Chapter 1

General introduction

Secondary metabolites

Humanity is currently facing unprecedented challenges such as climate change, increasing antimicrobial resistance, loss of biodiversity, and food security. Traditionally, we have relied on petroleum-based chemistry for industrial and consumer products, but now we are witnessing a transition to more natural approaches (Pham et al., 2019). It is urgent to discover novel chemistry, both to address our escalating global issues and to fulfill our demand for new, effective, and sustainable chemical compounds. Thus it is important to explore natural products, which encompass a variety of substances and compounds derived from living organisms (Louwen et al., 2023). They include both primary metabolites and secondary metabolites (SMs). Primary metabolites are essential for normal growth and reproduction, being directly involved in vital biological processes. They are produced at a high rate and can be easily extracted through simple biochemical methods. This has led to their early and extensive use by humans. Examples of such metabolites include starch and sugars, which are fundamental in various industrial and culinary applications (Sanchez & Demain, 2008). In contrast, SMs, which are typically of low molecular weight and structurally complex, facilitate the interaction between organisms and enable organisms to dynamically respond to environmental challenges (Hoffmeister & Keller, 2007). For instance, cyclosporin A, a fungal SM, can induce apoptosis and help to overcome the immune system in arthropod hosts, leading to the colonization of the host by the fungus (X. Yang et al., 2018). Similarly, SMs generated by plant pathogenic fungi can act as virulence factors, causing significant agricultural losses (Collemare & Lebrun, 2011). In competitive scenarios, certain bacteria, such as different *Pseudomonas* species, synthesize 2,4-diacetylphloroglucinol as an anti-microbial agent (Velusamy et al., 2006), while fungi deploy the antibiotic cephalosporin to suppress the growth of rival bacteria by disrupting their cell wall synthesis (Liu et al., 2022). Within challenging habitats, some microbes utilize siderophores to scavenge iron from their surroundings (De Serrano et al., 2016), a pathogenic bacteria, *Acinetobacter baumannii*, produces ectoines to safeguard its cells from osmotic stress (Zeidler & Müller, 2019), and melanin protects fungal spores against threats such as UV irradiation, enzymatic lysis, and extreme temperatures (Langfelder et al. 2003). In summary, SMs are structurally complex compounds that play key roles in organismal interactions and environmental adaptations, offering significant potential for innovative and sustainable solutions in various sectors.

Based on the wide range of biological activities of SMs, humans have explored the applications of SMs in medicine, agriculture, and various other industries (Pham et al., 2019). In the medical field, SMs are pivotal for drug development and therapeutic strategies, serving as a reservoir of biologically active compounds with antibiotic, antiviral, antifungal, and antitumor properties (Jakubiec-Krzesniak et al., 2018). For instance, penicillin, the first broad-spectrum antibiotic, has proven effective against bacterial infections and marked the beginning of the antibiotic era in modern medicine (Aly et al., 2011). Griseofulvin and amphotericin act

as antifungal agents (Newman & Cragg, 2016), while compounds like cyclosporine A (Laupacis et al., 1982) and psilocybin (Khan et al., 2022) function as immunosuppressants and can be applied to treat trauma-related disorders, respectively. In agriculture, SMs are employed as biopesticides, thereby providing an eco-friendly alternative to traditional pesticides as they have specific pest targets and do not contribute to chemical pollution. For example, azadirachtin, derived from the Indian neem tree, has been commercialized and is utilized as a botanical pesticide worldwide (Kilani-Morakchi et al., 2021), and strobilurin, isolated mainly from mushrooms, contributes to controlling fungal diseases (Balba, 2007). In various industries, SMs are also crucial for providing flavors, colors, and antioxidants (Sanchez-Ballesta et al., 2022). For instance, curcumin, a yellow pigment derived from *Curcuma longa*, is commonly used as a food-coloring agent and in cosmetic products (Menon & Sudheer, 2007). Chromologics (<https://www.chromologics.com/>) sells a natural red pigment “Chromored” produced by the fungus *Talaromyces atroseus* at the bioreactor scale (Morales-Oyervides et al., 2020). The Living Color Database documents approximately 445 pigment entries from both fungi and bacteria (Sharma & Meyer, 2022). Current research aims to understand how SMs are produced, discover novel SMs, uncover the functions and biological activities of SMs, and investigate methods to produce SMs on an industrial scale.

Fungal biosynthesis gene clusters

The fungal kingdom is remarkably large and diverse, comprising approximately 1.5 to 5 million species, which inhabit various ecological niches and exhibit different morphologies and life cycles (Choi & Kim, 2017). Interestingly, many fungi are known to be prolific producers of diverse SMs (Mosunova et al., 2021). SM biosynthesis in fungi is orchestrated by a series of enzymatic reactions that are catalyzed by diverse proteins, including the backbone (or core) enzymes, tailoring enzymes, and those proteins responsible for transcriptional control, transport, and/or host resistance (Figure 1) (Keller, 2019; Keller et al., 2005). Fungal SMs are categorized into several major chemical groups based on the precursors (acyl-coAs, amino acids, or prenyl diphosphates) they utilize to synthesize and the types of backbone enzymes. Backbone enzymes such as polyketide synthase (PKS), non-ribosomal peptide synthetase (NRPS), hybrid PKS-NRPS enzymes, dimethylallyl tryptophan synthetase (DMATS), and terpene cyclase (TC), catalyze the production of polyketides, non-ribosomal peptides, PKS-NRPS hybrids, indole alkaloids, and terpenes, respectively (Mosunova et al., 2021). Following this initial step, tailoring enzymes modify the chemical structure of the intermediate compounds through processes such as methylation, acylation, glycosylation, or hydroxylation (Mosunova et al., 2021), giving rise to a diverse array of structurally complex and functionally distinct SMs. Transport-related genes encode proteins to export the final products from the fungal cell into the extracellular space (Gomez-Escribano and Bibb 2011), and genes associated with resistance, provide protection to the fungi against the toxic effects of some SMs (Gomez-Escribano & Bibb, 2011). Considering that certain biosynthetic pathways contain

more than one backbone gene, leading to hybrid molecules, and that one biosynthetic pathway can include several tailoring steps, the combination of these factors allows to production of a vast and yet underexplored SMs from a limited set of chemical precursors.

