast-enhanced MRI or MR angiography [25], are safe and useful for peritumoral administration and SLN mapping in humans.

To review MR lymphography for SLN detection using paramagnetic gadolinium-based contrast agents in early-stage OSCC, a systematic literature search was conducted. This led to retrieval of 53 PubMed indexed articles for MR lymphography; 7 were considered relevant [26–32]. Of these 7 articles, 6 were animal studies [27–32]. Cross-reference led to identification of 1 relevant study with healthy volunteers [33].

In the only study that performed MR lymphography with a gadolinium-based contrast agent (i.e., gadobutrol) in OSCC patients ( $n = 26$ ) [26], SLNs were consistently visualized in all patients and lymph node vessels were visualized in the majority of patients (81%) (Figure 3). Following MR lymphography, identified SLNs were injected with 1% patent blue dye under sonographic guidance. Subsequently, primary tumor resection and ipsilateral elective neck dissection were performed in all patients. Blue stained SLNs were dissected, marked and sent separately for histopathological assessment.

Among the 11 patients with pathologically positive necks, SLNs containing metastases

were accurately identified by MR lymphography in 10 patients. In the remaining patient, MR lymphography depicted SLNs in ipsilateral neck level III. However, in the neck dissection specimen, 3 metastatic lymph nodes in ipsilateral neck level I were found, whereas no metastasis was found in level III. With histopathological assessment of the neck dissection specimen as reference standard, this approach reached a sensitivity of 90.9% with a NPV of 92.8%.

Another type of contrast agent that can be used for MR lymphography are superparamagnetic iron oxide nanoparticles (SPIO), which provide a negative contrast on MR lymphography as opposed to gadolinium-based contrast agents (Figure 4). Following peritumoral administration of SPIOs, transportation through the lymphatic system is mainly facilitated by macrophages, although unbound transport is seen as well [34]. SPIO accumulates primarily in lymph node sinuses and can be detected preoperatively on MRI and intraoperatively with a handheld magnetometer [34–38]. MR lymphography using SPIO has been investigated for several tumor types, including breast and prostate cancer [35,36].

**Figure 3.** A 38-year-old woman with oral tongue cancer and palpably negative neck. **(A,B)** Fat-saturated T2-weighted MRI scans show a shallow infiltrative tumor on the left lateral surface of oral tongue (arrow) and several small lymph nodes in the submandibular areas. **(C,D)** After peritumoral injection of contrast, MR lymphography revealed two first-enhanced lymph nodes in left level IB and IIA (arrows) on the first phase of the dynamic scan, respectively. **(E)** The maximum intensity projection reconstruction image of MR lymphography shows the contrast injection site in the tongue (thick arrow), the assumed sentinel lymph node (thin arrow), and the lymph vessel connecting them (arrowhead). After neck dissection, the assumed sentinel lymph nodes observed on MR lymphography revealed no metastasis on histologic examination [26]. Figure used with permission of John Wiley and Sons©, permission license number 4807630108259.

The systematic literature search retrieved 116 PubMed indexed articles, of which 6 were considered relevant [32,37–41]. Of these 6 articles, 3 were animal studies [32,38,39]. Cross-reference did not lead to identification of additional relevant articles, resulting in a total of 3 included human studies [37,40,41]. One of these studies did not perform preoperative SPIO-enhanced MRI, but was the only study in early-stage OSCC patients that achieved intraoperative localization of SLNs with the magnetometer [37].

Mizokami et al. performed MR lymphography using SPIO in three tongue cancer patients (cT2N0), planned for tumor resection and ipsilateral elective neck dissection [40]. Seven days before surgery, patients received peritumoral injections with Resovist (Bayer Schering Pharma) of 0.1–0.3 mL, corresponding with 2.78–8.37 mg iron. MR lymphographic images were acquired at 10 min, 30 min and 24 h post-injection. On the day before surgery, [<sup>99m</sup>Tc]-phytate was administered peritumorally, followed by planar lymphoscintigraphy. Intraoperatively, SLNs were localized using a conventional  $\gamma$ -probe and were submitted for individual histopathological assessment. All SLNs depicted on 10 min MR lymphography were in accordance with planar lymphoscintigraphy and  $\gamma$ -probe findings. MR lymphography at 30 min and 24 h post-injection showed more uptake of SPIO in SLNs. However, MR lymphography 24 h post-injection also visualized higher echelon nodes (HEN). Besides, on MR lymphography SPIO-induced streak artifacts were seen around the injection site, but did not prevent identification of SLNs in vicinity of the tracer injection site. Histopathological assessment confirmed presence of iron in all harvested SLNs. In one patient nodal metastases were found in a harvested SLN; no additional metastases were seen in the neck dissection specimen. No follow-up results were reported in this study. In two patients, tissue swelling was observed at the injection site after administration of SPIO, which was attributed to the volume of SPIO injected.

Maza et al. evaluated fusion of lymphoscintigraphic SPECT, SPIO MR lymphography and CT, for identification of SLNs in rather complex anatomical regions [41]. Fourteen patients were included of whom two diagnosed with tongue cancer; scheduled for tumor resection and ipsilateral elective neck dissection. A mixture of [<sup>99m</sup>Tc]-nanocolloid and SPIO (Resovist), in total 0.5 mL, was peritumorally injected on the day before surgery. MR lymphography was acquired 2 h post-injection. Lymph nodes were assessed as SLN if they corresponded with SPECT images and exhibited signal loss on T2\*-weighted sequences. SPECT-MRI fusion was successful in both OSCC patients and showed corresponding SLNs. Intraoperatively, SLNs were localized using a  $\gamma$ -probe and were sent for individual histopathological assessment. SLN metastases were found in the contralateral neck of one OSCC patient, leading to a complementary contralateral neck dissection. No (additional) lymph node metastases were found in the neck dissection specimens of both patients. No follow-up results were reported.

**Figure 4.** MR lymphography using superparamagnetic iron oxide nanoparticles in a 77-year-old man with oral tongue cancer and a clinically negative neck. **(A)** T1-weighted 3D fast-field echo (FFE) show uptake of SPIO in two SLNs in level IIa (dotted arrow) & level IIb (arrow) left. **(B)** T2-weighted FFE shows clear negative contrast in corresponding SLNs, as a result of SPIO uptake. **(C,D)** Sagittal and coronal reconstruction of **(A)** shows the SLN in level IIa left (dotted arrow). **(A–D)** Informed consent has been obtained from this patient.

### CT Lymphography

Another approach for high-resolution lymphography regards computed tomography (CT) lymphography using peritumoral administered iodine-based contrast agents. The use of CT lymphography has been investigated in several tumor types including breast, lung, esophageal, gastric and skin cancer [42–53]. In these studies, CT lymphography provided high-resolution visualization of SLNs, lymphatic vessels and surrounding anatomical structures.

For reviewing the application of CT lymphography in early-stage OSCC, the systematic literature search led to retrieval of 112 PubMed indexed articles for CT lymphography, of which 17 were considered relevant [27,28,54–68]. Of these 17 articles, 11 were animal studies [27,28,60–68]. Cross-reference did not lead to any additional relevant articles.

The case report of Saito et al. [59] was the first article that described the application of CT lymphography in an early-stage OSCC patient. Using CT lymphography with peritumoral injection of iopamidol (2.0 mL), a right lateral lingual lymph node was identified as SLN from a cT2N0 right oral tongue tumor. Following partial glossectomy, without any management of the neck or extirpation of the SLN, the patient showed no evidence of disease after 14 months follow-up. This case-report demonstrated that CT lymphography is suitable for visualization of small SLNs located near the primary tumor, such as lingual lymph nodes.

The first series regarding CT lymphography in early-stage OSCC patients ( $n = 31$ ; *oral tongue*) was reported by Honda et al. [58]. In this study, CT images were obtained 1, 3, 5, and 10 min after administration of 1.5 mL iopamidol mixed with 0.5 mL 1% lidocaine hydrochloride. Both contrast-enhanced lymph vessels draining the tumor injection site as well as SLNs were identified in 90.3% of patients. Identified SLNs were marked for biopsy using a lattice marker, combined with intraoperative peritumoral patent blue dye injection. All patients, except for those with T1N0 OSCC and negative frozen-section assessment of SLNs ( $n = 11$ ), underwent selective neck dissection following tumor resection. Using histopathological examination of the neck dissection specimen and a

follow-up of 30 months as reference standard, this approach reached a sensitivity of 80% with a NPV of 95.8%.

In the sequel study of Honda et al., including 18 patients with cT1-2N0 oral tongue carcinoma, similar methods were used for CT lymphography, resulting in a preoperative SLN detection rate of 89% [57]. For intraoperative localization of SLNs, indocyanine green (ICG) and near-infrared imaging was used, instead of patent blue dye. In contrast to their previous study [58], only patients with advanced cT2N0 disease or positive frozen-section assessment of SLNs underwent selective neck dissection ( $n = 9$ ). In the 16 patients with at least one detected SLN on CT lymphography, a sensitivity of 71.4% and NPV of 81.8% after 38 months median follow-up were reported.

More recently, Sugiyama et al. [56] performed CT lymphography in 20 early-stage OSCC patients. Following peritumoral administration of 2.0 mL iopamidol, SLNs and lymphatic vessels draining the injection site were detected in 95% and 90% of patients, respectively. Two lingual lymph nodes were identified as SLNs (5.4%). The optimal timing for CT scanning in this study was at both 2 and 5 min post-injection, visualizing all 37 contrast-enhanced SLNs. Intraoperative SLN detection was performed under ICG fluorescence guidance; the authors stated to have localized all CT lymphographic identified SLNs during surgery using intraoperatively administered ICG. Both number of patients with metastatic SLNs as well as follow-up results were not reported.

In the sequel study of Sugiyama et al. [54], preoperative CT lymphographic images were reevaluated in 32 early-stage OSCC patients with an approach similar to their previous study [56]. During follow-up 4/27 patients with negative SLNB (14.8%), based on CT lymphography, developed regional recurrence and 1/5 patients with SLN metastasis (20%) developed recurrence between primary tumor site and the neck. Accordingly, their approach reached a sensitivity of 55.6% and NPV of 85.2%. Reevaluation of CT lymphographic images showed a subtle increase in Hounsfield units (HU) of overlooked SLNs ( $n = 5$ ) when compared to non-contrast CT images. Besides, their results showed that HU decreased at 10 min post-injection, indicating that iopamidol is only briefly retained in SLNs.

Figure 5 shows CT lymphographic images from a recent long-term follow-up study with early-stage OSCC patients ( $n = 27$ ; *oral tongue*) [55]. In this study, SLNs were detected in 96.3% of patients using CT lymphography after peritumoral administration of 2.0 mL iopamidol. Intraoperatively, SLNs were localized using ICG and near-infrared imaging. In total, 5 patients had metastatic SLNs (18.5%) and 3 patients without SLN metastases developed regional recurrence (13.6%) after median follow-up of 76 months. This resulted in a sensitivity and NPV of 62.5% and 86.3%, respectively.

### PET Lymphoscintigraphy

Alternatively, a potential nuclear imaging modality for improving the diagnostic accuracy of SLNB is positron emission tomography (PET). Since PET is able to detect and record a higher percentage of radioactive emitted events compared to SPECT, PET provides both higher spatial and temporal resolution (i.e., acquires higher number of frames per time unit for dynamic studies) [69]. Consequently, PET could be highly suitable for lymphoscintigraphy and may identify SLNs with higher precision than conventional lymphoscintigraphy with SPECT. Instead of a  $\gamma$ -emitter (e.g., [ $^{99m}\text{Tc}$ ], [ $^{60}\text{Co}$ ])-labelled radiotracer, generally used for conventional lymphoscintigraphy, PET lymphoscintigraphy requires a positron emitting isotope (e.g., [ $^{89}\text{Zr}$ ], [ $^{68}\text{Ga}$ ], [ $^{18}\text{F}$ ])-labelled radiotracer [70].

A systematic literature search was conducted to review PET lymphoscintigraphy in early-stage OSCC. This led to retrieval of 64 PubMed indexed articles; 4 were considered relevant [71–74]. Of these 4 studies, 1 regarded an animal study [74] and 1 a review [72] that briefly discusses results from 2 of 3 included studies in our review [73,74]. Cross-reference did not lead to any additional relevant articles.

In 2013, Heuveling et al. were the first to perform dynamic and static PET lymphoscintigraphy in 5 patients with early-stage OSCC, following peritumoral administration of zirconium-89 [ $^{89}\text{Zr}$ ]-labelled nanocolloid [73]. Subsequently, 7–9 days after PET lymphoscintigraphy, the routine SLNB procedure with [ $^{99m}\text{Tc}$ ]-labelled nanocolloid was performed. The results of PET and SPECT lymphoscintigraphy were compared. PET lymphoscintigraphy was able to visualize all foci ( $n = 22$ ) that were

identified on SPECT-CT and even visualized 5 additional foci that were considered to be SLNs; all of which were located near the injection site of the primary tumor (Figure 6). Of these 5 additional foci, considered to be SLNs, 2 regarded lingual lymph nodes. Furthermore, in 4 patients (80%) lymphatic vessels were visualized on dynamic PET lymphoscintigraphy. Intraoperatively, the additionally visualized PET foci close to the injection site could not be localized with the conventional portable  $\gamma$ -probe, due to difficulties in differentiating between SLN and injection site. In two patients metastatic SLNs were found, follow-up results were not reported.

