terrestrial environments requires knowledge of their interactions with complex mineral assemblages. To advance knowledge along this front, we examined the reactivity of pipemidic acid (PIP), a typical quinolone antibiotic, with quartz particles coated with a mixture of manganese oxide  $(MnO<sub>2</sub>)$  and goethite  $(a-FeOOH)$  under static and dynamic flow conditions. Batch and dynamic column experiments showed that PIP binding to MnO<sub>2</sub> proceeded through a heterogeneous redox reaction, while binding to goethite was not redox-reactive. Mixed columns of aggregated goethite-manganese particles however enhanced redox reactivity because (i) goethite facilitated the transport of dissolved Mn(II) ion and increased the retention of PIP oxidation products, and (ii)  $MnO<sub>2</sub>$  was protected from passivation. This mobility behavior was predicted using transport models

accounting for adsorption and transformation kinetics of PIP on both goethite and MnO<sub>2</sub>. This work sheds new light on reactivity changes of mixtures of Fe and Mn oxides under flow-through conditions and will have important implications in predicting the fate and transport of redox-active organic compounds as well as development of new geomedia filters for environmental remediation. KEYWORDS: *pharmaceuticals, goethite, manganese oxide, redox, geomedia filter, transport, modeling*

# ■ **INTRODUCTION**

Iron (Fe) and manganese (Mn) are the two most common redox-active elements in the Earth's crust. They are present in a wide range of environments with different composition, mineralogy, and morphology.<sup>1,2</sup> For example, Fe- and Mnoxides may coexist with each other as discrete particles, a mixture of component phases, or particulate coatings in soils and sediments.<sup>[3](#page-6-0)</sup> In deep sea waters, Mn and Fe are oxidized to form ferromanganese crusts and nodules on the oceans floor, a mineral of immense economic interest. Because of their specific nanoscale properties, high surface area, low cost, strong oxidation, and sorption abilities, iron and manganese oxides are widely used in various environmental applications.<sup>[4](#page-6-0)-[8](#page-6-0)</sup> They play a key role in controlling the fate and mobility of elements and toxic compounds in nature and can also be used as an environmentally friendly geomedia filter in water treatment technologies and/or aquifer recharge management. $9-11$  $9-11$  $9-11$ 

Goethite (*α*-FeOOH) is one of the most thermodynamically stable iron oxyhydroxides under ambient conditions and the most abundant one in natural settings. $2,12$  $2,12$  For this reason, numerous theoretical and experimental studies explored organic or inorganic compound binding mechanisms to goethite surfaces and their impact on migration in nature.<sup>[13,14](#page-7-0)</sup> Birnessite-type layered manganese oxides are, at the same time, of great interest given their strong redox- and cation-exchange reactivity.<sup>[8](#page-6-0)[,15,16](#page-7-0)</sup> Their interest is also motivated by their structural similarity to the biogenically precipitated natural manganese oxides, which are the most commonly occurring forms of  $MnO<sub>2</sub>$  in surficial environments.<sup>1</sup>

Although the reactivity of each individual or single phase has been widely investigated,<sup>[7](#page-6-0),[17](#page-7-0)–[21](#page-7-0)</sup> knowledge is limited on how binary mixtures of these two phases, goethite and  $MnO<sub>2</sub>$ , alter the overall reactivity of environmental compounds. Previous studies<sup>[22](#page-7-0)−[24](#page-7-0)</sup> have reported that binary mixtures of Fe(OH)<sub>3</sub> with  $\text{Al}(\text{OH})_3$  or  $\text{SiO}_{2(\text{am})}$  have exhibited different adsorption properties from their component parts due to changes in surface site availability and surface charge. This has been ascribed to the dissolution of  $Al(OH)_3$  or  $SiO_{2(am)}$  and sorption/precipitation of the dissolved ions at Fe-oxides surfaces. Other studies<sup>[25](#page-7-0)</sup> have reported that mixtures of  $MnO_2$  with other oxides like  $Al_2O_3$  or  $SiO_{2(am)}$  or  $TiO_2$ inhibited  $MnO<sub>2</sub>$  reactivity mainly through heteroaggregation between particles and/or adsorption of metal ions released from the second oxides on the  $MnO<sub>2</sub>$  surface. Two recent studies<sup>[26,27](#page-7-0)</sup> even showed that Fe oxides inhibited  $MnO<sub>2</sub>$ 