Figure 1 Step-wise biosynthesis of secondary metabolites (SMs) encoded by biosynthetic gene clusters (BGCs). This schematic represents a single BGC, composed of genes that encode for a backbone and several tailoring enzymes, in addition to genes fulfilling other specific functions. The biosynthesis process of an SM is sequential: it is initiated by the transformation of a primary metabolite into a precursor, facilitated by a backbone enzyme. This is followed by the action of tailoring enzymes, which further modify the precursor to yield the final SM.

The genes related to the biosynthesis of a fungal SM are often physically co-localized along the chromosome and co-regulated, an organization that is referred to as the biosynthetic gene cluster (BGC) (Figure 1). This special organization not only facilitates the sharing of intermediate compounds among sequential enzymes, enhancing the production of SMs (Pfannenstiel & Keller, 2019), but also may act as a suitable unit for the duplication, deletion, or transfer of the complete SM pathway (Rokas et al., 2018). Moreover, the clustering might minimize the risk of the accumulation of toxic intermediates (Rokas et al., 2018; Wisecaver et al., 2014). An examination of 100 fungal genomes shows a bias for the physical pairing of genes encoding enzymes that share a toxic intermediate (McGary et al., 2013), underscoring the evolutionary advantage and functional significance of this genomic organization of genes involved in the biosynthesis of SMs. Despite the strong selection pressure to maintain genes involved in SM biosynthesis in gene clusters, extensive diversity in the presence and organization of SM-BGCs has been detected by genome mining across the fungal kingdom, ranging from a few to several dozen SM-BGCs per species (Figure 2) (Mosunova et al., 2021). Species within the phylum Ascomycota on average encode more backbone genes compared to other fungal phyla, in which Eurotiomycetes, Lecanoromycetes, and Sordariomycetes are the top three classes with more than 45 backbone genes, especially in PKS, NRPS-like, and NRPS (Figure 2). Basidiomycota, including wood-decaying species and edible mushrooms, generally encodes fewer backbone genes compared with Ascomycota and it is relatively enriched in NRPS-like and TC groups (Figure 2). Neocallimastigomycetes are especially rich in NRPS genes, while other fungal classes show a reduced production capacity of this type of backbone enzyme. In light of these observations, it is necessary and also most effective to

focus on species within the same genus to understand the diversity of SMs in newly sequenced species. For comparisons across different fungal genera, careful attention should be given to the inherent diversity and complexity of SM-BGCs given their significant variations across the fungal kingdom.

Figure 2 Distribution of BGCs in the fungal kingdom. Mosunova et al. highlight the phylum Ascomycota as having the highest abundance of BGCs among fungi. Data on the number of genomes and SM genes are presented at the class level, with classes within the same phylum unified by the same background color. Distinct SM groups are differentiated using various colors in the bar plots, providing a clear visual breakdown of their presence across different fungal classes. Figure adapted from (Mosunova et al., 2021).

Local and global transcriptional regulation of SM-BGCs

Given that the functions of SMs are diverse and considering the energy cost of their production, SMs are only synthesized when necessary. The biosynthesis of fungal SMs is tightly regulated by transcription factors (TFs), both on a local scale as well as globally (Brakhage, 2013). Some

BGCs have one or several genes encoding TFs as part of the cluster, which can govern the co-expression of BGC. For instance, aflR, one of the earliest-studied TFs within BGC, regulates the expression of the aflatoxin and sterigmatocystin genes in *Aspergillus* species (Woloshuk et al., 1994). To activate silent BGCs, scientists have tried to overexpress local TFs by introducing an extra copy, which led to the discovery of aspyridone in *Aspergillus nidulans* (Bergmann et al., 2007). Moreover, replacing the local promoter with an inducible one can turn on the biosynthesis of asperfuranone in *A. nidulans* (Chiang et al., 2009). In response to environmental stimuli, global transcriptional regulators affect the expression of some BGCs as well as other genes throughout the genome (Macheleidt et al., 2016). Global TFs, such as CreA, AreA, or Hap, control the gene expression response to the carbon source (Lyu et al., 2020), nitrogen source (B Tudzynski et al., 1999; Bettina Tudzynski, 2014), and iron starvation (Hortschansky et al., 2017), respectively. Furthermore, PacC regulates BGC expression in response to pH (Lyu et al., 2020), while the Velvet and LaeA protein complexes control the response to light (Bayram et al., 2008). The manipulation of global TFs leads to diverse effects of different BGCs and other genes. For instance, the deletion of *mcrA* (*LaeA*-like) in *A. nidulans* results not only in upregulations of sterigmatocystin, terrequinone A, and cichorine, but also alters the expression of more than 100 genes throughout the genome (Grau et al., 2019). In summary, these intricate regulatory networks highlight the potential for developing new methods to harness the production of valuable SMs by fine-tuning the expression of both local and global TFs.