In their sequel study, Heuveling et al. achieved both preoperative SLN detection with PET lymphoscintigraphy, as well as intraoperative SLN localization using a handheld PET-probe, after peritumoral administration of [ $^{89}\text{Zr}$ ]-labelled nanocolloid [71]. This study included 5 OSCC patients who underwent tumor resection including neck dissection (i.e., clinically N1 disease or access of the neck was required for tumor resection or flap reconstruction). Preoperatively 13 SLNs were identified by PET lymphoscintigraphy, whereas the PET-probe detected 10 of 13 SLNs intraoperatively (77%). In this population, 3 patients (60%) had nodal metastases; in 1 patient the histopathologically positive SLN, found in the neck dissection specimen during histopathological assessment, was not localized with the PET-probe, although it was depicted on preoperative PET lymphoscintigraphy. None of the patients developed locoregional recurrence after a median follow-up of 25 months. With histopathological examination of the neck dissection specimen and follow-up as reference standard, this approach reached a sensitivity of 67% with a NPV of 67%. The authors concluded that PET lymphoscintigraphy using [ $^{89}\text{Zr}$ ]-labelled nanocolloid may improve preoperative SLN detection, although it should be combined with other tracers for intraoperative localization.

### **Contrast-Enhanced Lymphosonography**

In contrast-enhanced ultrasound (CEUS), echogenic particles such as microbubbles are administered to obtain information on vascularization or delineation of body cavities during ultrasound (US) imaging. FDA and EMA approved microbubbles consist of perfluorocarbons or sulfur hexafluoride ( $\text{SF}_6$ ) gas surrounded by a thin biocompatible shell generally made of phospholipids or proteins [75,76]. Due to their compressibility and the large difference in acoustic impedance between gas and the surrounding liquid (i.e., blood or lymph) they strongly scatter ultrasound pulses. In addition, due to nonlinear microbubble oscillations, the scattered signal contains higher harmonic frequencies. These higher harmonic frequencies can be distinguished from the fundamental frequency scatter emitted by relatively incompressible tissue surroundings, consequently enhancing microbubble containing structures [75–77] (Figure 7).

Microbubbles are typically administered intravenously, but have more recently been proposed as a radiation-free tracer for lymphosonography. In breast cancer, studies reported SLN localization rates between 60–100%. For CEUS-guided SLNB a pooled

sensitivity of 54% (95% CI 47–61%) and a NPV of 83–92%, were reported [78]. Few to no adverse events of the procedure were registered; any minor adverse events consisted of localized redness, pain or bruising at the injection site [78,79].

**Figure 6.** (A,D) Axial (A) and coronal (D) SPECT-CT image of injection site (i) of patient 1, i.e., floor of mouth, in which only a large hot spot from injection site could be visualized. (B,E) PET-CT image of injection site of same patient in which level IB lymph node (arrow) clearly could be identified. (C,F) Fused SPECT and PET-CT images showing that lymph node visualized on PET-CT is hidden behind large hot spot on SPECT-CT images [73]. This research was originally published in JNM [73]. Figure used with permission of original authors. ©SNMMI.

To review contrast-enhanced lymphosonography in OSCC, a systematic literature search was conducted, which led to retrieval of 107 PubMed indexed articles. A total of 6 studies were considered relevant (i.e., 2 clinical studies [80,81] and 4 large animal studies [82–85]). Cross-reference did not lead to identification of additional relevant articles.

Figure 7 illustrates the procedure used in the two clinical studies [80,81]. Gvetadze et al. [80] used sulfur hexafluoride ( $\text{SF}_6$ ) phospholipid microbubbles (SonoVue; Bracco International B.V.) in 12 patients with T1-2cN0 oral tongue carcinoma and looked for lymph node enhancement after repetitive peritumoral injections. Fifteen SLNs were identified in 11/12 patients (91.7%). No attempt was made at intraoperative localization of identified SLNs and therefore the correlation between identified SLNs and histopathological assessment was lacking. In the second clinical study, Wakisaka et al.

[81] studied lymphosonography with perfluorobutane phospholipid ( $C_xF_y$ ) microbubbles (Sonazoid; GE Healthcare, UK) in 10 patients with T1-4N0 oral or oropharyngeal carcinomas. Sonazoid was injected in four peritumoral locations. In 8/10 patients, 12 SLNs were identified. In one patient with a T4 tumor, Sonazoid had to be injected intratumorally and no SLNs were identified. SLN locations were marked on the skin. The next day indigo carmine blue dye was injected intraoperatively at the same injection sites. All lymph nodes marked during lymphosonography, which were not always dyed blue, were examined with frozen section analysis. Since frozen section analysis was negative in all cases, a less extensive neck dissection was performed. No metastatic lymph nodes were found during histopathological examination of neck dissection specimens. No follow-up results were reported for both studies. Contrast-related adverse events did not occur [80,81].

**Figure 7.** Contrast-enhanced lymphosonography in oral cancer. After microbubble injection at one or multiple peritumoral locations, contrast-enhancement of the injection site is visualized in ultrasound contrast mode. Using real-time imaging, the transportation of the microbubbles through lymphatic vessels may be followed until they accumulate in the sentinel lymph nodes. Subsequently, the neck is scanned for additional contrast-enhanced lymph nodes. Contrast-enhanced lymph nodes can be either marked for surgical resection or

directly subjected to biopsy or aspiration cytology. Peritumoral injections can be repeated if necessary. **(a)** Schematic representation of a microbubble; **(b)** Principle of contrast-enhanced ultrasound (CEUS): oscillating microbubbles produce strong nonlinear scattering which can be distinguished from scattering by the surrounding tissue; **(c)** Contrast-enhanced ultrasonography with Sonazoid. On the left half is a contrast-enhanced image, and on the right is the B-mode image. Contrast-enhancement of sentinel lymph nodes (SLNs) (arrowheads) was observed concomitant with lymphatic ducts (arrows) draining the nodes. ## DISCUSSION

This paper reviewed new developments in preoperative SLN imaging techniques in patients with early-stage OSCC. None of the included clinical studies contradicted outcomes or clinical translation predictions from corresponding animal studies, in regard of SLN identification using these novel techniques [26,29–33,37–41,54–60,62,63,65–68]. The overall reported rate of patients in which SLNs were identified using the presented techniques ranged from 89–100%. The overall reported sensitivity ranged from 56–91%, with a NPV of 67–96% (Table 1).

Although the diagnostic accuracy of most presented techniques appears to be inferior to conventional lymphoscintigraphy including SPECT-CT, there are several promising advantages to the presented preoperative SLN imaging techniques which will be discussed individually in the subsections below. Accordingly, drawbacks of the presented techniques and methodology of the included studies will be discussed as well. While other (head and neck) tumor sites were not included in this review, the discussed strengths and flaws of performing SLNB using these techniques may also be relevant to other (head and neck) tumor sites. A summary of relative merits and disadvantages for each technique is listed in Table 2.

### MR Lymphography

Bae et al. showed that MR lymphography using gadobutrol, is a promising technique for SLN detection in early-stage OSCC, with a sensitivity of 90.9%, a NPV of 92.8% and lymphatic vessel visualization in 81% of patients [26].

The high spatial resolution, high signal-to-noise ratio and few artifacts that MR lymphography with gadolinium-based contrast agents provides, even when compared to MR lymphography with SPIO, is the foremost asset of this technique [35,40,86–88]. These features result in accurate anatomical detail and facilitate visualization of lymphatic vessels, which is helpful in assessing whether a contrast-enhanced lymph node is a true SLN or a higher echelon node (HEN) [73]. Moreover, the high spatial resolution of MR lymphography eliminates the shine-through phenomenon, allowing identification of SLNs in vicinity of the tracer injection site. Additionally, MR lymphography is free of radiation exposure and does not require radioisotopes, which is of particular benefit if specific nuclear medicine facilities are unavailable [89,90].

**Table 2.** Merits and drawbacks per technique.

Technique	Advantages	Drawbacks
Conventional lymphoscintigraphy & SPECT-CT	Widely investigated and implemented Allows intraoperative localization of depicted SLNs Differentiation in intensity of radioactive signal Allows (intraoperative) differentiation between SLNs and HENs	Subject to shine-through phenomenon Requires nuclear facilities Low spatial resolution (~5 mm) Poor soft tissue contrast
MR Lymphography (Gd <sup>3+</sup> )	High spatial resolution (~1 mm) High signal-to-noise ratio and few artifacts Accurate anatomical detail Eliminates shine-through phenomenon Visualization lymphatic vessels May facilitate more targeted radiotherapy No nuclear facilities required Free of radiation exposure	Lacks intraoperative localization of depicted SLNs Rapid lymphatic transportation tracer No retention of tracer in SLNs Gd <sup>3+</sup> -based contrast agents not registered for lymphography
MR Lymphography (SPIO)	High spatial resolution (~1 mm) Accurate anatomical detail Allows intraoperative localization of depicted SLNs Eliminates shine-through phenomenon May facilitate more targeted radiotherapy No nuclear facilities required Free of radiation exposure	Limited clinical experience in OSCC Retention in SLNs depends on particle size Excess amounts of iron leads to signal voids Negative contrast may confound effectivity SLN detection Local inflammation following administration Metal elements interfere with magnetometer
CT Lymphography	High spatial resolution (~0.5 mm) High temporal resolution Eliminates shine-through phenomenon Visualization lymphatic vessels Visualization of lingual SLNs May facilitate more targeted radiotherapy No nuclear facilities required Widely available and low costs	Lacks intraoperative localization of depicted SLNs Rapid lymphatic transportation tracer No retention of tracer in SLNs Prone to artifacts Poor soft tissue contrast
PET lymphoscintigraphy	High spatial resolution (~2 mm) High temporal resolution Diminishes shine-through phenomenon Visualization lymphatic vessels Visualization of lingual SLNs Differentiation in intensity of radioactive signal Can be performed with known radiotracers Tri-model agent: IRD-800CW-[ <sup>68</sup> Ga]-[ <sup>99m</sup> Tc]-tracer Allows intraoperative localization of depicted SLNs	Requires nuclear facilities Poor intraoperative localization of SLNs with PET-probe Poor soft tissue contrast
Contrast-enhanced lymphosonography	Good safety profile of microbubbles High spatial resolution (~0.5mm) High temporal resolution and real-time imaging Eliminates shine-through phenomenon Possibly no uptake of microbubbles in HENs Can be combined with USgFNA May be extended to other head and neck sites Widely available and low costs Free of radiation exposure	Limited clinical experience in OSCC Suspected low reproducibility High operator dependency Rapid lymphatic transportation tracer Challenging to mark SLNs for biopsy

SPECT-CT; single photon emission computed tomography - computed tomography, SLN; sentinel lymph node, HEN; higher echelon node, MR; magnetic resonance, Gd<sup>3+</sup>; gadolinium, SPIO; superparamagnetic iron oxide, OSCC; oral squamous cell carcinoma, CT; computed tomography, PET; positron emission tomography, IRD; infrared dye, <sup>68</sup>Ga; gallium-68, <sup>99m</sup>Tc; technetium-99m, USgFNA; ultrasound guided fine-needle aspiration.

Nevertheless, the low molecular weight of gadolinium-based contrast agents result in rapid lymphatic transportation, little retention in SLNs and rapid washout of the contrast agent [33,91]. This could increase the risk to overlook SLNs and of contrast-enhanced HEN(s) to erroneously being considered SLN(s). Since Bae et al. performed elective neck dissection in all patients, used only histopathological examination of the neck dissection specimen as reference standard and did not report any follow-up results (e.g., nodal recurrence), it is uncertain whether SLNs were overlooked with this technique [26]. Therefore, the diagnostic accuracy of SLNB using MR lymphography with gadolinium-based contrast agents in early-stage OSCC patients is yet to be established in larger studies with histopathological examination and follow-up as reference standard.

In addition, MR lymphography with gadolinium-based contrast agents cannot be performed when MRI or administration of these agents is contraindicated [89]. Besides, gadolinium-based contrast agents are not registered for lymphography and clinical trials on MR lymphography using these contrast agents are required before this technique can be implemented in routine clinical care.

Moreover, it is important to note that gadolinium-based contrast agents cannot be detected intraoperatively. The solution offered by Bae et al. [26], i.e., injection of identified SLNs with blue dye, is probably not reliable enough to assess whether the observed SLNs depicted on MR lymphography exactly matched the same nodes in the neck dissection specimen. A proposed alternative for intraoperative localization of SLNs is fluorescence guided surgery following peritumoral injection of ICG [92,93]. However, due to limited tissue penetration of the fluorescent signal and rapid flow through lymphatics of unbound ICG, matching of preoperative depicted SLNs and intraoperative fluorescent lymph nodes is challenging [90].