Received: August 18, 2022 Revised: November 18, 2022 Accepted: November 21, 2022 Published: December 5, 2022

reactivity through heteroaggregation of positively charged Fe oxides particles with negatively charged  $MnO<sub>2</sub>$  particles, thereby reducing the number of surface sites of  $MnO<sub>2</sub>$ . However, little is known on how this reactivity is affected under dynamic, flow-through conditions that are far more prevalent in environmental and/or engineered systems than the static (batch) modes more commonly employed in laboratory studies. This is particularly relevant because dissolved ions and/or redox byproducts (e.g., dissolved Mn(II)) concurrently affect surface reactivity of manganese and iron oxides minerals and the mobility of target compounds. As such, experimental work under continuous flow conditions can better emulate natural environments (e.g., geochemical systems containing Fe- and Mn-oxides) or engineered infiltration systems (e.g., managed aquifer recharge (MAR) and water treatment systems), where the target pollutants and the generated reaction products travel through and are then flushed out of the column system. In addition, most traditional environmental models are based on a single phase or simple system, and little is known about the redox reactivity within complex mineral assemblages. Knowledge of the adsorption and redox reactions that take place in the mixed mineral phases or complex environmental systems and under flow-through conditions is consequently needed to explore contaminant transport.

This study aims to assess the roles that coexisting iron and manganese oxides play on the fate and transport of contaminants under conditions of water flow. This was achieved by working with columns packed with sand microparticles  $(CS)$  coated with  $MnO<sub>2</sub>$   $(MCS)$ , goethite (GCS), or mixed goethite-MnO<sub>2</sub> (MGCS). Pipemidic acid (PIP) was, in turn, chosen as a representative redox-active quinolone antibiotic widely used in human and veterinary medicine<sup>28</sup> and commonly found in ng/L to  $\mu$ g/L levels<sup>[29](#page-7-0)</sup> in aquatic environments and agricultural settings.[32](#page-7-0)−[34](#page-7-0) Investigation of redox transformation of compounds associated with reactive minerals is also required for an accurate assessment of ecological impacts of quinolone antibiotics. As the redox reaction is strongly dependent on the pH value and  $MnO<sub>2</sub>/compound ratio, dynamic flow experiments of PIP$ were performed with two different  $MnO<sub>2</sub>$  amounts in the MGCS system and at pH 5.2 and 7.0, which are within the typical pH range for shallow groundwater and soil pore waters.<sup>[35](#page-7-0)</sup> A transport model that accounts for adsorption and oxidation kinetics was used to predict changes in PIP transport in coated sands under flow. This work additionally explains how goethite-MnO<sub>2</sub> interactions affect PIP reactivity, and potentially how these mechanisms affect other similar environmental emerging contaminants.

## **2. MATERIALS AND METHODS**

**2.1. Synthesis of Minerals and Coated Phases.** Pure Fontainebleau quartz sand (200−300 *μ*m; ≤0.06 m<sup>2</sup> /g) was chosen as an inert support, due to its very low reactivity and aqueous solubility under our experimental conditions.<sup>[36](#page-7-0)</sup> The quartz sand was cleaned with HCl,  $H_2O_2$ , and ultrapure water to remove any colloidal or amorphous silica particles and organic/inorganic contaminants (see the [SI](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) for the detailed cleaning procedure). Acid birnessite  $(MnO<sub>2</sub>)$  prepared according to McKenzie $37$  was coated on quartz sand (MCS) as in our previous study<sup>17</sup> and summarized in the [SI.](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) Likewise, goethite (*α*-FeOOH) and goethite-coated quartz sand (GCS) were synthesized as described in previous studies<sup>[18,38](#page-7-0)−[40](#page-7-0)</sup> and

summarized in the [SI.](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) The B.E.T. specific surface area of uncoated goethite and birnessite phases was 81  $\pm$  4 and 65  $\pm$  1 m<sup>2</sup> g<sup>-1</sup>, respectively, and the point of zero charge (PZC) determined at 298 K in 0.01, 0.1, and 1 M NaCl solutions by the potentiometric titration method was pH 9.1 for goethite and 2.4 for birnessite. Coating coverage was thereafter evaluated by total Mn and Fe concentrations of acid digested MCS and GCS. Concentrations, measured by Inductively Coupled Plasma-atomic Emission Spectrometry (ICP-AES), revealed  $0.60 \pm 0.02$  (SD) mg Mn per 1 g of MCS and 6.2 mg ± 0.20 (SD) Fe per 1 g of GCS. These coating amounts are within the previously reported range for natural coated subsurface materials,  $35/41$  $35/41$  and they allow stable coated minerals to be achieved.

The possible dissolution of the used quartz sand was additionally checked in 1 and 10 g/L sand suspensions that were continuously stirred over a range of pH values (4−10) in pure water or 0.01 M NaCl for up to one month. In all cases, the dissolved silicate concentrations were below the detection limit of the molybdenum blue spectrophotometric method (<1  $\mu$ M) and ICP-AES (<0.2  $\mu$ M).

Binary mixtures of iron and manganese oxides (MGCS) were prepared by adding different amounts of  $MnO<sub>2</sub>$ suspension to GCS. Small aliquots of  $MnO<sub>2</sub>$  suspension were pipetted homogeneously over the GCS surface, then mixed with a polypropylene spatula, and dried overnight at room temperature. The resulting solid was thereafter washed four times with 10 mM NaCl to remove any uncoated  $MnO<sub>2</sub>$  and then dried again at room temperature. Two different MGCSs were prepared: 1) 0.05 MGCS and 2) 0.1 MGCS, where 0.05 and 0.1 indicate the percentage of  $MnO<sub>2</sub>$  in the MGCS system.