Histone PTMs-based regulation of SM-BGCs

Within the eukaryotic nucleus, the genetic material is organized into repeating basic units, nucleosomes. They are formed by a 145–147 bp DNA strand that is wrapped around a histone octamer composed of two copies each of histone protein 2A (H2A), H2B, H3, and H4 (Luger et al., 1997). Each histone protein has a globular central domain that facilitates the interaction with nucleosomal DNA, a lysine- and arginine-rich N-terminal tail, and a short C-terminal tail (van Holde, 1989). Multiple nucleosomes, connected by a 30-50 bp of DNA and a linker histone protein H1, can aggregate to form a higher structure that is referred to as chromatin (Luger et al., 1997). The compaction of nucleosomes within the chromatin is thought to be dynamic and chromatin alternates between the ‘open’ euchromatin, a loosely packed and transcriptionally active state, and the ‘closed’ (facultative or constitutive) heterochromatin, a condensed and transcriptionally silent state (Grewal & Jia, 2007). Chemical post-translational modifications (PTMs) on the tails of histone proteins as well as chemical modifications of the DNA itself contribute to the formation and maintenance of chromatin states as well as dynamic transitions between states. Especially histone PTMs can directly alter histone proteins’ net charges or mediate the interaction with other inter-nucleosomal proteins, and consequently, histone PTMs and DNA modifications are thought to influence chromatin compaction (Henikoff & Shilatifard, 2011). Therefore, the chromatin state and dynamic transitions between states

are crucial for organisms to regulate gene expression in response to both developmental and environmental stimuli (Klemm et al., 2019).

Over recent years, a multitude of different histone PTMs have been identified across a range of organisms. The enzymes responsible for these modifications have typically classified into three distinct types: (i) 'writers' that introduce specific chemical modifications to histone proteins; (ii) 'erasers' that remove these modifications; and (iii) 'readers' that initially detect specific changes and then guide writers, erasers, or other proteins to the relevant genomic sites (Ueda & Seki, 2020). Evolutionary analyses suggest that these enzymes originated early and underwent significant expansion throughout the history of eukaryotes. An examination of 94 gene families involved in histone PTMs shows that 87 of them originated over a billion years ago, with 48 already existing in the last common ancestor of all eukaryotes (Weiner et al., 2020). Histone methylation and acetylation are the most common and abundant histone PTMs found in a wide range of organisms, while other histone PTMs such as acylation, phosphorylation, ubiquitination, and sumoylation have only been deeply studied in model organisms such as humans and the baker's yeast *Saccharomyces cerevisiae* (Tan et al., 2011). However, besides the few model species, we have little knowledge of histone PTMs in less-studied fungal species.

The functional implication of different histone PTMs on chromatin organization and functioning has been derived from data in only a few eukaryotic systems. Euchromatin is a lightly packed form of chromatin that is enriched in gene-rich regions of the genome, characterized by its accessibility to TFs and RNA polymerases (K. Yang et al., 2022). This open chromatin structure facilitates active transcription, allowing for accurate and quick gene expression and regulatory processes essential for normal cellular function and response to environmental stimuli (K. Yang et al., 2022). It is predominantly associated with histone acetylation, such as acetylation of amino acid residues on histone protein H3 (lysine 4 (K4), K9, K14, K18, K23, and K27) and H4 (K5, K8, K12, and K16), and with methylations on histone protein H3 at K4, K36, and K79 (Bhaumik et al., 2007; Shilatifard, 2006). Distinct histone modifications have been observed on different regions of genes. In *S. cerevisiae*, H3K4ac (acetylation on histone protein H3 at lysine 4) is positioned upstream of protein-coding genes, while H3K4me3 (trimethylations on histone protein H3 at lysine 4), H3K9ac, and H3K14ac are enriched at the transcriptional start sites of active genes (Pokholok et al., 2005). Moreover, H3K4me2 (dimethylation) is most enriched throughout the coding region, while H3K4me1 (monomethylation), H3K36me3, and H3K79me3 are found predominantly at the end of active genes in *S. cerevisiae* (Pokholok et al., 2005). Conversely, constitutive heterochromatin, which describes chromatin that remains consistently condensed in an organism's lifespan, is situated at centromeres, telomeres, and regions typically enriched in transposons, thus contributing to the maintenance of genomic integrity and stability (Tamaru, 2010). H3K9me3

is associated with the formation and maintenance of constitutive heterochromatin in several fungal species, including the fission yeast *Schizosaccharomyces pombe* (Yamada et al., 2005) and the filamentous model fungus *Neurospora crassa* (Rountree & Selker, 2010). Facultative heterochromatin is chromatin that is thought to be able to dynamically transit between euchromatin and constitutive heterochromatin in response to developmental and environmental cues and has been linked with the presence of H3K27me3 (Grewal & Jia, 2007). In many filamentous fungi, this histone PTM is found near sub-telomeric regions as well as in regions rich in transposable elements (Ridenour et al., 2020; Schotanus et al., 2015). Last but not least, even though numerous PTMs have been linked to either euchromatin or heterochromatin, their impact can vary based on the regions they are located. For example, in *N. crassa* and *Fusarium fujikuroi*, H3K36me1/2/3 catalyzed by SET-2 activates gene expression, while H3K36me1/2/3 deposited by Ash-1 is located in sub-telomeric regions and is linked to gene silencing (Bicocca et al., 2018; Janevska et al., 2018).