The inability to detect gadolinium intraoperatively, may be overcome by using SPIO for MR lymphography, as SPIO can be detected by both MRI and a handheld magnetometer [37,40]. Accordingly, SPIO may facilitate intraoperative localization of preoperative depicted SLNs, while maintaining benefits of MR lymphography over other imaging modalities (Table 2). Still, a correlation between preoperatively identified SLNs on MR lymphography and intraoperative localized SLNs with the handheld magnetometer has not yet been reported for early-stage OSCC patients.

The first results of MR lymphography using SPIO are auspicious, as all identified SLNs by MR lymphography corresponded with those identified by conventional lymphoscintigraphy [40,41]. Besides, adequate differentiation of SLN from injection site was seen [40] and precise anatomical information on SLN location was acquired when fused with SPECT [41]. However, some challenges for MR lymphography with SPIO remain. First of all, both ideal SPIO particle size and amount of iron administered are still under consideration. A hydrodynamic diameter of 59 nm was considered most suitable due to its fast uptake in lymphatics, retention in SLNs and its high accumulation when compared to SPIOs with a hydrodynamic diameter of 32 nm and 111 nm [38]. Hence, Resovist (45–60 nm) and

Magtrace (59 nm) may be fitting candidates [37,40,41]. With respect to the volume of SPIO administered with corresponding iron quantity, a considerable difference is seen among reports [37,40,41]. While a higher concentration may assist intraoperative localization of SLNs [37], excessive concentrations of SPIO can lead to disproportionate signal voids on MR lymphography and may hamper preoperative SLN identification [87]. Vice versa, a lower concentration may benefit preoperative SLN identification [40], but may impede intraoperative localization [35]. Furthermore, the negative contrast that SPIO provides on MR lymphography, which can be induced by other factors as well (i.e., dental implants, tissue interfaces, background noise, air), may confound the efficiency of detecting SLNs [41,87,88]. Moreover, in regard of intraoperative localization of SPIO-enhanced SLNs using the magnetometer, magnetic signals deriving from metal elements (e.g., pacemakers, prosthetics, surgical instruments) interfere with the magnetometer. This can instigate some logistical issues, such as requiring plastic surgical instruments, and can even lead to a contraindication for using the magnetometer in some cases (e.g., patients with pacemakers or prosthetics) [37]. Finally, concerns were addressed concerning swelling, local inflammation and pain of the injection site following administration of SPIO, which may depend on the volume of SPIO administered [37,40]. Some reports mention a higher number of identified SLNs on MR lymphography with SPIO when compared to conventional lymphoscintigraphy and SPECT-CT, due to the better resolution of MR lymphography [35,36]. It can be debated if the higher number of identified SLNs by MR lymphography with SPIO includes not only true SLNs, but HENs as well. Since Mizokami et al. showed more enhanced lymph nodes at 24 h post-injection, which were considered HENs, the timing of MR lymphography following SPIO administration seems to be pertinent in selecting the right contrast-enhanced lymph nodes for SLNB [40]. To distinguish true SLNs from HENs, visualization of lymphatic vessels may provide a solution. However, visualization of contrast-enhanced lymphatic vessels was not reported in any of the included studies [40,41]. To enable visualization of contrast-enhanced lymphatic vessels administration of smaller SPIOs is suggested, but is criticized by their faster migration through the lymphatic system [40].

Currently, the limited number of early-stage OSCC patients who underwent MR lymphography with SPIO prevents assessment of its diagnostic accuracy. Larger studies with adequate reference standards (i.e., histopathological assessment including follow-up) should be conducted to establish the diagnostic accuracy of MR lymphography with SPIO in OSCC patients.

In conclusion, MR lymphography using gadolinium-based contrast agents may currently not offer an alternative for conventional SLNB using radiotracers, mainly due to the lack of reliable intraoperative localization of preoperatively depicted SLNs. MR lymphography with SPIO may provide a solution, as it allows for intraoperative localization of SLNs with a magnetometer. However, MR lymphography with SPIO is subject to other limitations that may confound the efficiency of preoperative detection and intraoperative

localization of SLNs. Nonetheless, MR lymphography using either contrast agent can provide precise preoperative anatomical localization and identification of SLNs, particularly in situations with close spatial relation between injection site and SLN(s). Accordingly, MR lymphography might be a valuable addition to radiotherapy planning (e.g., higher radiation dose on SLNs), by performing MR lymphography as part of MRI that is increasingly used for radiotherapy planning in head and neck cancer [94]. MR lymphography-guided nodal irradiation may improve regional control, reduce acute and late radiation-related toxicity and enhance health-related quality-of-life [95].

### **CT Lymphography**

CT lymphography has been proposed as a high potential alternative for conventional lymphoscintigraphy, with a sensitivity ranging from 56–80% and a NPV ranging from 82–96% [54,55,57,58]. Two series reported enhanced lymphatic vessel visualization in 90% of their patients [56,58]; in two studies lingual lymph nodes were identified as SLNs using CT lymphography [56,59].

CT lymphography shares several beneficial properties with MR lymphography: high spatial resolution, visualization of lymphatic vessels and elimination of shine-through phenomenon. The latter has been demonstrated by the identification of lingual lymph nodes as SLNs using CT lymphography [56,59]. Besides, CT lymphography does not require specific nuclear facilities and is easily implemented due to the wide availability of CT and iodine-based contrast agents [57,89]. Compared to MRI, CT has lower costs and is considered more comfortable for patients [89].

Yet, challenges for CT lymphography are similar to those in MR lymphography using gadolinium-based contrast agents. First of all, iodine-based contrast agents cannot be detected intraoperatively. Most authors used fluorescence guidance with intraoperatively administered ICG for SLN localization of preoperatively depicted SLNs by CT lymphography [54–57]. As previously mentioned, matching of preoperative depicted SLNs and intraoperative fluorescent lymph nodes is challenging [90]. Secondly, the rapid lymphatic transportation, limited retention in SLNs and rapid washout of iopamidol increases the risk to overlook SLNs and of contrast-enhanced HEN(s) to erroneously being considered SLN(s). This risk has been especially emphasized by Sugiyama et al., who showed that overlooked SLNs were only marginally contrast-enhanced on CT lymphography and that iopamidol was only briefly retained in SLNs [54].

Additional challenges arise for CT lymphography, especially when compared to MR lymphography, since CT has poor soft tissue contrast and is prone to artefacts from dental amalgam or orthopedic material, if present, which may hamper adequate visualization of SLNs. Besides, CT implies radiation exposure and, although only a low volume (2 mL) is used compared to regular intravenous use, iodine-based contrast agents may induce anaphylactic reactions, contrast-induced nephropathy or thyroid dysfunction [89]. However, contrast-related adverse events did not occur in any of the included studies

[54–59].

Further developments regarding CT lymphography should address these limitations (i.e., dual-tracer methods, high velocity lymphatic drainage tracer, limited retention of tracer in SLNs) to improve its diagnostic accuracy for SLNB.

As an alternative for iopamidol as CT lymphographic tracer, lipiodol might be worth considering. In contrast to iopamidol, lipiodol is oil-based with higher viscosity and is registered and widely used for lymphographic purposes [96]. The higher viscosity of lipiodol might result in increased retention in SLNs and delayed tracer wash-out, possibly improving preoperative SLN detection on CT lymphography. Moreover, lipiodol has been combined with ICG as a single emulsion, which could overcome the limitations of dual tracer methods, potentially enabling reliable intraoperative localization of preoperative depicted SLNs [97]. This has yet to be investigated in a clinical trial with an adequate reference standard (i.e., histopathological examination and follow-up).

Although CT lymphography requires some further developments, it has the potential for highly accurate identification of SLNs in early-stage OSCC patients. Especially in cases where SLNs are in close vicinity to the tracer injection site. Besides, analogous to MR lymphography, CT lymphography, performed concomitantly with conventional CT imaging for radiotherapy planning, may facilitate more targeted radiotherapy and consequently improve regional control, reduce acute and late radiation-related toxicity and enhance health-related quality-of-life [94,95].

### **PET Lymphoscintigraphy**

Heuveling et al. demonstrated the high potential of preoperative PET lymphoscintigraphy using [<sup>89</sup>Zr]-labelled nanocolloid for SLN detection in OSCC patients, by visualizing all foci identified on SPECT-CT and even detecting 5 additional SLNs in vicinity of the tracer injection site. Additionally, in 80% of patients, lymphatic vessels were visualized and 2 lingual lymph nodes (7%) were identified as SLNs [73].

In correspondence with MR-and CT lymphography, the high spatial resolution of PET lymphoscintigraphy enables identification of SLNs located close to the tracer injection site, which was demonstrated by detection of 2 lingual SLNs using PET lymphoscintigraphy. Moreover, PET lymphoscintigraphy provides both high temporal resolution as well as visualization of lymphatic vessels, contributing to better differentiation between true SLNs and HENs [73].

In contrast to the other presented techniques in this review, PET lymphoscintigraphy permits the use of commonly administered tracers for SLNB (e.g., nanocolloids, tilmanocept), whose kinetics have proven to be particularly suitable for SLNB [14,98]. Moreover, Heuveling et al. achieved reliable intraoperative localization of SLNs that were preoperatively identified by PET lymphoscintigraphy, using a handheld PET-probe [71]. Consequently, this method is unaffected by limitations of dual tracer methods.

Although intraoperative localization of SLNs using a handheld PET-probe was considered

feasible, some concerns were addressed [71]. First of all, the PET-probe detected only 12/15 SLNs as identified by PET lymphoscintigraphy, which was attributed to the PET-probe's limited sensitivity, resulting in a relatively low accuracy of the procedure (i.e., sensitivity 67%; NPV 67%). Secondly, a handheld PET-probe is relatively large in size because of features necessary for detection of high-energy photons from positron emitting isotopes [71,99]. Due to the limited sensitivity and large size of the PET-probe, wider skin incisions and exploration of the neck were required for SLN localization [71]. To overcome the problems with the use of a PET-probe, a radiotracer labelled with both [ $^{89}\text{Zr}$ ] and a  $\gamma$ -emitter (e.g., [ $^{99\text{m}}\text{Tc}$ ]) could allow high-resolution preoperative PET lymphoscintigraphy and intraoperative localization of SLNs using the conventional portable  $\gamma$ -probe. However, due to its half-life of 78.4 h, [ $^{89}\text{Zr}$ ] will interfere with the [ $^{99\text{m}}\text{Tc}$ ]-signal [100]. Therefore, a positron emitting isotope with a shorter half-life is required to enable detection of the [ $^{99\text{m}}\text{Tc}$ ]-signal for intraoperative localization of SLNs using the conventional portable  $\gamma$ -probe.

Fluorine-18 [ $^{18}\text{F}$ ] is considered the ideal radioisotope for PET imaging owing to the low positron energy (0.64 MeV), providing high-resolution images. Furthermore, [ $^{18}\text{F}$ ] has a half-life of only 110 min [101]. However, [ $^{18}\text{F}$ ] relies on C-F bond formation and is therefore difficult to label to currently used radiotracers for SLNB (e.g., nanocolloids or tilmanocept) [102]. Recently, PET lymphoscintigraphy with interstitially injected [ $^{18}\text{F}$ ]-FDG has been investigated in patients with cervical or endometrial cancer and in healthy subjects [103,104]. Hypothesized was that the small size of the tracer allows passage through channels infiltrated with tumor cells, and that its molecular function allows uptake by tumor cells, which is not achieved by any of the currently used radiotracers for SLNB [103]. In the study with cervical or uterine cancer patients, SLN mapping was successful in 80% of patients [103]. In the study with healthy subjects however, PET lymphoscintigraphy using [ $^{18}\text{F}$ ]-FDG was not considered feasible due to significant tracer washout to systemic capillaries [104].

Alternatively, gallium-68 [ $^{68}\text{Ga}$ ] is a good candidate due to its half-life of only 68 min and its production with a [ $^{68}\text{Ga}$ ]-generator, which provides an opportunity to prepare PET-radiopharmaceuticals on site when needed [100,105]. Moreover, its chemical properties allow labelling to various diagnostic molecules [106].

Whereas labelling of nanocolloids with [ $^{68}\text{Ga}$ ] is complicated, mainly due to instability of the bond between [ $^{68}\text{Ga}$ ] and nanocolloids [106], [ $^{68}\text{Ga}$ ] has been successfully labelled to tilmanocept [107]. Moreover, fluorescent (IRD-800CW)-labelled tilmanocept can be radiolabelled with both [ $^{68}\text{Ga}$ ] and [ $^{99\text{m}}\text{Tc}$ ]. The resulting tri-modal agent provides high-resolution preoperative PET-images for SLN mapping and intraoperative localization of SLNs with both a conventional portable  $\gamma$ -probe and fluorescence imaging [108]. This tri-model agent has been successfully tested with reliable SLN identification in animal models [109,110]. Although PET lymphoscintigraphy using this tri-model agent might provide a solution to the issues addressed for SLNB in early-stage OSCC, it is indisputable

that first it has to be investigated in a clinical trial with adequate reference standards.