The Mn content in the MGCS was determined by dissolving in 30 mM ascorbic acid following the protocol of Charbonnet et al. $42$  and analyzed by ICP/AES. The measured amount was 0.29  $\pm$  0.02 (SD) mg of Mn in 1 g of 0.05 MGCS and 0.60  $\pm$ 0.02 (SD) mg of Mn in 1 g of 0.1 MGCS. Scanning electron microscopy (SEM) was applied to study the surface morphology of the MGCS matrix. Samples were examined with a JSM JEOL 7100 F microscope with a field emission gun and an OXFORD Genesis energy-dispersive X-ray spectrometer at 20 kV at a working distance of 5−10 mm and magnifications from 15000× to 30000×. SEM images of MGCS showed a mixture of goethite and  $MnO<sub>2</sub>$  particles deposited on the sand [\(Figure](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) S1). Due to the extremely low Mn amount in the MGCS, X-ray diffraction could not be used for MGCS characterization.

**2.2. Batch and Column Experiments.** Three different sets of batch experiments were conducted to determine the 1) pH dependent adsorption of PIP on GCS with or without  $Mn(II)$ , 2) pH dependent  $Mn(II)$  adsorption on GCS with or without PIP, 3) kinetics of PIP removal on 0.05 MGCS at pH 5.2, and 4) kinetic Mn(II) sorption on MCS and MGCS at pH 5.2 under static conditions. Details on the experimental setup are provided in the [SI.](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf)

Dynamic breakthrough experiments were conducted at room temperature and under water-saturated conditions. Briefly, 15 g of GCS, MCS, or MGCS was packed in glass columns with an internal diameter of 1.6 cm and a bed length of 4.7 cm. The column was wrapped with aluminum foil to avoid any photoinduced degradation. The bulk density of the packed MGCS was  $1.52 \pm 0.05$  g/cm<sup>3</sup>, and the column pore volume (PV or  $V_p$ ) was  $4 \pm 0.1$  mL. The column was first saturated with a background solution of 10 mM NaCl

(previously purged with  $N_2$ ) at pH 5.2 or 7.0 (depending on the experimental pH) with a constant flow rate of 0.5 mL/min (residence time of 8 min). A bromide tracer experiment was performed using an input solution containing 10 mM NaBr in 10 mM NaCl at pH 5.2 or 7.0. Br<sup>−</sup> breakthrough curves for different columns (GCS, MCS, 0.05 MGCS, 0.1 MGCS) were obtained by analysis of the effluent solution using ion chromatography [\(Figure](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) S2).

Different column experiments were performed by injecting input solutions consisting of a constant amount of 10 mM NaCl and 10 *μ*M PIP but at two different pH values, 5.2  $(\pm 0.1)$  or 7.0  $(\pm 0.1)$ . The investigated inflow concentration of PIP may appear higher than the level amounts of pharmaceuticals commonly detected in environmental systems[29](#page-7-0)<sup>−</sup>[31](#page-7-0) but close to a total dose of organic compounds found in industrial effluents or urban stormwater and municipal wastewater used in aquifer recharge.<sup>[42](#page-7-0)</sup> Furthermore, since the Mn-based redox reaction is strongly dependent on the red/ox ratio, different  $MnO<sub>2</sub>$  amounts and thus different PIP/MnO<sub>2</sub> ratios were investigated. The experimental flowrate was constant throughout the course of the experiment at 0.5 mL/min. The input solution was purged with  $N_2$  to avoid  $CO<sub>2</sub>$  contamination and to maintain the experimental pH throughout the course of the experiment. The flow interruption method was applied in selected experiments to check the occurrence of kinetic limitations. All effluent solutions were collected using a fractional collector. The pH of the effluent solution was determined through the experiment by using an online pH meter. The effluent solution was also analyzed for PIP and byproducts with high-performance liquid chromatography (HPLC) and an ultrahigh-performance liquid chromatography−tandem mass spectrometry (UPLC-MS/MS) system and for dissolved metal ions using ICP-AES. More details about experimental conditions and measurements are reported in the SI ([Table](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) S1).