In several fungal species, it has been demonstrated that experimentally induced changes to histone PTMs can influence the biosynthesis of SMs (K. Yang et al., 2022). For example, the deletion of a histone deacetylase changes the conformation of the chromatin from the transcriptionally silent 'closed' to the transcriptionally 'open' state, which increases the expression of nine out of 14 NRPSs in *Aspergillus fumigatus* (Lee et al., 2009) and the production of kojic acid in *Aspergillus niger* (Li et al., 2019). By contrast, the knockout of histone acetyltransferase can lead to defects in secondary metabolism in *A. nidulans* (Cánovas et al., 2014). Similar observations have also been made for histone methylations linked with euchromatin. For example, H3K36me3 can activate the transcription of genes involved in fumonisin B1 and bikaverin biosyntheses in *Fusarium verticillioides* (Gu, Wang, et al., 2017). Knocking out the catalytic enzyme of H3K4m3 leads to a significantly decreased production of deoxynivalenol, fusarin C, zearalenone, and fusarielin H in *Fusarium graminearum* (Bachleitner et al., 2019) and decreased biosynthesis of gibberellic acid in *F. fujikuroi* (Studt et al., 2017). In contrast, knocking out enzymes related to histone methylations of (facultative or constitutive) heterochromatin can induce the biosynthesis of SMs. For instance, the deletion of the writer for H3K27me3 up-regulates 20 out of 47 predicted SM genes in *F. fujikuroi* (Studt et al., 2016). Similarly, H3K9me3 mutant strains exhibit increased black pigmentation and fumonisin B1 production in *F. verticillioides* (Gu, Ji, et al., 2017). Thus, considering the abundant and diverse SM gene clusters encoded in fungal species, and the regulation of gene expression by various histone PTMs, there is significant potential to unlock more SM biosynthesis pathways.

The *Aspergillus* genus

The fungal genus *Aspergillus* encompasses approximately 350 species that display a wide range of morphological variation and ecological flexibility (Samson et al., 2014). Some

Aspergillus species can be detrimental by acting as pathogens to humans, animals, and crops, or as food contaminants (Lamoth et al., 2015). For instance, *A. fumigatus* leads to severe infections in individuals with weakened immune systems (Lamoth et al., 2015). Some species are vital for industrial and medical applications; for example, *A. niger* produces citric acid, the market for which is expected to reach three billion dollars by 2027 (Cairns et al., 2021; Mead et al., 2021). Importantly, species belonging to the *Aspergillus* genus are thought to be highly bioactive and can produce a variety of diverse SMs (Kjærboelling et al., 2018; Mosunova et al., 2021). Computational research spanning the fungal kingdom underscores the *Aspergillus* genus' rich reservoir of predicted BGCs (Figure 2) (Mosunova et al., 2021). A comprehensive study of 32 *Aspergilli* from the *Nigri* section revealed over 400 predicted BGCs. Intriguingly, 82% of these BGCs are identified in less than ten species, with 49% being unique to a single individual species (Vesth et al., 2018). Despite the vast number and variety of BGCs encoded in *Aspergilli* genomes, only a few hundred SMs have been experimentally identified. This discrepancy arises because these compounds are produced only under specific ecological conditions, making it difficult to express BGCs in a lab setting (Brakhage, 2013).

Several histone PTMs have been demonstrated to affect the SM biosynthesis in a handful of model *Aspergillus* species. In addition to the examples mentioned above, other studies have highlighted the impact of various histone PTMs on SM biosynthesis. For example, acetylation of histone H3 is required for the biosynthesis of SMs in *A. nidulans* (Cánovas et al., 2014; Reyes-Dominguez et al., 2010). In *A. fumigatus*, mutants lacking H3K4me2/3 show increased production of several SMs, including gliotoxin (Palmer et al., 2013). Importantly, research thus far in *Aspergillus* as well as in other fungi has primarily focused on the alterations of a few well-established histone PTMs. However, there is a notable absence of a comprehensive overview regarding the prevalence, evolution, and regulatory role of histone PTMs in the *Aspergillus* genus, especially concerning SM biosynthesis. In this context, an in-depth exploration of both histone PTMs and SM-BGCs needs to be performed. The *Aspergillus* genus is an excellent system considering its significant position as the prolific producer of SMs. Such an investigation could pave the way for a more profound understanding of the regulatory mechanisms of SM biosynthesis, potentially revealing novel avenues to express and exploit novel biochemistry, potentially with benefit for humankind.

To study SM biosynthesis and unravel the roles of PTMs in *Aspergilli*, **in this thesis**, I perform both wet-lab experiments and computational analyses. **In chapter 2**, I provide an extensive overview of BCG abundance and diversity across *Aspergilli*. Subsequently, I examine the genomic localization of these BGCs and how it relates to variation in gene expression and histone modifications. To get an overview of histone PTMs in the *Aspergillus* genus, I summarize the genes related to histone PTMs from the literature and check their absence and presence patterns and evolution across the *Aspergillus* genus in **chapter 3**. To verify the

Chapter 1

computational analysis, I optimize a protocol to extract high-quality histone proteins and then conduct a proteomics study to detect the occurrence of single and multiple histone PTMs in three *Aspergilli* in **chapter 4**. Lastly, in **chapter 5**, I introduce the concept of 'histone code' and summarize its condition in *Aspergilli*. I pinpoint the interesting histone PTMs that can be further studied based on my studies and predict their functions in SM biosynthesis.