### **Contrast-Enhanced Lymphosonography**

Compared to conventional lymphoscintigraphy, lymphosonography has many advantages (Table 2). Importantly, microbubbles are free of ionizing radiation and have a good safety profile, which was extensively documented for intravenous administration [111–113]. Secondly, lymphosonography is not affected by the shine-through phenomenon. Furthermore, none of the studies in humans or large animals found HEN enhancement [80–85]. It is possible that this is prevented by phagocytosis of microbubbles (which was histologically confirmed in animals for Sonazoid [85]) and the size of microbubbles compared to small-molecule dyes. Another advantage is the possibility to use lymphosonography preoperatively to improve lymph node selection for USgFNA. The sensitivity of USgFNA alone ranges from 45 up to 90% [114,115]. Adding lymphosonography could lead to more true positive patients, in whom the complex SLNB procedure may be omitted. A clinical trial using the combination of lymphosonography and USgFNA preceding SLNB will have to determine the value of this technique in head and neck oncological practice. Finally, ultrasound equipment is globally widely available and its mobility provides the option to use it in the operating room. Accordingly, lymphosonography may extend the application of SLNB from OSCC to less reachable sites of the head and neck (i.e., nasopharynx, oropharynx, larynx and hypopharynx), by allowing both peritumoral injection as well as SLN identification under general anesthesia.

However, lymphosonography has some disadvantages (Table 2). Foremost, the procedure is highly operator dependent and fast (a few seconds to minutes) transportation of microbubbles through the lymphatic system can make SLN identification challenging. Therefore, experienced staff will have to be appointed and trained. Future research will need to determine interobserver variability. Furthermore, if used without FNA it might be challenging to intraoperatively localize SLNs identified with preoperative lymphosonography; a reliable system to mark the exact location of SLNs is necessary. This drawback however is valid for several preoperative SLNB imaging techniques (i.e., CT lymphography, MR lymphography), and can be circumvented by combining lymphosonography with USgFNA or by performing lymphosonography intraoperatively. Besides, further research is needed to find out which CEUS imaging method and which microbubble are most suitable. The two clinical studies report a specific contrast imaging mode at a low mechanical index (MI), thus leaving the microbubbles intact [80–83,85]. Four animal studies performed lymphosonography in the head and neck region using Sonazoid, combined with either blue dye or ICG, in swine and rabbits without tumors [82,83,85] and with Definity in dogs with spontaneously arisen tumors [84]. The studies in swine added color flow Doppler at a high (microbubble destructing) mechanical index of 1.0 to confirm the presence of microbubbles [82,83]. In dogs power Doppler with a mechanical index of 1.3 was used primarily, which produces a color flair upon

microbubble destruction [84]. To select the most suitable microbubble, it is necessary to consider practicalities: using a microbubble that quickly reaches SLNs and is retained and detectable in the SLN for a long time might increase reproducibility. SonoVue consists of SF<sub>6</sub> phospholipid microbubbles with a mean bubble diameter of ~2.5 μm [77], while Sonazoid consists of perfluorobutane phospholipid (C<sub>x</sub>F<sub>y</sub>) microbubbles with a mean bubble diameter ~2.1 μm [116]. In most studies the time between peritumoral administration and lymph node enhancement (transit time) was described. Although no within-study comparisons have been made and clinical studies cannot be compared directly to preclinical studies, the transit time appears to be shorter for SonoVue (10–50 s post-injection [80]), than for Sonazoid (1–11 min post-injection [82,83,85]). Sonazoid enhancement seems to persist longer, namely ≥90 min [85], versus 2–4 min with SonoVue [80]. This could explain why multiple injections were necessary to identify SLNs in the clinical study using SonoVue [80]. However, Sonazoid has not yet been approved by FDA and EMA as a US contrast agent, which could complicate its application in clinical lymphosonography trials.

To conclude, lymphosonography is a promising method, but current clinical experience in OSCC is sparse. The two published clinical studies indicate that this technique is feasible, with SLN detection rates of 80 and 92% [80,81]. Unfortunately, correlation with histopathology is still lacking: in the only study that attempted this, no metastatic lymph nodes were detected [81]. Larger studies, preferably with histopathological examination and follow-up as reference standard, are needed to determine the diagnostic accuracy (i.e., sensitivity and NPV) of this technique for SLNB in OSCC and its place in the diagnostic workflow.

## MATERIALS AND METHODS

A systematic literature search for relevant English written literature published up to 25 May 2020 was conducted in the PubMed database. Search syntaxes combined synonyms and medical subject headings (MeSH) terms for both OSCC and SLNB and was performed for all imaging techniques separately (i.e., MR lymphography, CT lymphography, PET lymphoscintigraphy and contrast-enhanced lymphosonography). Subsequently, title and abstract screening was performed by four authors (R.M, J.d.M., E.N and R.d.B.). The reference lists of included studies were screened to identify any additional relevant publications. No critical appraisal of the selected literature was performed. This review adheres to the PRISMA guidelines [117].

### MR Lymphography

The following keywords and MeSH terms were included for MR lymphography: (“Mouth”[MeSH]) or (“Oral”) or (“Head and Neck”) and (“Sentinel lymph node”[MeSH])

or (“Lymph”) and (“Node”) or (“Sentinel”) and (“Node”) or (“Sentinel node”) and (“Lymphography”[MeSH]) or (“Lymphography”) or (“Lymphangiography”) and (“Magnetic resonance imaging”[MeSH] or (“Magnetic”) and (“Resonance”) and (“Imaging”) or (“Magnetic resonance imaging”) or (“MRI”) or (“MR”).

For magnetic detection of SLNs using superparamagnetic iron oxide, the following keywords and MeSH terms were included: (“Mouth”[MeSH]) or (“Oral”) or (“Head and Neck”) and (“Sentinel lymph node”[MeSH]) or (“Lymph”) and (“Node”) or (“Sentinel”) and (“Node”) or (“Sentinel node”) and (“Iron”[MeSH]) or (“Iron oxide”) or (“SPIO”) or (“SPION”) and (“Magnetics”[MeSH] or (“Magnetic”) or (“Superparamagnetic”) or (“superparamagnetic iron oxide”).

### **CT Lymphography**

The following keywords and MeSH terms were included for CT lymphography: (“Mouth”[MeSH]) or (“Oral”) or (“Head and Neck”) and (“Sentinel lymph node”[MeSH]) or (“Lymph”) and (“Node”) or (“Sentinel”) and (“Node”) or (“Sentinel node”) and (“Lymphography”[MeSH]) or (“Lymphography”) and (“CT”) or (“Computed Tomography”) or (“Computed”) or (“Tomographic”).

### **PET Lymphoscintigraphy**

The following keywords and MeSH terms were included for PET lymphoscintigraphy: (“Mouth”[MeSH]) or (“Oral”) or (“Head and Neck”) and (“Sentinel lymph node”[MeSH]) or (“Sentinel lymph node”) or (“Sentinel”) and (“Node”) or (“Sentinel node”) and (“Positron Emission Tomography Computed Tomography”[MeSH]) or (“Positron-Emission Tomography”[MeSH]) or (“PET”) or (“Positron”) or (“PET/CT”) or (“PET-CT”).

### **Contrast-Enhanced Lymphosonography**

The following keywords and MeSH terms were included for contrast-enhanced ultrasound lymphography: (“Mouth”[MeSH]) or (“Oral”) or (“Head and Neck”) and (“Sentinel lymph node”[MeSH]) or (“Sentinel lymph node”) or (“Sentinel”) and (“Node”) or (“Sentinel node”) and (“Contrast-enhanced”) or (“Contrast-assisted”) or (“CEUS”) or (“Microbubbles”) or (“Sonovue”) or (“Sonazoid”) or (“Optison”) or (“Levovist”) or (“Imagent”) or (“Imavist”) or (“Definity”) and (“Diagnostic Imaging”) or (“Diagnostic”) and (“Imaging”) or (“Ultrasound”) or (“Ultrasonography”[MeSH]) or (“Ultrasonography”) or (“Ultrasonics”[MeSH]) or (“Ultrasonics”).

## **CONCLUSIONS**

Novel diagnostic imaging techniques for detection of SLNs have the potential to bring the diagnostic accuracy of SLNB to a higher level for all early-stage OSCC subsites.

However, technical improvements and further research of these novel techniques are required, if they are to replace the conventional SLNB procedure with [<sup>99m</sup>Tc]-labelled radiotracers. Nevertheless, several of these novel techniques may already become valuable by facilitating more targeted radiotherapy; adjusting the radiation dose based on the tumor's individual lymphatic drainage pattern.

## AUTHOR CONTRIBUTIONS

Conceptualization, R.M., B.d.K. and R.d.B.; methodology R.M., J.d.M., E.N. and R.d.B.; validation, B.d.K., R.d.B., R.D., C.M., L.A. and B.t.H.; formal analysis, R.M., J.d.M. and E.N.; investigation R.M., J.d.M. and E.N.; writing—original draft preparation, R.M., J.d.M., E.N., B.d.K. and R.d.B.; writing—review and editing, B.d.K., R.d.B., R.D., C.M., L.A. and B.t.H.; visualization, R.M., J.d.M., E.N. and B.d.K.; supervision B.d.K., R.d.B., R.D., C.M., L.A. and B.t.H.; project administration, R.M. and R.d.B. All authors have read and agreed to the published version of the manuscript.

## FUNDING

SUMMARIZING DISCUSSION AND FUTURE PERSPECTIVES  
NEDERLANDSE SAMENVATTING (*DUTCH SUMMARY*)  
DANKWOORD (*WORD OF THANKS*)  
CURRICULUM VITAE

## SUMMARIZING DISCUSSION AND FUTURE PERSPECTIVES

While the results of cancer therapy continue to improve, not all patients diagnosed with cancer are cured and those who survive longer often have to live with long-term side effects. Heterogeneous drug distribution is one of the causes for ineffective cancer treatment: an effective drug is only effective when it reaches the right location at the right dose. Optimizing drug delivery to the target location aims to tilt the balance towards maximal effect and minimal side effects. In this thesis we discussed methods to optimize drug delivery using imaging and therapeutic ultrasound.

The review in **chapter 1** concludes that spatial heterogeneity in nanoparticle distribution occurs at all scales and can reduce efficacy of nanomedicine. A wide range of imaging modalities help visualize nanoparticle distribution or factors contributing to heterogeneous distribution, by imaging the drug, the nanoparticle and the tumour environment. Clinically, spatially heterogeneous distribution of therapeutic nanoparticles, creates a risk of both under- and overtreatment. While this review focuses on heterogeneity in distribution of nanomedicine, heterogeneity is of importance for any drug formulation [1-3]. Imaging drugs or nanoparticles in clinical studies can help predict treatment effect and therefore select which patients will benefit most and in which patients for example an adjusted dose or a different therapy are necessary. An alternative is to use imaging to select eligible patients for a combination treatment, such as the therapeutic ultrasound methods investigated in this thesis. Combining imaging of nanoparticle and drug distribution with imaging of characteristics of the tumour environment promises to help personalize treatment further. Choosing and combining imaging modalities wisely will hopefully lead to more successful applications of nanomedicine in the future.

Widespread clinical application of imaging drug distribution and heterogeneity can be hampered by costs (of the imaging method itself or for labelling nanoparticles and drugs), the anticipated burden on patients (e.g. long imaging procedures and extra hospital visits) safety or regulatory aspects (labelling slightly changes drug formulations) or the invasive nature of the procedure (for optical imaging and mass spectrometry imaging tissue samples are necessary). However, when evaluation of heterogeneity in drug distribution is omitted from clinical trials, effective drugs could wrongly be discarded as not effective, and an opportunity for personalized treatment could be missed. Future clinical researchers should therefore take into account which imaging method is most suitable to image heterogeneity on the scale of interest and for the nanoparticle/drug of interest. Ideally, future clinical studies should invest in imaging of both nanoparticle/drug distribution and heterogeneity of the tumour environment on multiple scales. Because the results could indicate predictive characteristics useful to select patients or adjust treatment for future patients, less extensive imaging might afterwards be suffi-

cient for a personalized treatment plan. Researchers should take feasibility and patient burden into account while designing such clinical studies; a recommendation would be to combine study procedures with standard-of-care imaging procedures and tumour sampling as much as possible. In this setting also retrospective studies with reanalysis of routinely collected images and tissue samples can be of great value for hypothesis generation, as we should try to learn as much as possible from each patient.