**2.4. Transport Modeling.** First, the hydrodynamic parameters were obtained by fitting the bromide breakthrough data using the classical Advection Dispersion Equation (ADE):

$$
\frac{\partial C}{\partial t} = D \frac{\partial^2 C}{\partial x^2} - v \frac{\partial C}{\partial x} \tag{1}
$$

Breakthrough curves (BTCs) for Br<sup>−</sup> suggest the absence of great dispersion/diffusion or the physical nonequilibrium effect ([Figure](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) S2 in the SI). Macroscopic dispersivity (∼1.89 mm) was obtained by the ratio of the dispersion coefficient (*D*) and pore velocity (*v*). Molecular diffusion was considered negligible with respect to the dynamic dispersion. The Péclet number (Pe =  $vL/D$ ) was ~25 in the column, suggesting the predominance of a convective regime, and the flow can be assumed to be homogeneous. During water saturation and tracer experiments, total dissolved Mn, Fe, and Si in the outflow were below the ICP-AES detection limit (0.1 *μ*M for Mn, 0.2 *μ*M for Fe, and 0.2 *μ*M of Si), and therefore, the possibility of mobilization and/or dissolution of minerals can be excluded. Blank tests conducted also confirmed no adsorption of Mn(II) ions to the quartz sand ( $\leq$ 0.06 m $^2$ /g).

The reactive transport model is based on a two-site, advective-dispersive transport model with degradation and Freundlich-Langmuir kinetic sorption. The liquid and sorbed concentrations are ruled by the following differential equation that governs the chemical nonequilibrium transport for a homogeneous system under steady-state water flow $43,44$  $43,44$  $43,44$ 

$$
\frac{\partial C}{\partial t} + \frac{\rho \partial (S)}{\theta \partial t} = D \frac{\partial^2 C}{\partial x^2} - \nu \frac{\partial C}{\partial x} - \mu_1 C - \frac{\rho}{\theta} \mu_S
$$
 (2)

where  $\theta$  is the volumetric water content  $(L^3/L^3)$ , C is the volume-averaged solution concentration  $(M/L^3)$ ,  $t$  is time  $(T)$ ,  $\rho$  is solid bulk density, *S* is the sorbed concentration  $(M/M)$ , *D* is the dispersion coefficient in the liquid phase  $(L^2/T)$ ,  $\nu$  is the water velocity ( $L/T$ ), and  $\mu$ <sub>l</sub> and  $\mu$ <sub>s</sub> are first-order degradation rate constants  $(T^{-1})$  for the liquid and sorbed phases.

Because quinolones binding to oxide surfaces may proceed through a nonspecific and fast surface complexation reaction, such as outer-sphere or hydrogen-bound, and a specific surface complexation reaction, generally slower, such as metal-bound complexes, we assume that adsorption sites can be divided into two fractions, instantaneous (Type-1) and kinetic (Type-2) sites $44$ 

$$
S = S_1 + S_2 \tag{3}
$$

where  $S_1$  and  $S_2$  are solid phase concentrations associated with Type-1 and Type-2 sites, respectively. Considering Type-1 adsorption sites are always at equilibrium,  $S<sub>1</sub>$  can be expressed as

$$
S_1 = fK \frac{C^{\beta}}{1 + \eta C^{\beta}}
$$
\n<sup>(4)</sup>

The Type-2 adsorption sites are assumed to be a first-order kinetic rate process

$$
\frac{\partial S_2}{\partial t} = \alpha \left[ (1 - f)K \frac{C^{\beta}}{1 + \eta C^{\beta}} - S_2 \right] - \mu_s S_2 \tag{5}
$$

where  $\alpha$  is a first-order kinetic rate coefficient  $(T^{-1})$ ,  $f$  is the fraction of instantaneous adsorption sites (Type-1), and *K*, *β*, and *η* are empirical coefficients.

Transport modeling was performed with HYDRUS 1D.<sup>[43](#page-7-0)</sup> This code allows for the numerical resolution of eqs 2-5 for several boundary and initial conditions: concentration flux at the inlet, zero concentration gradient at the outlet, and no solute at time zero. By using a least-squares optimization routine, HYDRUS 1D also allows inverse modeling to fit the model solution to the data to estimate fate and transport parameters.<sup>[43](#page-7-0)</sup> Because of PIP transformation reactions only occurring at  $MnO_2$  surfaces and not in solution,  $\mu_1$  was set to 0. This also allows reducing the number of estimated parameters and thus avoiding nonuniqueness issues (a sensitivity analysis has been done in previous work<sup>[7](#page-6-0)</sup>). Values for the sorption parameter *K*, fraction of equilibrium sites *f*, kinetics adsorption  $\alpha$ , and the first-order degradation rate  $\mu$ <sub>s</sub> were determined through fitting the breakthrough curves of PIP and are reported in [Table](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) S2.