Chapter 2

Secondary metabolite gene clusters and their genomic localization in the fungal genus *Aspergillus*

Xin Zhang, Iseult Leahy, Jérôme Collemare+, Michael F. Seidl+

+These authors contributed equally

Abstract

Fungi are well-known producers of bioactive secondary metabolites (SMs), which have been exploited for centuries by humankind for various medical applications like therapeutics and antibiotics. SMs are synthesized by biosynthetic gene clusters (BGCs) – physically co-localized and co-regulated genes. Because BGCs are often regulated by histone post-translational modifications (PTMs), it was suggested that their chromosomal location is important for their expression. Studies in a few fungal species indicated an enrichment of BGCs in sub-telomeric regions, however, there is no evidence that BGCs with distinct genomic localization are regulated by different histone PTMs. Here, we used 174 *Aspergillus* species covering 22 sections to determine the correlation between BGC genomic localization, gene expression, and histone PTMs. We found a high abundance and diversity of SM backbone genes across the *Aspergillus* genus, with notable diversity increases between sections. Being unique or conserved in many species, BGCs showed a strong bias for being localized in low-synteny regions, regardless of their position in chromosomes. Using chromosome-level assemblies, we also confirmed a significantly biased localization in sub-telomeric regions. Notably, SM backbone genes in sub-telomeric regions and about half of those in low-synteny regions exhibit higher gene expression variability, likely due to the similar higher variability in H3K4me3 and H3K36me3 histone PTMs. In contrast, variations in histone H3 acetylation and H3K9me3 are not correlated to genomic localization and expression variation. Overall, our results indicate that BGCs tend to be located in low-synteny regions and that regulation of expression in those regions likely involves different histone PTMs than the most commonly studied modifications.

Introduction

Filamentous fungi are prolific producers of bioactive molecules, termed secondary metabolites (SMs) or natural products (Mosunova et al., 2021). While these metabolites are not directly necessary to sustain fungal growth, development, or reproduction, they play indispensable roles in inter-organismal interactions and fungal survival in diverse ecological niches (Keller, 2019). SMs have multifaceted functions, from acting as pigments that shield fungal spores from UV radiation and serving as virulence factors in pathogenic interactions to providing competitive edges through antibiotic properties (Keller, 2019). Humans have harnessed the bioactive potential of these metabolites to significantly enhance their quality of life (Cairns et al., 2021). Fungal SMs have found significant applications in medical treatments, serving as therapeutic agents, exemplified by lovastatin and ergotamine, as well as immunosuppressants like cyclosporine (Newman & Cragg, 2016; Wiemann & Keller, 2014). They also play crucial roles as antibiotics, with penicillin being a notable example, and as antifungal agents, such as griseofulvin (Newman & Cragg, 2016).

The biosynthesis of fungal SMs is orchestrated by a series of enzymatic reactions. First, backbone (or core) enzymes use precursors derived from primary metabolism to synthesize an intermediate that is then further modified by so-called tailoring enzymes to produce the final compound(s) (Mosunova et al., 2021). Backbone enzymes responsible for the synthesis of diverse SMs have been classified into categories based on their enzymatic functions such as polyketide synthase (PKS), non-ribosomal peptide synthetase (NRPS), hybrid PKS-NRPS enzymes, dimethylallyl tryptophan synthetase (DMATS), and terpene cyclase (TC) (Mosunova et al., 2021). Genes encoding backbone and tailoring enzymes, as well as genes responsible for transcription control, transport, and/or self-resistance, are co-regulated and often physically co-localized along the chromosome in biosynthetic gene clusters (BGCs) (Mosunova et al., 2021).

The discrepancy between the predicted bioactive potential based on genome mining and the number of known molecules effectively produced can be explained by the tight transcriptional control of SM biosynthetic pathways (Brakhage, 2013). In addition to the regulation by local and global transcription factors (Chiang et al., 2009; Macheleidt et al., 2016), SM production is regulated globally by chromatin dynamics that, in response to both internal and external stimuli, transitions between different chromatin states: the 'open' euchromatin, loosely packed and transcriptionally active state, and the 'closed' heterochromatin, tightly packed and transcriptionally silent state (Collemare & Seidl, 2019; Gacek & Strauss, 2012). Histone post-translational modifications (PTMs) – chemical modifications on specific amino acids localized on the 'tails' of histone proteins contribute to the control of the chromatin status. Most histone acetylations and some histone methylations on H3K4 (histone protein H3 at lysine 4) and H3K36 are associated with euchromatin, while histone methylations on H3K9 and H3K27 are associated with heterochromatin (Lawrence et al., 2016). In *Aspergillus fumigatus*, the deletion

of histone deacetylases, which changes the chromatin from 'closed' heterochromatin to 'open' euchromatin, increases the activity of nine out of 14 NRPSs (Lee et al., 2009) and the production of kojic acid in *Aspergillus niger* (Li et al., 2019). The knockout of histone acetyltransferases also leads to defects in SM biosynthesis in *Aspergillus nidulans* (Cánovas et al., 2014).