In **chapter 2** Dutch patients with *de novo* metastatic breast cancer (MBC) diagnosed between 2008 and 2018 were compared to a group of patients with metachronous MBC in the same period. We found differences in characteristics, treatment and survival, which highlight that these are two distinct subgroups and that the presence of a primary breast tumour is not the only difference. Compared to metachronous patients, patients with *de novo* metastatic breast cancer were more likely to be 70 years or older, to have invasive lobular carcinoma, clinical T3 or T4 tumours, loco-regional lymphnode metastases, HER2 positivity, bone only disease and to have received systemic therapy in the metastatic setting. They were less likely to have triple negative tumours and liver or brain metastases. Unlike patients with *de novo* MBC, many patients with metachronous MBC have already received systemic treatment in addition to loco-regional treatment following diagnosis of the primary tumour. Recurrence despite these previous systemic therapies could reflect 1) disadvantageous tumour-characteristics, 2) patient comorbidity / fitness and 3) primary or acquired therapy resistance. Patients with *de novo* metastases survived longer (median 34.7 months) than patients with metachronous metastases (median 24.3 months) and the hazard ratio (0.75) varied over time.

Future studies into the differences between patients with *de novo* and metachronous MBC would ideally also take into account indicators of fitness (such as performance score, comorbidity), indicators of metastatic burden (such as number and volume of metastases) and in more detail the type of systemic therapy administered. This would be helpful to make even more accurate prognosis possible for individual patients, which could help patients make informed treatment decisions. Furthermore, comparison of patients with *de novo* MBC with *all* patients diagnosed with metachronous MBC in the same period (regardless of metastasis free interval) would provide even more accurate results and the opportunity to compare changes over time as well.

The findings in this study could help clinicians better inform patients about their prognosis and to provide more personalized treatment. Moreover, it could facilitate design of *de novo* specific trials of innovative treatments such as the trial described in **chapter 3**.

In **chapter 3** we discussed the study design of the i-GO study. This is the first clinical trial that will investigate the combination of LTLD and MR-HIFU induced hyperthermia in breast cancer. We think that this combination leads to improved treatment of the primary tumour, without changing the systemic doxorubicin concentration and thus without

compromising effective treatment of metastases or increasing toxicity.

If this phase I trial demonstrates that safety, feasibility and tolerability are adequate, this approach could in the future lead to improved neoadjuvant treatment of the breast tumour in patients with stage II or III breast cancer, without increasing toxicity. It could lead to less extensive surgery or even in selected patients make surgery (and the associated burden and side effects) redundant.

Unfortunately, this trial has not yet included its first participant at the moment of publication of this thesis. We chose to position this trial in the palliative setting of *de novo* MBC to evaluate safety of the treatment first, before continuing in the neo-adjuvant setting, where the potential benefit for patients is expected. This limits the number of available study participants (circa 5% of all newly diagnosed breast cancer patients present with *de novo* MBC). In addition, it makes an altruistic motivation of the patient necessary, in patients who already have a lot to process after their diagnosis of metastatic breast cancer. Due to ongoing developments and new treatment options in the palliative setting, that arose between the first idea for the study and the start of accrual, the eligible study population became smaller than anticipated. One of these developments is the use of chemotherapy other than anthracycline containing or targeted regimens in the first, second and even third line of metastatic treatment. Amendments to the study design are currently being proposed to improve feasibility of patient recruitment, while still maintaining optimal safety for trial participants. We expect that determining safety and feasibility of LTLD plus MR-HIFU in this population will be possible and ethical, while changing the standard of care treatment (doxorubicin, cyclophosphamide and paclitaxel, AC-P) as little as possible.

For future applications of MR-HIFU hyperthermia and temperature sensitive liposomes the following conditions should be met for the treatment to be feasible and successful in providing a solution to a clinical need. First, there must be a need for a local treatment effect. This could arise with a primary tumour or a metastasis which is symptomatic, incurable with standard treatment, or can only be addressed by an intervention that induces significant morbidity (i.e. amputation of a limb or reduction of an organ). Improving local drug delivery could then provide better palliation, increase chance of survival or decrease treatment related toxicity. An advantage over other local treatment options such as radiotherapy or surgery would be that the treatment occurs simultaneously with systemic treatment and is not invasive. Future studies should incorporate quality of life assessments to determine if this indeed benefits patients. Sometimes standard of care local treatment options are suitable alternatives, but a patient could prefer a non-surgical treatment due to e.g. fear of surgical toxicity, change of body-image or risks of general anaesthesia. In any case, patient preference and shared decision making are very important when deciding between conventional local treatment options (surgery, radiotherapy) and enhanced local drug delivery using MR-HIFU plus LTLD. Second, there should be at least some suggestion that drug distribution with conventional systemic

treatment is sub-optimal in this patient or tumour type, or that reaching the desirable drug distribution with systemic treatment would lead to more side effects. Third, the tumour should be accessible for safe and feasible MR-HIFU (based on tissue type, tumour location and technical properties of the MR-HIFU system). Fourth, the tumour type should be sensitive to the envisioned drug when used in sufficient concentrations. For example, with LTLD the tumour type should be known to respond to anthracyclines. It should be noted that previous resistance may also have been caused by inadequate drug distribution. In tumour types resistant to anthracyclines, temperature sensitive liposomes with other drugs such as cisplatin or gemcitabine could be investigated, although these are less far in development [4].

Considering this, we expect MR-HIFU hyperthermia combined with LTLD could potentially provide a benefit for patients with soft tissue sarcomas (STS), as these tumours are known for their sensitivity to anthracyclines. STS often lead to painful local symptoms, and in the majority of patients extensive surgery is required to relieve symptoms, while standard-of-care chemotherapy is likely to lead to heterogeneous drug distribution due to heterogeneity in the tumour environment [5].

In addition to the application of MR-HIFU for hyperthermia in combination with temperature sensitive liposomes, other applications of MR-HIFU are currently being investigated as well. MR-HIFU ablation of small breast tumours could in the future provide the possibility to omit surgery in selected patients. A previous trial in our hospital showed that (deliberately partial) ablation of breast tumours is feasible and safe [6, 7], a trial evaluating feasibility of complete tumour ablation is currently ongoing (ClinicalTrials.gov Identifier: NCT02407613).

Moreover, MR-HIFU can be used not only to increase temperature, but also to mechanically fractionate part of the tumour, also known as histotripsy. HIFU histotripsy creates a sterile local inflammation and release of tumour associated antigens and danger-associated molecular patterns, which activate dendritic cells. Preclinical studies have shown that histotripsy can enhance the effect of immune checkpoint inhibition, by converting a non-immunogenic (cold) tumour into a (hot) tumour sensitive to immune checkpoint inhibition [8]. An important next step is to show that this combination can be used safely in patients with cancer. A phase I clinical trial is currently being designed.

Before implementing new treatment options, health technology assessments can help evaluate if the benefits of a technique outweigh its financial burden on our society and health care system[9]. Early evaluations showed that MR-HIFU ablation for breast cancer was more expensive than conventional breast conserving treatment [10]. MR-HIFU ablation as palliative treatment for painful bone metastases did seem cost effective compared to radiotherapy alone[11]. Formal health technology assessments for MR-HIFU plus LTLD to our knowledge have not yet been performed. At the moment, costs for MR-HIFU plus LTLD treatment are considerably higher than standard-of-care treatment with doxorubicin. However, costs are expected to decrease with increasing clinical expe-

rience and future studies will need to determine whether the benefits (including quality of life but also financial benefits of possibly reducing need for surgery) outweigh the costs.

In **chapter 4** we described *in vitro* experiments to evaluate the effect of ultrasound and microbubbles (USMB) therapy in combination with chemotherapy on a head and neck cancer cell line. Clinical translation of USMB therapy is currently compromised by the large variety of (non-clinical) US set-ups and US parameters that are used in preclinical studies, which are not easily translated to clinical practice. In this chapter we took a step towards facilitating clinical translation, by proving that USMB therapy, using a clinical ultrasound system in combination with clinically approved microbubbles, leads to efficient *in vitro* uptake of a drug mimicking fluorescent dye and enhanced effect of chemotherapy with bleomycin. In contrast to previous clinical studies that used B-mode and contrast mode [12] or power Doppler [13], we used the PW Doppler mode and performed an extensive evaluation of multiple transducers and available US settings. With the PW Doppler settings used, we were able to achieve similar or even higher intracellular uptake compared to the settings used on a dedicated system with optimized parameters [14]. Future studies should determine the safety and efficacy of our methods and US parameters in patients. To bridge the gap between *in vitro* application and the first clinical trial, we performed a veterinary trial, which is discussed in chapter 5.

**Chapter 5** describes a small veterinary clinical trial, evaluating the combination of bleomycin chemotherapy and USMB therapy in cats with oral squamous cell carcinoma. In these cats, the USMB treatments were feasible and well tolerated. Adverse events were considered mild and related to anaesthesia, comorbidity or progressive tumour growth. Eventually, all cats had progressive disease. However, while the median overall survival is (historically) around 44 days with supportive care alone [15], survival in our (albeit small and uncontrolled) study was somewhat longer (46- 85 days). Moreover, CEUS imaging immediately before and after USMB treatment in 4 of the cats indicated an increase in tumour perfusion, which may be beneficial for drug delivery.

This was a small feasibility study. An ideal veterinary clinical trial would include a larger number of patients and a control group of patients treated with bleomycin alone. Simultaneous cavitation-detection to monitor microbubble response during USMB therapy could further benefit safety and efficacy [16]. Blood samples would be taken to monitor pharmacokinetics of bleomycin in cats treated with and without USMB. Tumour biopsies before and after treatment would be used for imaging of bleomycin distribution throughout the tumour (for example using mass spectrometry imaging) and to quantify the amount of bleomycin in the tumours. Additionally, the tumour biopsies would be cultured as organoids and tested *in vitro* for bleomycin sensitivity, with and without USMB. In this way we could determine if non-responders were inherently resistant to

bleomycin or if the bleomycin still reached the target location in an insufficient dose *in vivo*. Finally, it would be interesting to continue the study treatment longer, perhaps a total number of 3 sessions was insufficient. Although this trial design would provide a wealth of information it is unlikely that it is feasible in the setting of veterinary patients. The advantage of the study design in **chapter 5** is that it was relatively simple and posed a small burden on the cats and their owners, which gave us the opportunity to include five patients.

In the future, we expect USMB therapy in combination with chemotherapy could provide a benefit in human patients with (for example) head and neck cancer. Based on previous *in vitro* results from our group, the effect of the standard-of-care chemotherapy or chemoradiotherapy with cisplatin could be improved by addition of USMB [17]. Furthermore, the combination of USMB therapy with radiotherapy in the absence of drug is promising, considering the effect of USMB on perfusion. Clinical studies are already ongoing (Clinicaltrials.gov NCT04431674, NCT04431648). Since we already used a clinical US system, and EMA/FDA approved microbubbles in this study, the step to a clinical trial in human patients can be taken in the near future. In other centres, early clinical trials using USMB in combination with chemotherapy in patients with various tumour types have already shown promising results or are still ongoing [12, 18, 19] (Clinical-Trials.gov Identifiers: NCT04146441, NCT04821284, NCT03477019 and NCT03458975, NCT03385200). As a first clinical trial in patients with head and neck cancer, I propose to evaluate safety and feasibility of USMB therapy to enhance tumour perfusion (without chemotherapy). USMB therapy could be performed before surgery and CEUS before and after USMB would be used to investigate the effect on perfusion. This type of trial would pose a small burden and low risk on the patient. When this is proven safe and feasible, USMB therapy could be evaluated in addition to standard of care chemo(radio)therapy (such as cisplatin and/or cetuximab) to improve drug delivery or in addition to radiotherapy (to enhance tumour perfusion and reduce hypoxia). In the future the combination of USMB therapy with a decreased dose of chemoradiotherapy could lead to similar efficacy while reducing local toxicity.

**Chapter 6** is a review about preoperative sentinel lymph node imaging techniques which could help select which head and neck cancer patients, in particular patients with early stage oral cavity squamous cell carcinoma, need additional therapy to treat lymph node metastases. With improving the diagnostic accuracy of these techniques, invasive treatments of the neck could safely be omitted in more patients. Although diagnostic accuracy of most presented techniques is still inferior to conventional lymphoscintigraphy, each technique has its own strengths and flaws, and further development may in the future lead to better results.

Related to the topic of ultrasound and microbubbles, lymphosonography is a promising technique but clinical experience is currently still insufficient. A future trial combining

preoperative US guided fine needle aspiration (USgFNA) with lymphosonography, prior to the conventional sentinel node procedure would be very useful to determine if lymphosonography could increase the sensitivity of USgFNA [20, 21] and perhaps decrease the need for sentinel node procedures in the future.

To conclude, this thesis describes methods to optimize drug delivery using imaging and therapeutic ultrasound and focuses on ways to achieve personalized treatment with optimal effect and minimal side effects. It demonstrates the value of multidisciplinary collaboration between both technical and clinical researchers, radiologists and oncologists and veterinary and human clinicians. These collaborations will become increasingly important in the future. Future studies should be designed with both theoretical benefit and clinical feasibility in mind. In this way, clinical translation of promising techniques will hopefully benefit future patients.