#### **3. RESULTS AND DISCUSSION**

**3.1. Influence of Goethite and/or Birnessite Coating on the PIP Breakthrough.** MnO<sub>2</sub> in MGCS columns strongly slows down PIP mobility with respect to the  $(MnO<sub>2</sub>-free) GCS column (Figure 1). This can be recognized$  $(MnO<sub>2</sub>-free) GCS column (Figure 1). This can be recognized$  $(MnO<sub>2</sub>-free) GCS column (Figure 1). This can be recognized$ by extensive tailing of the breakthrough curve (BTC) and incomplete breakthrough of PIP in the MCS column (0.60 mg Mn/g 0.1 MCS), compared to the GCS column with a sigmoidal-shaped low-tailing BTC with total breakthrough (*C*/  $C_0 = 1$ ) by 60 PV. In strong contrast, the 0.1 MGCS with the same Mn loading as MCS (0.60 mg Mn/g 0.1 MGCS) exhibited breakthrough at 81 PV, achieving a brief steady state

<span id="page-3-0"></span> $1.2$ 

 $1.0$ 

 $0.8$ 

Figure 1. PIP breakthrough curve  $MnO<sub>2</sub>$ -bearing columns (0.60 mg Mn/g MCS; 0.29 mg Mn/g 0.05 MGCS; 0.60 mg Mn/g 0.1 MGCS). The dashed line indicates the theoretical complete breakthrough of PIP  $(C/C_0 = 1)$ , and solid lines are model predictions. Inflow conditions: 10 *μ*M PIP; pH 5.2 ± 0.1; 10 mM NaCl; PV 4 mL; flow rate 0.5 mL/min.  $V/V_p$  is the ratio of the injected volume to the pore volume.

just below ∼200 PV at  $C/C_0 \sim 0.45$  and a final steady state at  $C/C_0 \sim 0.91$ , just as in MCS, after 744 PV. However, halving Mn loadings to 0.29 mg Mn/g in 0.05 MGCS produced BTC attributes intermediate to those of GCS and MCS, with the breakthrough point of PIP at 45 PV and a steady breakthrough at *C*/*C*<sub>0</sub> ∼ 0.94 at 308 PV.

The pH of the output solution from the GCS column initially slightly decreased by ∼0.4 unit but finally returned to 5.5 when a steady-state breakthrough was reached ([Figure](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) S3). However, the transformation of PIP on  $MnO<sub>2</sub>$  or the reductive conversion of  $MnO<sub>2</sub>$  released  $Mn(II)$  through

$$
MnO_2 + 2e^- + 4H^+ \to Mn^{2+} + 2H_2O
$$
 (6)

As this is a proton-promoted process, the pH initially increased to 5.9 and then decreased to the initial pH value on the MCS column ([Figure](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) S3). In the MGCS column, there were no pH changes in 0.05 MGCS, while the pH followed the same behavior as for the MCS column in 0.1 MGCS [\(Figure](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) [S3](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf)). As PIP was mostly present in the zwitterionic form  $(pK_{a1})$   $= 5.20$ ,  $pK_{a2} = 6.38$ ) ([Figure](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) S4), adsorption to goethite occurred via surface complexation reactions involving carboxylic and keto groups, with a possibility of the oxidation reaction involving the piperazine ring.<sup>45</sup> However, the BTC shape and the lack of byproducts in the effluent did not provide evidence for PIP oxidation by goethite. The modeling results also support the absence of PIP oxidation since no heterogeneous

degradation rate  $(\mu_s)$  was required to fit the BTC of PIP (Figure 1, [Table](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) S2). Conversely, modeling of the partial PIP breakthrough in the Mn-bearing MCS and MGCS columns did

require  $\mu$ <sub>s</sub> (Figure 1, [Table](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) S2). The total amount of PIP removal (by adsorption and/or oxidation) was calculated by integrating the area above the BTC of PIP. In the MCS column, the total PIP removal was ∼5 *μ*mol at ∼800 PV, while the same Mn loadings in the 0.1 MGCS column removed ∼11 *μ*mol of PIP at the same breakthrough time. This consequently implies that the 0.1 MGCS column removed almost twice the amount of PIP than in the MCS column despite having the same Mn loading. As the 0.1 MGCS and GCS columns contained the same goethite loadings, the contribution of goethite in PIP removal can be estimated at ∼1.5 *μ*mol.

Enhanced  $MnO<sub>2</sub>$  content not only improved PIP removal in the MGCS column (3.2 *μ*mol PIP removal in the 0.05 MGCS column vs 11 *μ*mol in the 0.1 MGCS column) but also modified the breakthrough behavior. Indeed, a two-step behavior, two fronts and two plateaus, was observed corresponding to the pH variation during the transport experiment [\(Figure](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) S3). This breakthrough behavior can be described by considering three stages, and different parameters are necessary to describe each stage of the full BTC of PIP ([Table](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) S2). If the same adsorption and oxidation parameters (i.e.,  $\alpha$ ,  $K$ ,  $f$ ,  $\mu$ <sub>s</sub>) were used for the full BTC description, the calculated curve failed to describe the transport process of PIP, especially for the transitional plateau [\(Figure](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) S5). This mobility behavior could be explained by the pH impact on the heterogeneous redox reaction and/or (re)adsorption of redox products. It has been reported that fluoroquinolone binding to negatively charged Mn-oxide surfaces proceeds through a heterogeneous redox reaction, whereby two oneelectron transfers or a single two-electron transfer oxidizes PIP and reduces surface-bound metal sites. $17,19,46$  $17,19,46$  $17,19,46$  This will be investigated in the next section.