Following the discovery that histone PTMs play an important role in the regulation of SM biosynthesis, it was hypothesized that the chromosomal location of BGCs was crucial for their regulation (Palmer and Keller, 2010). Indeed, several studies reported that BGCs tend to be preferentially located at, or close to, sub-telomeric regions, such as in *Fusarium graminearum* (Connolly et al., 2013), and in some well-studied Aspergilli: *Aspergillus oryzae* (Kjærboelling et al., 2020), *Aspergillus flavus* (Yang et al., 2022), *A. fumigatus* (Keller, 2019; Perrin et al., 2007), and *A. nidulans* (Klejnstrup et al., 2012). Sub-telomeric regions in fungi are rich in repetitive sequences such as transposable elements and are typically associated with histone PTMs linked to heterochromatin, especially with the presence of H3K9me3 and H3K27me3 (Keller, 2019; Palmer & Keller, 2010; Wiemann et al., 2013). For instance, in *Fusarium fujikuroi*, the PKS19 BGC, which produces fujikurins, is embedded within a region rich in H3K9me3 on the long arm of chromosome VIII (Wiemann et al., 2009). Similarly, in *A. nidulans*, some BGCs occur in proximity to H3K9me3-rich regions (Gacek-Matthews et al., 2016). Thus, the peculiar genomic localization of BGCs might explain why these BGCs remain transcriptionally silent. Moreover, because of their high repeat content, sub-telomeric regions are prone to rearrangements and typically exhibit low synteny, characterized by reduced conservation of physical co-localization of genes compared to other species (Nakao et al., 2009). In *A. nidulans*, compared to *A. oryzae* and *A. fumigatus*, BGCs often occur at less conserved and heavily rearranged genomic regions, even though the majority (77–79%) of the genomes show conserved synteny (Inglis et al., 2013). However, not all SM gene clusters are associated with heterochromatin and sub-telomeric regions. While previous studies have predominantly focused on a limited number of well-known *Aspergillus* sections and species, often finding an association of SM gene clusters with heterochromatin and sub-telomeric regions, it is crucial to note that not all SM gene clusters are confined to these areas. To address this knowledge gap, we examined the correlation among the BGC diversity, their genomic organizations, gene expression, and histone PTMs together across a more diverse range of species. We here include 174 diverse Aspergilli species including 22 sections to provide a more nuanced analysis of the distribution, conservation, and genomic localization of SM genes, particularly in relation to genome-wide syntenic regions and histone PTMs. This extensive approach allows us to explore the implications of BGC localization and histone PTMs on SM gene expression regulation.

Results and discussions

A comprehensive phylogenetic analysis of the fungal genus *Aspergillus*

To provide a comprehensive analysis of BGCs in *Aspergilli*, we included 174 publicly available *Aspergilli* genomes and three outgroup *Penicillium* species derived from the Joint Genome Institute (Table S1). The assembled genomes range in size from 23.2 to 42.9 Mb and 90% of them fall within the range of 25.8 to 38.8 Mb (Figure 1, Table S1). Four *Aspergillus* species - *A. fumigatus*, *A. nidulans*, *A. niger*, and *Aspergillus ochraceus* - have chromosomal-level genome assemblies (Nierman et al., 2005), which are comprised of eight chromosomes (Figure 1, Table S1). The other well-studied model system, *A. oryzae*, has also a good genome assembly of eleven scaffolds. Twenty-four *Aspergilli* assemblies have 100 or fewer scaffolds, while *Aspergillus rambellii* has the most fragmented assembly with 4,177 scaffolds (Figure 1, Table S1). The number of predicted protein-coding genes ranges from 7,761 to 15,687, with 90% of *Aspergilli* having between 9,561 and 14,061 genes (Figure 1, Table S1). Because the genome contiguity and the number of genes varied between different *Aspergilli*, we sought to calculate the genome completeness by querying each genome assembly for the occurrence of single-copy orthologous BUSCO genes (Table S2). Importantly, we observed very high genome completeness with 90% of all *Aspergilli* scoring higher than 98.0% BUSCO completeness (Figure 1, Table S1). Even *A. rambellii* with the most fragmented assembly and the fewest genes (7,761) attains a high genome completeness of 97.1%. Similarly, four other *Aspergilli* with more than 1,000 scaffolds also have high genome completeness (*Aspergillus udagawae* (97.8%), *Aspergillus avenaceus* (99.1%), *Aspergillus haitiensis* (98.3%), and *Aspergillus coremiiformis* (99.5%)) (Figure 1, Table S1). Thus, all species included in this study are of sufficient quality to perform accurate comparative analyses.

To provide a robust phylogenetic framework to study BGC and genomic diversity in *Aspergilli*, we constructed a species phylogeny based on the concatenated alignment of 758 conserved, single-copy BUSCO genes (in total 758 positions with 132,397 informative sites). The tree reveals 22 distinct *Aspergillus* sections, each supported by bootstrap values exceeding 99% (Figure 1), suggesting that our phylogenetic analysis is robust. Moreover, our species phylogeny confirms the associations among distinct *Aspergillus* sections as reported in previous studies and enlarges the taxonomic breadth by incorporating a much larger set of diverse *Aspergilli*; we included 174 *Aspergillus* species compared to less than 90 *Aspergilli* in previous publications (Steenwyk et al., 2019; C M Visagie et al., 2023; Cobus Meyer Visagie et al., 2014; X. Zhang et al., 2022). The 22 sections exhibit notable variation in the number of sequenced species: section *Nigri* has 28 sequenced species, whereas sections *Janorum*, *Bispori*, and *Silvati* are each represented by only a single sequenced species (Figure 1). Despite these differences, the genome assemblies in most sections are relatively uniform concerning assembly length, number of scaffolds, genome completeness, and gene count, and thus provide a comprehensive and robust reference to study the diversity and evolution of *Aspergilli* and a solid framework for further analysis.

Aspergilli encode an abundant secondary metabolite biosynthetic gene cluster repertoire

To evaluate the potential for SM biosynthesis encoded in the genomes of *Aspergillus* species, we focused on SM backbone genes as these genes are crucial for the first step in SM biosynthesis (Keller, 2019). We used antiSMASH (Blin et al., 2021) to identify regions that comprise a predicted BGC, and employed an in-house BGCToolkit to further classify SM backbone enzymes into groups that correspond to major chemical families and retrieve their sequences.