## NEDERLANDSE SAMENVATTING

### **Optimale medicijnverdeling bij kanker met behulp van beeldvorming en therapeutisch ultrageluid**

De laatste jaren is er veel vooruitgang geboekt op het gebied van de behandeling van kanker. In Nederland leven patiënten met kanker steeds langer [1]. Deze verbetering is helaas niet bij alle kankertypes even sterk, nog niet alle patiënten genezen van hun ziekte en daarnaast kunnen bijwerkingen van de behandelingen op de langere termijn veel problemen opleveren [2-5]. Eén van de oorzaken van niet-effectieve kankerbehandeling is een ongelijkmatige (heterogene) verdeling van de medicijnen tegen kanker. Verschillen in de verdeling van medicijnen tussen patiënten, maar ook tussen verschillende organen van een patiënt en zelfs tussen verschillende gebieden binnen een tumor dragen daaraan bij [6-8]. Een medicijn is alleen effectief wanneer het de juiste plek bereikt in de juiste hoeveelheid. In dit proefschrift beschrijven we twee behandelmethodes om medicijnafgifte zo optimaal mogelijk te maken. Deze methodes (die we hieronder toelichten) maken gebruik van therapeutisch ultrageluid:

1. **MR-HIFU hyperthermie** gecombineerd met **temperatuurgevoelige vetbolletjes** met chemotherapie
2. **Ultrageluid en microbellen behandeling**

Beide behandelingen hebben als doel om de medicijnverdeling zo optimaal mogelijk te maken. De meest optimale situatie is een maximaal effectieve behandeling die zorgt voor minimale schade aan gezond weefsel (schade aan gezond weefsel wordt ‘toxiciteit’ of ‘bijwerking’ genoemd).

Beeldvorming (het maken van scans en beelden voorafgaand aan en tijdens een behandeling) kan ons meer informatie geven over de kenmerken van patiënten en zo helpen om de behandeling zo goed mogelijk te richten op de plek waar deze nodig is, de behandeling zo veilig mogelijk te maken en om de behandeling aan te passen aan de individuele patiënt (ook wel ‘gepersonaliseerde behandeling’ genoemd).

Deze Nederlandse samenvatting omschrijft de belangrijkste achtergrondinformatie en bevindingen van de hoofdstukken in dit proefschrift.

### **Ultrageluid**

Ultrageluid staat bekend om haar toepassing bij het maken van beelden. In het Nederlands wordt dit onderzoek ‘echografie’ genoemd. Het meest bekend is de echo bij een zwangere, maar echografie kan informatie geven over vrijwel alle organen. Bij echografie worden ultrageluidsgolven door het echoapparaat uitgestuurd richting het lichaamweefsel. Deze golven reflecteren op de overgangen tussen verschillende weefsels en worden

weer opgevangen door het echoapparaat, dat vervolgens een zwart-wit beeld van de weefsels maakt [9]. Bij een contrast-echografie worden daarnaast heel kleine gasbelletjes intraveneus (via het infuus) toegediend (dit worden ook wel ‘microbellen’ genoemd), deze zorgen voor een sterkere weerkaatsing van het ultrageluid. Dit kan bijvoorbeeld helpen om meer informatie te krijgen over de bloedvaten [9-11].

In dit onderzoek gebruiken we ultrageluid niet alleen voor het maken van beelden, maar ook als een behandeling om lokale medicijnverdeling te verbeteren. Daarom noemen we dit ‘therapeutisch ultrageluid’. Twee voorbeelden van therapeutisch ultrageluid zijn MR-gestuurde hoge intensiteit gebundeld ultrageluid (MR-HIFU) en behandeling met ultrageluid in combinatie met microbellen (USMB behandeling).

### **Magnetische resonantie - gestuurde hoge intensiteit gebundeld ultrageluid (MR-HIFU)**

MR-HIFU is een combinatie van MRI (magnetische resonantie beeldvorming) en HIFU (hoge intensiteit gebundeld ultrageluid), met als doel om weefsel (zoals een tumor) op te warmen of mechanische effecten te veroorzaken. HIFU bestaat uit sterke ultrageluidsgolven die in één punt worden gebundeld. Dit is vergelijkbaar met het bundelen van zonnestralen op één punt met een vergrootglas om zo vuur te maken. Afhankelijk van het doel van de behandeling kan het weefsel verwarmd worden tot 55-70°C (‘thermale ablatie’ [12-14] of tot 40-43°C (‘hyperthermie’ [15-17]. MR-gestuurd betekent dat we op basis van MRI beelden precies kunnen plannen welk gedeelte van de patiënt verwarmd wordt. Daarnaast kunnen we met MRI beelden tijdens de HIFU behandeling de temperatuur in de patiënt meten en volgen wat het effect van de behandeling is [18].

### **Nanomedicijnen zoals temperatuurgevoelige vetbolletjes met doxorubicine.**

Om medicijnafgifte op de gewenste plek te verbeteren kan MR-HIFU hyperthermie gecombineerd worden met temperatuurgevoelige nanomedicijnen. Nanomedicijnen zijn kleine deeltjes (op nanometerschaal, ook nanodeeltjes genoemd) gebonden aan medicijnen of als verpakking voor medicijnen. Nanodeeltjes zijn gemaakt om deze medicijnen zoveel mogelijk af te leveren op de plek waar ze nodig zijn. Dit heeft als doel om de effectiviteit te verhogen (hogere hoeveelheden (concentraties) van medicatie in de tumor) en de toxiciteit te verlagen (beperken van schade aan het gezonde weefsel) [24]. In dit onderzoek hebben we het nanomedicijn ThermoDox onderzocht. Dit zijn temperatuurgevoelige vetbolletjes (liposomen) van circa 100 nanometer die bestaan uit een membraan met een dubbele laag fosfolipiden en binnenin verpakt het chemotherapiemiddel doxorubicine. Deze vetbolletjes worden in de bloedbaan toegediend en stromen door het lichaam terwijl de tumor wordt verwarmd. Alleen daar waar de vetbolletjes verwarmd worden (in de tumor), komt er snel een grote hoeveelheid doxorubicine vrij [25-27]. In de rest van het lichaam (op lichaamstemperatuur) lekken de vetbolletjes een beetje en komt er heel langzaam evenveel doxorubicine vrij als bij een behandeling met doxorubicine die niet is verpakt in een vetbolletje. Zo willen we het lokale effect van chemotherapie in de tumor versterken,

zonder dat er meer bijwerkingen en schade ontstaan in de rest van het lichaam. Er is al veel onderzoek gedaan bij patiënten naar de combinatie van ThermoDox met andere methoden van verwarming [28-32]. In dit proefschrift beschrijven we hoe we het willen onderzoeken in combinatie met MR-HIFU hyperthermie.

### **Ultrageluid en microbellen behandeling (USMB behandeling)**

De tweede methode van therapeutisch ultrageluid die we toepassen in dit onderzoek is ultrageluid en microbellen (USMB) behandeling. Microbellen zijn zoals hierboven genoemd contrastmiddelen voor echografie. Het zijn kleine deeltjes van 1-10 micrometer doorsnede, gevuld met gas en omgeven met een laagje fosfolipiden of eiwitten [19, 20]. Naast de rol van microbellen bij het maken van beelden, biedt de combinatie van ultrageluid met microbellen ook de mogelijkheid om lokaal de werking van medicijnen te versterken. Afhankelijk van de gebruikte ultrageluid instellingen zoals frequentie en druk gaan microbellen trillen ('stabiele cavitatie') of kunnen ze kapot gaan ('inertiële cavitatie'). Beide soorten cavitatie kunnen biologische effecten veroorzaken in het omringende weefsel, zoals het maken van kleine gaatjes in celmembranen, het stimuleren van opname van stoffen door endocytose, het meer doorgankelijk maken van de bloedvatwand en het beperken of juist stimuleren van de bloedtoevoer. Alle effecten van behandeling met ultrageluid en microbellen die kunnen zorgen voor meer lokale afgifte van medicijn op de gewenste plek heten samen 'sonopermeatie' [21-23].

### **Patiëntengroepen in dit proefschrift**

In dit proefschrift beschrijven we de toepassing van therapeutisch ultrageluid om medicijnverdeling te verbeteren in het kader van twee groepen patiënten:

1. Patiënten met '**de novo uitgezaaide borstkanker**' voor de toepassing van MR-HIFU plus ThermoDox
2. Patiënten met **hoofd-halskanker** voor de toepassing van USMB behandeling plus chemotherapie

#### *Patiënten met de novo uitgezaaide borstkanker*

Dit zijn patiënten bij wie bij het stellen van de diagnose borstkanker ook gelijktijdig uitzaaiingen buiten de borst (op afstand) worden gevonden. De diagnose borstkanker wordt in Nederland elk jaar bij ongeveer 14.500 nieuwe patiënten gesteld [33]. Ongeveer 5% van hen heeft op dat moment uitzaaiingen ergens anders in het lichaam [34]. Bij de meeste mensen met uitgezaaide borstkanker ('stadium IV') worden de uitzaaiingen ontdekt in de jaren na de diagnose en behandeling (zogenaamde 'metachrone uitzaaiingen'). Omdat mensen met *de novo* uitgezaaide borstkanker zowel een tumor in de borst hebben als uitzaaiingen op afstand is het mogelijk om het effect (lokaal in de borst en op afstand in de uitzaaiingen) én de bijwerkingen van de combinatie van ThermoDox

met MR-HIFU hyperthermie goed te onderzoeken. We hebben een fase 1 studie opgezet (de eerste fase van onderzoek bij mensen) om bij deze patiënten te onderzoeken of de combinatiebehandeling veilig en haalbaar is.

#### *Patiënten met hoofd-halskanker*

De diagnose ‘hoofd-halskanker’ wordt in Nederland elk jaar bij ongeveer 3.000 nieuwe patiënten gesteld [35] | 6B. Het gaat om een groep van tumoren in het hoofd-hals gebied (bijvoorbeeld in de mond, neus, keelholte of strottenhoofd). De meeste patiënten hebben lokaal uitgebreide ziekte [36, 37], waarbij een operatie soms niet mogelijk is doordat de tumor niet volledig weggehaald kan worden of doordat de operatie onacceptabel veel omliggend weefsel zou beschadigen of lokale functies zou verminderen. Ondanks combinaties van behandeling (operatie, chemotherapie, bestraling, doelgerichte medicijnen en/of immuuntherapie) met veel bijwerkingen komt de tumor bij ongeveer de helft van de patiënten in het hoofd-halsgebied terug. De kanker is dan vaak niet meer genezen [38, 39]. Omdat dit kankertype zoveel lokale problemen kent, denken we dat een verbetering van lokale medicijnverdeling met behulp van therapeutisch ultrageluid bij deze patiënten zou kunnen helpen, door de effectiviteit van de behandeling te verbeteren, zonder voor meer bijwerkingen te zorgen.

#### *Hoofd-hals kanker bij katten*

De behandeling met ultrageluid en microbellen is al vaak onderzocht met celexperimenten in een laboratorium, dit noemen we ‘*in vitro*’ (Latijn voor ‘in glas’, oftewel buiten een mens of dier, bijvoorbeeld in een kweekschalpje of reageerbuis). Ook is het onderzocht bij levende proefdieren zoals ratten en muizen (*in vivo*). Vervolgens is er onderzoek gedaan bij kleine groepen mensen, maar nog niet specifiek bij patiënten met hoofd-halskanker. Om een stap verder te komen richting het toepassen van deze behandeling bij mensen, kan dieronderzoek helpen. In dit proefschrift hebben we niet gekozen voor proefdieronderzoek, maar voor een klinische studie bij huisdieren, namelijk katten. Deze katten zijn patiënten van een dierenarts, bij wie een behandeling veel kan lijken op die van menselijke patiënten. Hoofd-hals kanker komt vaak voor bij oudere katten en 10% van alle tumoren bij katten zitten in de bek [40]. Helaas overleven deze katten met alleen ondersteunende behandeling gemiddeld slechts 1,5 maand [41]. Er zijn veel overeenkomsten tussen hoofd-hals tumoren bij mensen en bij katten, en door de afmetingen van een kat kunnen dezelfde echoapparatuur en ultrageluidsinstellingen gebruikt worden als bij mensen [42-44]. Een onderzoek bij deze veterinaire patiënten kan ons daarom een stap vooruit brengen in het onderzoek bij mensen.

#### **Overzicht van de hoofdstukken**

Het review artikel in **hoofdstuk 1** geeft een overzicht van verschillende onderzoeken die laten zien dat nanodeeltjes en nanomedicijnen zich niet altijd op een gelijkmatige manier

verdelen. Er zijn verschillen in de verdeling tussen patiënten, tussen organen in één patiënt, tussen tumoren of binnen één tumor. Kortom, er is op elke schaal heterogeniteit in de verdeling van deze nanodeeltjes, terwijl we weten dat een medicijn alleen effectief is wanneer het de juiste plek bereikt in de juiste hoeveelheid.