Figure 2. Breakthrough curves of a) PIP and Mn(II) and b) pH in the 0.05 MGCS column. The horizontal dashed line indicates the theoretical complete breakthrough of PIP ( $C/C_0 = 1$ ), and solid lines are model predictions. The vertical dashed lines indicate the moment of flow interruption (duration 24 h). The empty symbols in the shadow area indicate the second stage after flow resumption. Inflow conditions: 10 *μ*M PIP; pH 5.2 ± 0.1; 10 mM NaCl; PV 4 mL; flow rate 0.5 mL/min.  $V/V_p$  is the ratio of the injected volume to the pore volume.

**217**

<span id="page-4-0"></span>

Figure 3. Breakthrough curves of (a) PIP and PIP<sub>ox</sub> (peak area of the PIP byproduct; M-26) and (b) Mn(II), pH in the 0.1 MGCS column. The horizontal dashed line indicates the theoretical complete breakthrough of PIP (*C*/*C*<sub>0</sub> = 1), and solid lines are model predictions. The vertical dashed lines indicate the moment of flow interruption (duration 24 h). The empty symbols in the shadow area indicate the second stage after flow resumption. Inflow conditions: 10 *μ*M PIP; pH 5.2 ± 0.1; 10 mM NaCl; PV 4 mL; flow rate 0.5 mL/min. *V*/*V*<sup>p</sup> is the ratio of the injected volume to the pore volume.

**3.2. Impact of Manganese Oxide Content on PIP Oxidation in Columns.** To further investigate PIP transport in MGCS columns, redox byproducts (dissolved Mn(II) and the oxidized byproduct of PIP) were monitored in the outflow solution throughout the breakthrough experiment and upon flow interruption. Our flow/no flow/flow sequence protocol allowed us to check kinetic limitations through determination of the BTC of species before interruption and after resumption of flow.

In the 0.05 MGCS column, Mn(II) was detected in the effluent solution at the same time as PIP and then reached a steady-state concentration of 1.2 *μ*M. Increasing the residence time of PIP in the 0.05 MGCS column by interrupting the flow for 24 h (376 PV) did not influence the incomplete breakthrough as the same partial breakthrough  $(C/C_0 =$ 0.94) was still observed upon flow resumption ([Figure](#page-3-0) 2a). This flow interruption period allowed species to react over a longer period during flow-through conditions. Here, relative concentrations of PIP dropped from 0.94 to 0.76, while those of Mn(II) increased sharply from 1.2 to 5 *μ*M; yet, solution pH values were stable throughout the course of the experiment ([Figure](#page-3-0) 2b). This behavior pointed to rate-limited sorption/ redox processes from co-occurring adsorption reactions and heterogeneous redox reactions. Note that BTC curves in separate bromide tracer experiments did not change following a flow/no-flow/flow sequence, thereby excluding the possibility of physical nonequilibrium or diffusive mass transfer that might cause changes in PIP and Mn(II) concentrations. Upon flow resumption, both PIP and Mn(II) concentrations reached the steady-state concentrations prior to the stop-flow. Although Mn(II) was detected by ICP-AES as the reduced byproduct, no oxidized byproduct of PIP (hereafter referred as  $\text{PIP}_{\text{ox}}$ ) was detected in the effluent throughout the course of the experiment [\(Figure](#page-3-0) 2a). This could be explained by the very low concentrations of generated redox products and/or strong binding to minerals at the working pH value (5.2).

In the 0.1 MGCS column, redox products (Mn(II) and  $\text{PID}_{ox}$ ) were detected throughout the course of the experiment (Figure 3a). LC/MS analysis confirmed the  $\text{PID}_{\text{ox}}$  had a  $m/z$ value of 227 (M-26), formed through N-dealkylation of the piperazine ring of PIP [\(Figure](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) S6). As previously observed for quinolone compounds, $17,19$  $17,19$  $17,19$  one electron is transferred from the sorbed compound to the surface-bound  $Mn^{IV}$ , yielding radical

intermediates, and  $Mn^{III}$  that can be further reduced to give  $Mn^{II}$  as follows:

$$
\equiv Mn^{IV} + PIP \rightarrow \equiv Mn^{IV} - PIP_{ad} \rightarrow \equiv Mn^{III}/Mn^{II}
$$

$$
- PIP^{+} \rightarrow Mn^{II} + PIP_{ox}
$$
 (7)