We identified in total 16,243 SM backbone genes across 174 *Aspergillus* species and three *Penicillium* species, ranging from 18 in *Aspergillus caninus* to up to 160 in *Aspergillus implicatus* (Figure 1, Table S3). On average, we identified 92 SM backbone genes per Aspergilli compared to only 77 per *Penicillium* species. These SM backbone genes are unevenly distributed. The 41 early-diverging Aspergilli (comprising sections *Polypaecilum*, *Cremeri*, *Restricti*, *Aspergillus*, *Cervini*, *Clavati*, and *Fumigati*) have on average 65 SM backbone genes, while the other 133 Aspergilli have on average 99. The *Circumdati* section has the highest average number of SM backbone genes, with its 18 species encoding an average of 129 SM backbone genes. As one BGC can contain several SM backbone genes, the average number of SM backbone genes in Aspergilli is higher than the number of predicted BGCs that have been reported in previous studies. For instance, studies that focused on sections *Nigri* (Theobald et al., 2018) and *Flavi* (Kjærboelling et al., 2020) have detected on average 82 and 70 BGCs, respectively. Here, we found these sections have an average of 104 (section *Nigri*) and 101 (section *Flavi*) SM backbone genes. Five groups of SM backbone genes stood out due to their abundance in all genomes. NRPS-like with 3,888, rPKS with 3,175, NRPS with 2,943, nrPKS with 1,395, and DMATS with 1,203 backbone genes. In most of the species (145 in total, including three *Penicillium* species), NRPS-like, rPKS, and NRPS are the three most abundant SM backbone genes. In contrast, ten species in sections *Flavipedes* and *Fumigati* have highly abundant DMATS, and other 22 Aspergilli have also many nrPKSs. Interestingly, we also observed variation in the number of SM backbone genes within sections. For example, within the *Nigri* section, we could define two sub-groups based on their morphology, and biseriates tend to have more SM backbone genes encoded in their genomes compared to uniseriates; uniseriates and biseriates differ in the attachment of phialides to the vesicle (Nielsen et al., 2009). Similarly, two sub-groups in the *Fumigati* section show a diverse pattern of SM backbones, the clade to which *A. fumigatus* belongs has a higher number of SM backbone genes. Moreover, we also observed that often a section is out-grouped by one species with fewer genes, such as in sections *Circumdati*, *Flavi*, *Nigri*, and *Nidulantes*, suggesting that gene loss in these species may be a pivotal factor driving their evolutionary differentiation and niche specialization. In summary, our findings underscore that the SM repertoires tend to be consistent within a given section and vary between sections.

Figure 1 *Aspergilli* encode an extensive number of secondary metabolite (SM) backbone genes, with notable differences across sections. The phylogenetic relationships between 174 *Aspergillus* and three *Penicillium* species are built using a maximum-likelihood framework implemented in IQ-TREE using a concatenated alignment of 758 single-copy BUSCO genes. The dots on the branches indicate ultrafast bootstrap values over 95 and SH-aLRT ((Shimodaira-

Hasegawa-like approximate likelihood ratio test)) values over 80. Species from the same section are highlighted by the same background color. The names of five well-studied *Aspergilli* are shown in the tree and a dashed line highlights the separation of sub-groups within the *Nigri* section. The smallest and largest dot sizes correspond to the minimum and maximum number in each category, respectively. Genome completeness is indicated by the percentage of identified complete, single-copy BUSCO genes in each genome assembly. SM backbone genes are first detected with antiSMASH, then reclassified by BGCtoolkit. Bar plots representing different SM backbone groups are arranged from left to right from the most to the least abundant.

Previous studies used BGC network approaches to assess BGC conservation within *Aspergillus* sections (Kjærboelling et al., 2020; Vesth et al., 2018), which overestimates the BGC diversity as variation in gene content of the identified BGCs will directly result in non-conserved BGCs. In contrast, we here utilized a phylogeny-aware method (Figure S1) to determine orthologous groups for each type of SM backbone gene. To obtain an estimate of gene conservation in *Aspergilli*, we used Orthofinder to identify orthologous groups for all genes among all genomes. We included in total 1,546,732 orthologs defined by the Orthofinder (Table S4) and 16,638 SM backbone genes to test their uniqueness among *Aspergilli*. From 1,546,732 orthologous entries defined by the Orthofinder, we identified 34,144 unique genes (2.2%) among all species, of which the estimated growth rate β is 0.27 (Figure 2A), in which β represents the rate of growth of unique genes as the number of sampled species increases. For SM backbone genes, 2,426 out of 16,638 (14.6%) are unique, of which the growth rate β is 0.45 (Figure 2B). These β rates imply that sequencing more *Aspergillus* species is expected to expand the overall genomic diversity and specifically increase the diversity within the set of SM backbone genes. However, saturation is reached for many SM groups, but not for NRPS and NRPS-like, which indicates that we might have found nearly all polyketide and terpene biosynthetic pathways, but many non-ribosomal peptides likely remain to be discovered. Lastly, we observed a similar trend for both unique orthologues and SM backbone genes with continuous slight increases within sections and small jumps between sections (Figures 2C and 2D), suggesting that sections are indeed characterized by a sudden increase in BGC diversity that is consistent with divergence.