Beeldvorming (het maken van scans) kan helpen om de verdeling van nanodeeltjes en factoren die bijdragen aan heterogeniteit in kaart te brengen. Hierbij zijn er beeldvormende technieken voor het afbeelden van de verdeling van het medicijn, het nanodeeltje dat het medicijn vervoert en de omgeving van de tumor waar het medicijn moet werken. Dit soort beeldvormende technieken kunnen in klinische studies helpen voorspellen welke patiënten het meeste baat hebben bij een behandeling en bij welke patiënten de behandeling aangepast moet worden. Ook zouden zo patiënten geselecteerd kunnen worden die baat hebben bij het toevoegen van een behandeling, met als doel de verdeling van de medicijnen te verbeteren, zoals therapeutisch ultrageluid.

In **hoofdstuk 2** vergelijken we Nederlandse patiënten die tussen 2008 en 2018 de diagnose *de novo* uitgezaaide borstkanker hebben gekregen met een groep patiënten bij wie in dezelfde periode (metachrone) uitzaaiingen van eerdere borstkanker zijn ontdekt. We vonden verschillen in de kenmerken, behandeling en overlevingsduur van deze patiënten. Dit benadrukt dat het twee aparte groepen zijn, waarbij de aanwezigheid van een tumor in de borst zeker niet het enige verschil is. Het feit dat de kanker bij de patiënten met metachrone uitzaaiingen is teruggekeerd ondanks de eerdere behandeling kan wijzen op: 1) ongunstige tumorkenmerken 2) minder fitte patiënten die meer andere ziekten hebben naast de borstkanker en 3) dat de tumor al resistent was of is geworden tijdens de behandeling. Patiënten met *de novo* uitgezaaide borstkanker overleven langer (mediaan 34.7 maanden na de diagnose) dan patiënten met metachrone uitzaaiingen (mediaan 24.3 maanden).

Dit onderzoek kan dokters helpen hun patiënten nog beter voor te lichten en de behandeling nog meer te personaliseren. Daarnaast kan het helpen om klinische studies te ontwerpen met innovatieve behandelingen specifiek voor *de novo* uitgezaaide borstkanker, zoals de studie in hoofdstuk 3.

In **hoofdstuk 3** bespreken we de opzet van de i-GO studie. Dit is de eerste klinische studie naar de combinatie van het nanomedicijn ThermoDox in combinatie met MR-HIFU hyperthermie bij patiënten met borstkanker.

We willen deze behandeling onderzoeken bij patiënten met *de novo* uitgezaaide borstkanker. In de studie wordt de standaard chemotherapie doxorubicine vervangen door het nanomedicijn ThermoDox (doxorubicine in temperatuurgevoelige vetbolletjes) in combinatie met verwarmen van de borsttumor met MR-HIFU. We verwachten dat deze combinatie leidt tot betere behandeling van de tumor in de borst, zónder dat er meer chemotherapie in de rest van het lichaam terecht komt, zodat de uitzaaiingen in de

rest van het lichaam net zo goed behandeld worden als anders en de bijwerkingen niet toenemen. Het hoofddoel van het onderzoek is om bij een klein aantal patiënten (6- 12) te beoordelen of de behandeling veilig en haalbaar is. Als dit zo is, kan verder onderzoek laten zien of het ook tot betere uitkomsten voor de patiënten leidt. In de toekomst hopen we dat deze combinatiebehandeling bij patiënten met borstkanker zonder uitzaaiingen leidt tot minder uitgebreide borstoperaties, of operatie zelfs helemaal niet meer nodig is.

Voor **hoofdstuk 4** hebben we celexperimenten gedaan (*in vitro*) om het effect van ultrageluid en microbellen (USMB) behandeling in combinatie met bleomycine chemotherapie op gekweekte hoofd-halskankercellen te onderzoeken. Bleomycine kan kankercellen pas doden wanneer het in de cel aanwezig is, maar omdat het een wateroplosbaar medicijn is komt het niet makkelijk door de celmembraan naar binnen. USMB behandeling kan cellen doorgankelijk maken en medicijnopname stimuleren (sonopermeatie) om zo het effect te versterken.

Eerdere onderzoeken gebruiken veel verschillende (zelfgebouwde) apparatuur en instellingen van het ultrageluid, die niet altijd makkelijk vertaald kunnen worden naar de toepassing bij mensen in het ziekenhuis. Daarom hebben we in dit onderzoek een klinisch echoapparaat en voor toediening aan mensen goedgekeurde microbellen gebruikt. USMB behandeling met een klinisch echoapparaat leidt tot opname van een fluorescerende kleurstof (als model voor een medicijn) in kankercellen. Ook versterkt de USMB behandeling zoals verwacht het effect van bleomycine chemotherapie. Om de stap van *in vitro* experimenten naar de eerste klinische studie bij patiënten met hoofd-halskanker te verkleinen hebben we in hoofdstuk 5 deze behandeling toegepast bij katten.

**Hoofdstuk 5** gaat over een klinische studie bij vijf katten met plaveiselcelcarcinomen in de bek, die we hebben behandeld met de combinatie van bleomycine chemotherapie en USMB behandeling. Hierbij werd opnieuw een klinisch echoapparaat gebruikt en microbellen die zijn goedgekeurd voor toepassing bij mensen. De behandeling werd door de katten goed verdragen. De symptomen die ze hadden waren mild en hingen samen met de narcose, andere aandoeningen of groei van de tumor. Uiteindelijk groeiden helaas alle tumoren verder, maar was de overlevingsduur met 46- 85 dagen wel iets langer dan wat in eerder onderzoek beschreven was na alleen een ondersteunende behandeling (mediaan 44 dagen) [41]. Tijdens dit onderzoek deden we (zowel voor als na de behandeling met ultrageluid en microbellen) ook contrast-echografie. Hierbij viel op dat de doorbloeding (perfusie) van de tumoren na USMB behandeling in veel gevallen toenam. We denken dat dit ervoor kan zorgen dat chemotherapie zich beter verdeelt in tumoren en dat radiotherapie (bestraling) beter werkt omdat er meer zuurstof in het tumorweefsel komt. Waarschijnlijk speelde andere mechanismen van sonopermeatie in ons onderzoek maar een kleine rol, waardoor bleomycine (dat niet zozeer van perfusie afhankelijk is maar wel iets nodig heeft om de celwand door te gaan en in de cel werkzaam te zijn) maar

een beperkt effect had. In toekomstige studies raden we aan te onderzoeken wat de toegevoegde waarde van USMB behandeling is bij andere chemotherapie (zoals cisplatin of carboplatin) en/of radiotherapie bij patiënten met hoofd-halskanker. Omdat de USMB behandeling uitgevoerd kon worden met klinische echoapparatuur en microbellen die ook goedgekeurd zijn voor gebruik bij mensen, brengt deze veterinaire studie ons een stap dichterbij bij toepassing van USMB behandeling bij mensen.

**Hoofdstuk 6** is een review artikel over technieken voor het in beeld brengen van de schildwachtklier bij patiënten met hoofd-halskanker. Een van deze technieken maakt gebruik van ultrageluid en microbellen op een andere manier dan we hiervoor hebben beschreven.

De schildwachtklierprocedure heeft als doel te onderzoeken of kankercellen van de tumor waar ze zijn ontstaan (primaire tumor) naar de lymfeklieren zijn verspreid, zonder daarbij alle lymfeklieren te hoeven weghalen. Bij de schildwachtklier procedure wordt een stofje in of rondom de primaire tumor gespoten en vervolgens wordt gekeken in welke lymfeklier dit stofje als eerste terecht komt. Die eerste lymfeklier heet de schildwachtklier en de verwachting is dat eventuele kankercellen dezelfde route volgen en hier ook als eerste naartoe zouden gaan. Deze schildwachtklier wordt dan verwijderd en onderzocht onder de microscoop. Als hier geen kankercellen in blijken te zitten verwachten we dat dit ook in de rest van de lymfeklieren niet zo is en hoeven deze niet allemaal preventief verwijderd te worden. Zo kan de patiënt een extra operatie en de risico's daarvan bespaard blijven [45]. Dit review artikel beschrijft verschillende technieken van beeldvorming van de schildwachtklier voorafgaand aan een operatie, die verschillende voor- en nadelen hebben. Een van deze technieken is lymphosonografie waarbij microbellen in of rondom de primaire tumor worden gespoten en met echografie worden gevolgd tot ze via de lymfebanen uitkomen bij de schildwachtklier. Dit is een veelbelovende techniek, maar er is tot nu toe nog weinig ervaring mee in de kliniek.

**Samenvattend** beschrijft dit proefschrift methodes om medicijnverdeling zo optimaal mogelijk te maken, door gebruik te maken van beeldvorming en therapeutisch ultrageluid. Hierbij streven we naar gepersonaliseerde behandeling met een zo sterk mogelijk gewenst effect en zo min mogelijk bijwerkingen. Dit onderzoek laat daarnaast zien dat samenwerking tussen verschillende vakgebieden van grote waarde is, tussen technische en klinische onderzoekers, radiologen en oncologen en artsen en dierenartsen. Deze samenwerking zal in de toekomst alleen maar belangrijker worden, met als doel ervoor te zorgen dat zoveel mogelijk toekomstige patiënten profiteren van veelbelovende nieuwe technieken.

## DANKWOORD

Op 1 oktober 2016 begon ik aan dit avontuur en nu is het dan eindelijk zover: mijn proefschrift is af! Mijn promotietijd was er één om nooit te vergeten, met veel pieken en dalen, tegenvallers en opluchting. Met het uitbreiden van mijn capaciteiten en vaardigheden waarbij mijn comfort zone toch steeds weer wat groter bleek te zijn dan ik dacht, veel interessante gesprekken en discussies en ook veel gezelligheid in de samenwerking met zoveel mensen uit uiteenlopende disciplines. Hoewel ik zes jaar geleden een heel ander boekje voor mij zag ben ik ontzettend trots op het eindresultaat. Dit alles was mij nooit gelukt zonder de hulp van heel veel mensen die direct en indirect betrokken waren en die ik allemaal van harte wil bedanken. Een aantal mensen wil ik hier in het bijzonder noemen.

Ten eerste mijn fantastische promotoren prof. dr. Elske van der Wall en prof. Chrit Moonen.

Lieve **Elske**, jij was voor mij de ideale supervisor. Het is inspirerend hoe jij ervoor kunt zorgen dat iedere PhD-student het beste uit zichzelf haalt, en hoe jouw doel is om anderen in de spotlight te zetten. Onze afspraken, altijd met chocola, begonnen stevast met de vraag hoe het met mij ging en als ik me goed voelde was jij tevreden. Daarnaast wist je altijd de juiste vragen te stellen zodat ik op ideeën kwam om ons onderzoek te verbeteren en kwam ook zelf met nieuwe ideeën (zoals het IKNL-project) als ik het even echt niet meer wist. Bedankt dat jij voor mij een voorbeeld was (en altijd zult blijven) als dokter, wetenschapper en supervisor!

Beste **Chrit**, ik wil jou ook van harte bedanken voor de samenwerking! Door onze verschillende achtergronden heb ik in jouw MR-HIFU groep heel veel geleerd over de technische kant van de geneeskunde. Jouw enthousiasme bij onze gesprekken over nieuwe toepassingen van bijvoorbeeld de combinatie van histotripsie met immuun checkpoint inhibitie was erg aanstekelijk. Ik had altijd het gevoel dat mijn inbreng door jou erg gewaardeerd werd. Zelfs tijdens je pensioen blijf je betrokken en bereikbaar voor advies. Jouw voorstel om te solliciteren voor de opleiding tot radiotherapeut zie ik als een groot compliment en dat ik nu in opleiding ben tot internist betekent niet dat ik niet graag nog eens meedenk!

Mijn twee geweldige copromotoren, dr. Roel Deckers en dr. Britt Suelmann.

Beste **Roel**, zonder jou was dit proefschrift er nooit gekomen. We hebben samen veel tegenslagen meegemaakt, en steeds weer kwam je met ideeën voor nieuwe onderwerpen en onderzoeken. Ik had niet kunnen denken dat ik als klinische dokter bleomycine zou zitten te pipetteren, de finesses van de meest optimale ultrageluidsparameters met jou zou bediscussiëren, vlees zou koken in de MRI of een vijftal katten als mijn patiënten zou

beschouwen. Jij bent de reden dat ik mijn comfort zone zo heb kunnen uitbreiden en dat ik zo'n breed beeld van de wetenschap heb kunnen krijgen. Daarnaast heeft jouw feedback mijn artikelen naar een hoger niveau getild. Ik vond onze discussies over de klinische toepassing van nieuwe technieken altijd erg inspirerend en was het erg gezellig om samen te kliederen en klussen bij de praktische experimenten. Bedankt voor alles!