As seen in Figure 3a,  $PIP_{ox}$  concentration in the effluent solution reached its maximum and then decreased after ∼175 PV. Prior to flow-interruption, the BTC of  $\text{PID}_{\text{ox}}$  followed the outflow pH values, as  $PIP_{ox}$  binding to minerals is pHdependent. However, the peak area of the LC/MS data corresponding to  $\text{PID}_{ox}$  was not constant (no steady-state values) during the course of the experiment. Increasing the residence in the column with flow-interruption, decreased PIP concentration but increased that of  $\text{PID}_{ox}$ . When the flow was resumed, PIP concentration reached again a plateau, with a steady-state value lower than that before flow interruption (0.9 to 0.8). High  $MnO<sub>2</sub>$  content exhibited greater removal ability of PIP and more Mn(II) generation. For example, a higher *k* value, first-order degradation rate coefficient (including sorption and oxidation) was obtained in the 0.1 MGCS  $(k =$  $2.1 \times 10^{-4}$  min<sup>-1</sup>) compared to 0.05 MGCS ( $k = 1.4 \times 10^{-4}$ min<sup>−</sup><sup>1</sup> ) by

$$
k = -\frac{\ln\left(\frac{C_a}{C_b}\right)}{t} \tag{8}
$$

Here, *C* is the PIP effluent concentration before  $(C_b)$  and after  $(C<sub>s</sub>)$  flow-interruption, and *t* is the duration of interruption (24) h).

The shape of the breakthrough curve of Mn(II) in the 0.1 MGCS column was similar to that of the 0.05 MGCS column. However, Mn(II) did not exhibit breakthrough with PIP (as the 0.05 MGCS column) and was only detected after injection of ∼300 PV. This delayed Mn(II) breakthrough corresponds to an increase in the outflow pH value (see Figure 3b) and thus can be explained by the increase in  $Mn(II)$  binding onto goethite with an increasing pH (see batch data in [Figure](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) S7). The effluent concentration of Mn(II) thereafter reached a plateau-like, steady-state value when the pH decreased to the inflow pH (∼5.2). In MCS, no Mn(II) desorbed into the effluent solution ([Figure](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) S8). The presence of dissolved Mn(II) in outflow solutions of MGCS columns (0 *μ*M in the MCS column vs. 2.5 *μ*M in the 0.1 MGCS column at pH 5.2)

Figure 4. Breakthrough curves of (a) PIP and PIP<sub>ox</sub> (peak area of PIP byproduct; M-26) and (b) Mn(II), pH on different pH's in the 0.05 MGCS column. The horizontal dashed line indicates the theoretical complete breakthrough of PIP  $(C/C<sub>0</sub> = 1)$ , and solid lines are model predictions. The vertical dashed lines indicate the moment of flow interruption (duration 24 h). The empty symbols indicate the second stage after flow resumption. Inflow conditions: 10 *μ*M PIP, pH 5.2  $\pm$  0.1 and 7.0  $\pm$  0.1, 10 mM NaCl, PV 4 mL, flow rate 0.5 mL/min. *V*/*V<sub>p</sub>* is the ratio of the injected volume to the pore volume.

suggests that the presence of goethite altered the  $Mn(II)$ uptake by  $MnO<sub>2</sub>$  at this pH value and thus increased its mobility through the column system. This was confirmed further by Mn(II) batch adsorption data on MCS and MGCS ([Figure](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) S9), where 70% of dissolved Mn(II) was removed by MCS, while only 40% was removed with MGCS under the same experimental conditions (see [Figure](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) S9). Additional batch experiments showed that PIP was continuously removed (sorption + oxidation) by MGCS, yet only  $Mn(II)$  (no  $PIP_{ox}$ ) was detected in the solution ([Figure](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) S10). As observed in the column system, the presence of goethite likely ensured preferential adsorption of PIP or  $\text{PID}_{\text{ox}}$  over  $\text{Mn(II)}$  onto MGCS at pH 5.2. This aligns with our batch adsorption tests ([Figure](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) S7) revealing strong PIP and weak Mn(II) loadings at this pH value. PIP binding was also lower and Mn(II) binding was greater at a larger pH, even with competitive sorption at pH > 6. Taken together, these findings confirmed that interactions between positively charged goethite (PZC 9.1) and negatively charge  $MnO<sub>2</sub>$  (PZC 2.4) particles decreased overall cation adsorption in the MGCS system. As a result, dissolved Mn(II) ion was flushed out of the column, thus preventing further interactions with  $MnO<sub>2</sub>$  and mitigating surface passivation, which is generally observed in  $MnO<sub>2</sub>$ -based redox reactions (e.g., as in MCS column).<sup>[4](#page-6-0),[17,42](#page-7-0)</sup> Indeed, it has been reported that  $Mn(II)$  binding at the  $MnO<sub>2</sub>$  surface may decrease the oxidation rate of organic compounds because (i) Mn(II) may block redox reactive sites on the oxide surface, preventing adsorption of the organic compound or competitively reacting with  $MnO_2$ , and (ii) surface bound  $Mn(II)$  may decrease the average oxidation state of  $MnO<sub>2</sub>$  and therefore slow the rate of electron transfer.<sup>4,[17,42](#page-7-0),[46](#page-7-0)</sup> This may explain the higher reactivity of the MGCS system in total PIP removal with respect to MCS.