Lieve **Britt**, jouw tomeloze energie heeft mij keer op keer weer versteld doen staan. Niet alleen ben je een heel goede betrokken klinische dokter, ook stort je je steeds weer met hart en ziel op verschillende klinische studies. Jij bent bij uitstek degene die de vertaalslag kan maken van een idee naar de klinische toepassing voor de patiënt. Zelfs naast het afronden van je eigen promotieonderzoek en je drukke leven was je altijd beschikbaar voor advies en leefde je mee met mijn successen en tegenslagen, hiervoor wil ik je heel hartelijk bedanken!

Ik wil alle co-auteurs die hebben meegewerkt aan de artikelen van dit proefschrift van harte bedanken, in het bijzonder Marianne Luyendijk, Maurice Zandvliet en mijn paranimf Charis Rousou.

Lieve **Marianne**, bedankt voor alle hulp bij het analyseren en interpreteren van de IKNL data! Zonder jou was het artikel nooit afgekomen en zeker niet zo goed geworden. Bedankt dat je zoveel geduld had met mij, als relatieve epidemiologie- en absolute R-leek!

Beste **Maurice**, bedankt dat je de samenwerking met ons vanuit de diergeneeskunde bent aangegaan! Je hebt mij een kijkje gegeven in de wereld van de diergeneeskunde, die vaak niet eens zoveel verschilt van de ziekenhuiswereld die ik gewend ben (maar toch ook weer wel). Hier heb ik heel veel van geleerd en ik ben het meest trots op het multidisciplinaire karakter van onze kattenstudie. Ook bedankt dat je tijdens je drukke werkzaamheden steeds weer informatie en foto's van de katten voor mij bleef verzamelen voor de studie. Daarnaast wil ik alle andere medewerkers van de diergeneeskunde (waaronder **Mauricio** en **Stefanie**) bedanken voor hun hulp bij de studie, en alle patiënteigenaren die ons het vertrouwen hebben gegeven om hun katten te laten deelnemen aan het onderzoek.

Mijn paranimfen Charis Rousou en Milou Smit. Wat fijn dat jullie aan mijn zijde staan op 26 januari!

Dear **Charis**, I know you are pretty much fluent in Dutch now, but English still feels like 'our' language. Thank you so much for everything you did for me during my Phd. You introduced me into the wondrous world of *in vitro* experiments and taught me everything I know about cell culture. I will never forget your method to practice working in the flowhood (practice while you're cooking). You were always so patient with me and your smart comments helped me improve our work. I enjoyed working together during our experiments and the coffees, dinners and trips we had (remember when we were literally blown away in

Rotterdam). I am looking forward to your own PhD-defense!

**Milou**, lieve vriendin, bedankt dat je mijn paranimf wil zijn! We kennen elkaar al zo lang en hoewel we al op de middelbare school andere studierichtingen op zijn gegaan zijn we toch allebei in een promotietraject beland. Het is zo fijn dat we altijd al onze frustraties en ergernissen over onze PhD-perikelen met elkaar konden en kunnen delen. Ik weet zeker dat jij ook binnenkort succesvol je proefschrift zal verdedigen!

Ik wil ook graag de leden van de beoordelingscommissie bedanken voor de beoordeling van dit proefschrift: **Prof. dr. S.C. Linn, Prof. dr. S. Siesling, Prof. dr. H.J. Bloemendal, Prof. dr. R. de Bree en Prof. dr. ir. C.A.T. van den Berg**. De opponenten wil ik alvast hartelijk bedanken voor hun aanwezigheid op 26 januari, ik kijk uit naar een interessante discussie.

Daarnaast wil mijn (oud-) collega's uit het UMC Utrecht van harte bedanken:

Al mijn kamergenoten in de loop der tijd **Annemarie, Bianca, Dhabia, Esmée, Gerke, Liselore, Ludwike, Marcia, Mimount en Suzanne** en ganggenoten **Caren, Frans en Margot**, bedankt voor jullie empathie, hulp, interesse en gezelligheid bij alle koffiemomentjes, wandelingen en etentjes (met of zonder pannenkoeken)! Mede dankzij jullie heb ik een heel fijne promotietijd gehad!

Ook de andere collega's van de Epirad-groep: bedankt voor de gezelligheid en interessante presentaties **Ahmed, Atia, Carlo, Floor, Jonas, Justine, Martina, Nienke, Robbert, Wieke, Wouter, Sander en Sarah**.

Natuurlijk mijn opvolger **Mirjam** die zo stoer was om mijn klinische projecten over te nemen. Je kreeg nogal een klus overgedragen, bedankt voor al je inspanningen om mijn "kindje" de i-GO studie verder te brengen. Ik heb er alle vertrouwen in dat het je gaat lukken om patiënten te includeren!

Bedankt voor de mede-mamma-onderzoekers voor het samen coördineren van de MDO's en de gezelligheid bij bijeenkomsten, cursussen en congressen: **Bianca, Carmen, Erwin, Janine, Jeanine, Lieke, Liselore, Maureen, Marilot en Susana**.

Bedankt aan iedereen met wie ik heb samengewerkt om de klinische studies van de grond te krijgen en met wie ik interessante gesprekken heb gehad over mogelijke toekomstige studies: **de leden van de trialbureaus van oncologie en beeld** (onder wie **Roelien Kronemeijer**), **researchverpleegkundigen oncologie** (onder wie **Heleen Klein Wolterink**), **mammaverpleegkundigen, apothekers, internist-oncologen** (onder wie **Karijn Suijkerbuijk** en **Lot Devriese**), radiologen (in het bijzonder **Manon Braat** voor je expertise over en begeleiding van de MR-HIFU borstkanker studies), chirurgen (onder wie **Thijs van Dalen** en **Arjen Witkamp**), radiotherapeuten (onder wie **Desirée van den Bongard**).

Bedankt voor jullie samenwerking als onderdeel van de MR-HIFU groep **Annemiek, Beatrice, Clemens, Helen** (ook voor de gezellige etentjes!), **Isabel, Kim** (ook voor het FACS-en!), **Suzanne** en **Megan**.

Bedankt aan alle collega's die proefpersoon wilden zijn om het MR-HIFU apparaat te testen en de MR-HIFU laboranten **Greet, Jørgen en Niels**.

Bedankt aan iedereen voor het hartelijke ontvangst voor het uitvoeren van de celexperimenten in het David de Wiedgebouw (waaronder **Cristina, Joep, Louis, Mies en Roel**), LTO-lab en in de COVID-tijd het LKCH-lab waar ik in de avonden en weekenden mijn toevlucht kon zoeken. **Corlinda** bedankt dat ik jullie microscoop mocht gebruiken.

**Alice, Colette en Judith** bedankt voor alle praktische ondersteuning!

I would like to thank **Profound Medical** and **Celsion Corporation** for their cooperation in preparation for the clinical trials using the MR-HIFU system and ThermoDox.

Voor het financieren van mijn onderzoek wil ik het **KWF** hartelijk bedanken. Voor het mede-financieren gaat mijn dank uit naar de **Vrienden UMC Utrecht & Wilhelmina Kinderziekenhuis** (waaronder het Dirkzwager-Assink Fonds, de Louise Vehmeijer Stichting, de Schumacher-Kramer Stichting) en **het Center for Translational Molecular Medicine** (binnen de projecten VOLTAVALO en HIFU-chem).

Alle (oud-)collega's in het Diaconessenhuis Utrecht en het Radboudumc Nijmegen met wie ik samen heb gewerkt als ANIOS en sinds kort als AIOS interne terwijl ik daarnaast mijn promotie probeerde af te ronden: bedankt voor jullie steun, interesse en begrip en voor het feit dat jullie mij weer hebben laten thuis voelen in de kliniek na mijn onderzoeksjaren.

Mijn lieve vriendinnen wil ik bedanken, **Esther, Lisanne, Majsa, Mei-Jhi, Menke** en **Seline**, die altijd voor mij klaar stonden als alles even tegen zat en die altijd geïnteresseerd waren in waar ik mee bezig was. Bedankt voor alle gezellige thee-, eet-, borrel- en kletsmomenten samen! Daarnaast mijn fijne (oud-) tennisteam **dames 1 van Metgensbleek** die mijn hele promotietijd hebben meegemaakt en altijd geïnteresseerd waren. Net als de **Game-nighters** (no spam, vrees niet) **Elisa, Jeroen** en **Michiel** die mij tijdens de gezellige spelletjesavonden tot diep in de nacht met Monsters en dobbelstenen konden afleiden van METC's en ThermoDox houdbaarheidsdata.

Ook zonder de steun van mijn familie was ik nooit zover gekomen.

**Lieve mama**, bedankt dat je mij altijd hebt gesteund en gestimuleerd om te doen wat ik wilde en waar ik goed in was. Mijn creatieve kant heb ik aan jou te danken. Toen ik 30 werd vertelde je in je speech dat ik als baby liever nieuwsgierig de wereld in keek dan tegen de borst gedrukt werd, misschien zat mijn promotieonderzoek er toen al aan te komen.

Bedankt voor alle steun en liefde die je mij geeft, voor de gezelligheid en voor jouw mooie jurkjes die ik altijd mag overnemen (wie weet weer eentje voor de verdediging?).

**Lieve papa**, bedankt voor je rotsvaste vertrouwen in mij, dat ik alles kan bereiken wat ik wil. En voor je verontwaardiging wanneer iemand anders dat even niet ziet. Nu treed ik in je voetsporen als dr. de Maar en als internist in opleiding, en daar ben ik heel trots op (opa Egbert was dat vast en zeker ook geweest). Bedankt voor de internistische en wetenschappelijke genen (of opvoeding?), je interesse in mij, voor alle liefde, spontane dansjes en stevige knuffels. Wie weet een dansje wagen op de volgende internistendagen? En natuurlijk veel dank aan Plasgoed B.V.!

**Lieve Saskia en Frans**, wat zijn jullie allebei geweldige partners voor papa en mama. Jullie ook bedankt voor alle liefde, gezelligheid en steun de afgelopen jaren.

Lieve **Eduard, Juliette** en **Felice**, mijn lieve brussen, bij jullie kan ik altijd aankloppen voor gezelligheid, liefde en steun. We zitten altijd op één lijn en voelen altijd aan wat we bedoelen. Lieve Edu, blijf maar vaak een weekendje Utrecht boeken want hoe druk ik het ook heb maak ik daar altijd graag tijd voor vrij! Lieve Juul, wat hebben we het altijd gezellig samen, jij weet altijd wat ik bedoel als er gedoe is met een patiënt of als er andere doktersdilemma's spelen. Jij bent nu onze drs. de Maar en een hele goede! En Felice, mijn grote kleine zusje! Veel dank voor je hulp bij het ontwerpen van de kaft van dit boekje! Wat ben je toch creatief en wat was het gezellig om hier samen aan te werken!

De rest van mijn **familie** wil ik ook hartelijk bedanken voor alle geïnteresseerde vragen en ondersteunende woorden en daden inclusief mijn schoonouders **Albertina** en **Erik** en schoonopa **Jon** en-oma **An**. In het bijzonder mijn **lieve oma José** die altijd het meest trots van iedereen over haar borst strijkt bij elke mijlpaal. En mijn lieve nicht **Anouk**, we hebben het altijd zo gezellig samen en je bent altijd oprecht geïnteresseerd hoe het met mij gaat. Jouw scherpe maar liefdevolle psychologische analyses laten zelfs mij inzien dat het niet alleen aan mijzelf ligt wanneer ik niet op waarde wordt geschat.

Mijn liefste **Ron**, jij bent in al die jaren natuurlijk degene die dit promotietraject het meest intensief met mij heeft meegeleefd. Alle tegenslagen hebben we samen beleefd en alle mijlpalen hebben we samen gevierd. Zonder jouw steun weet ik niet hoe ik dit had moeten afronden, want jouw slimme en geïnteresseerde vragen, kalmerende woorden, liefdevolle knuffel en "komt wel goed schatje" zorgen dat ik altijd weer de zonnige kant kan zien. Bedankt dat je mijn momenten van stress en frustratie hebt geaccepteerd en altijd vertrouwen in mij hebt gehouden. Let maar op: nu krijgen we zeeën van vrije tijd! Ik hou heel veel van je en ik kijk uit naar de rest van ons leven samen!

## CURRICULUM VITAE

Josanne de Maar was born on March 3<sup>rd</sup> 1992 in Groningen, the Netherlands.

In 2009 she graduated cum laude from her pre-university education at Praedinius Gymnasium and started studying Medicine at University of Groningen.

After receiving her medical degree in 2015, she started working as a resident not in training (ANIOS) at the department of internal medicine of the Meander Medical Center in Amersfoort. In 2016 she started her PhD at the UMC Utrecht Division of Imaging and Oncology, focusing on optimizing drug delivery in oncology using imaging and therapeutic ultrasound, under supervision of professor Elsken van der Wall, professor Chrit Moonen, dr. Roel Deckers and dr. Britt Suelmann.

After working as a resident not in training (ANIOS) at the departments of internal medicine of the Diaconessenhuis in Utrecht and the Radboudumc in Nijmegen, she started her specialization in internal medicine in July 2022 at the Radboudumc in Nijmegen.

Josanne lives in Utrecht together with her partner Ron van Doorne.