**3.3. PIP Transport at Two pH Values.** An additional PIP breakthrough experiment in the 0.05 MGCS column was repeated but at pH 7.0. In contrast to experiments at pH 5.2 (Figure 4), no variations in pH occurred. Only 1.8 *μ*mol of PIP was removed at neutral pH, compared to that at pH 5.2 (3.2 *μ*mol), because acidic conditions favored PIP oxidation and adsorption onto  $MnO<sub>2</sub>$  and/or goethite. A steeper BTC and earlier breakthrough point, with complete breakthrough, were achieved, whereas no  $\text{PIP}_{\text{ox}}$  or  $\text{Mn(II)}$  was detected in the column effluent, indicating extreme low or no PIP transformation occurred at pH 7. This observation is consistent with our modeling result since setting  $\mu_s = 0$  can well fit the BTC of PIP at pH 7 [\(Table](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) S2).

No oxidation occurred during the first stage, but when the residence time is increased,  $Mn(II)$  and  $PIP_{ox}$  were detected upon flow resumption. The PIP relative concentration drops to 0.6 at pH 7 but only to 0.8 at pH 5.2 when the flow was resumed (Figure 4a). According to [eq](#page-4-0) 8, more PIP was removed, and a higher *k* value was obtained during the flow interruption period at pH 7 (1.4  $\times$  10<sup>-4</sup> min<sup>-1</sup> at pH 5.2, 3.5  $\times$ 10<sup>−</sup><sup>4</sup> min<sup>−</sup><sup>1</sup> at pH 7, [Table](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) S3). As only sorption happened in the first step, we suppose that the pristine  $MnO<sub>2</sub>$  surfaces may enable more PIP oxidation during the flow interruption period. Furthermore, less  $MnO<sub>2</sub>$  passivation can be expected, as more Mn(II) can be adsorbed by goethite at pH 7 (see batch data in [Figure](https://pubs.acs.org/doi/suppl/10.1021/acs.est.2c05963/suppl_file/es2c05963_si_001.pdf) S7).

In summary, both experimental and modeling results show that binary mixtures of manganese oxides and goethite are capable of oxidizing and removing PIP more efficiently than in the single phase. MGCS may overcome the major drawbacks of MCS to be used as a potential geomedia for antibiotic removal. Indeed, preferential adsorption of Mn(II) on negatively charged  $MnO<sub>2</sub>$  and the progressive buildup of Mn(II) in the column decreased the reactivity of the MCS column over breakthrough time. However, MGCS preferential adsorbed PIP or  $\text{PID}_{\text{ox}}$  over Mn(II) and thereby reduced the passivation effect by dissolved Mn(II).

#### **4. ENVIRONMENTAL SIGNIFICANCE**

This study contributed to mounting evidence that the environmental fate of pollutants cannot be predicted based on the sorption/oxidation data of single minerals. A thorough examination of the redox reactivity within complex mineral assemblages under both batch and continuous flow conditions is necessary for an accurate assessment of contaminant transport in natural environments (e.g., soils and sediments) or engineered infiltration systems (e.g., MAR). Here, we showed that coexisting minerals, in our case goethite, can alter the overall reactivity of the redox-active  $MnO<sub>2</sub>$ . In particular, interactions between the positively charged goethite and the negatively charged  $MnO<sub>2</sub>$  particles decreased  $Mn(II)$  surface loadings, thus facilitating its mobility through the column. In addition to advancing ideas on environmental processes,

# <span id="page-6-0"></span>**Environmental Science & Technology** *[pubs.acs.org/est](pubs.acs.org/est?ref=pdf)* **Article Article Article Article Article Article Article**

knowledge that goethite-MnO<sub>2</sub> interactions decrease MnO<sub>2</sub> passivation could be used to design novel geomedia filters. Fe and Mn binary oxides may overcome the major drawbacks of Mn-oxides to be used as a potential geomedia filter for antibiotic removal. As manganese oxides have the potential to be applied as a filter to prevent organic contaminants from percolating into the groundwater sources in both natural soils and artificial infiltration systems, this work could help in designing efficient geomedia in treatment technologies (industrial and/or municipal wastewater, agricultural runoff, stormwater, etc.). Those contaminated systems contain diverse organic groups such as pharmaceuticals and personal care products, pesticides, and detergents, with varying concentrations. Therefore, the amount  $MnO<sub>2</sub>$  and/or goethite coated on sand should be optimized to further enhance the reactivity and longevity of geomedia and prior to the application of GMCS in infiltration systems. Finally, as Fe- and Mn-oxides may coexist with each other as particulate coatings, the transport model developed here will help in understanding fate and transformation of emerging compounds in natural environments such as soils and sediments.