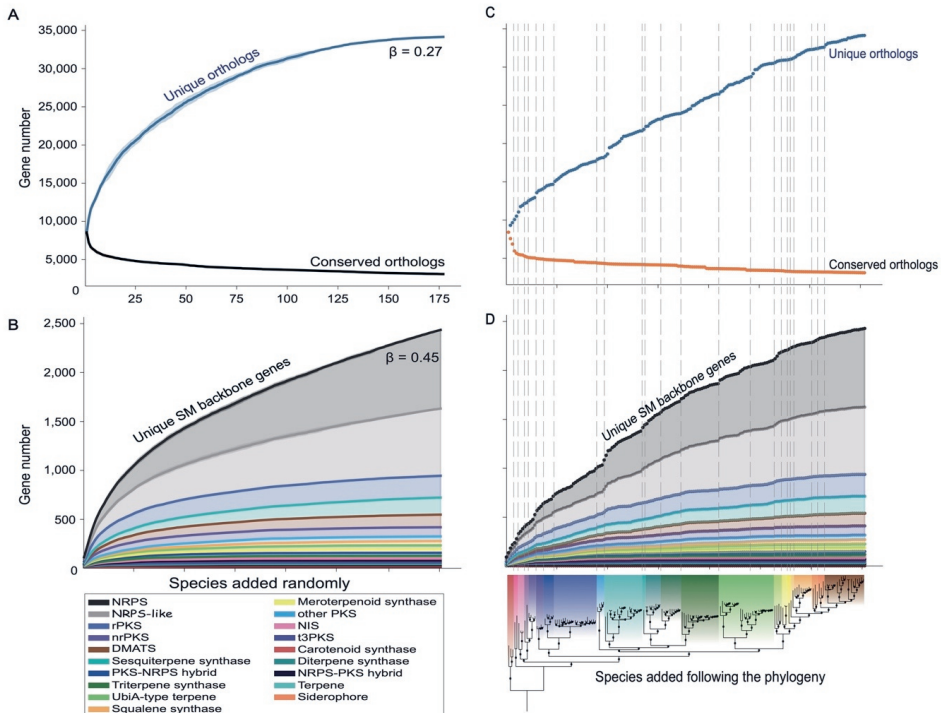

Figure 2 *Aspergilli* have an extensive repertoire of unique SM backbone genes. (A) The saturation curve plots the number of unique and conserved orthologous genes when species are added randomly. The calculations are performed ten times, and the standard deviations are shown as shadows around the curve. (B) Saturation curves plot the stacked number of unique SM backbone genes when species are added randomly. Different colors indicate distinct groups of SM backbone genes. The calculations are performed 10 times, and the standard deviations are shown as shadows around the curve. (C) Saturation curves of unique and conserved orthologous genes when species are added according to their taxonomy, starting with the outgroup, and the dash lines indicate distinct taxonomic sections. (D) Saturation curves of unique SM backbone genes with the species added according to their taxonomy and the dash lines indicate distinct taxonomic sections. A phylogenetic species tree is shown at the bottom for reference.

We observed that SM backbone genes are diverse and that increased diversity is observed across different *Aspergillus* sections. However, the number of unique genes is lower than estimated in two recent studies focused solely on the sections of *Nigri* (Vesth et al., 2018) or *Flavi* (Kjærboelling et al., 2020) that found around half of the SM BGCs were predicted to be species-specific. Here, we only focused on SM backbone genes and implemented a phylogeny-aware approach to evaluate SM backbone gene diversity across a diverse set of *Aspergillus* species, while these previous studies used complete SM gene cluster diversity

and relied on a limited taxonomic sampling. These previous studies thus overestimate the BGC diversity within *Aspergillus* sections. In contrast, our results are more conservative and underestimate the true biochemical diversity that is provided by the diversity of additional tailoring genes within BGCs that can lead to the production of complex secondary metabolites. However, our approach provides broader and more detailed estimations regarding the type of metabolite and BGCs that remain to be discovered in *Aspergillus* species.

Genome-wide synteny in Aspergilli is higher within than between sections

The tight regulation of BGC expression and the role of chromatin conformation in this regulation suggested that the genomic localization of BGCs might be important (Palmer et al., 2010). Several studies have indicated an over-representation of SM BGCs in sub-telomeric regions (Guzmán-Chávez et al., 2018; Keller, 2019; Kjærboelling et al., 2020; Klejnstrup et al., 2012). Sub-telomeric regions are known to be variable between strains and species, and consequently, these regions display low levels of synteny. The term 'synteny' here refers to the conservation of genomic regions that are maintained in a similar arrangement across different genomes through evolutionary time (Drillon et al., 2013) (Figure 3A). As most of the *Aspergillus* species do not have chromosome-level assemblies, we assessed BGC localization by examining synteny throughout the *Aspergillus* genus. We performed an all-versus-all pairwise comparison of all species, and we uncovered, in general, that the amount of shared synteny between species (synteny percentage) correlates with the divergence and is consistent with the phylogenetic relationship between species (Figure 3B); *i.e.*, two *Aspergillus* sections that are more syntenic indeed diverged more recently. Based on this observation, we propose that the *Nigri* section could be split in two, which is also coherent with the phylogeny. Similarly, the *Circumdati*, *Flavi*, *Nigri*, and *Nidulantes* sections show distinct groups of higher synteny that might indicate ongoing divergence within these sections. Section *Nidulantes* exhibits lower synteny, which seems coherent with the branch lengths in this clade compared to other clades where the divergence between species appears more recent in the *Nidulantes* section. Finally, early-diverging sections (*i.e.*, *Polypaecilum*, *Cremeri*, *Restricti*, *Aspergillus*, *Cervini*, *Clavati*, and *Fumigati*) show high synteny within sections compared with other sections (Figure 3C). Overall, the synteny between sections is low, ranging from only 34% to 54%, with a median of 46%.

Figure 3 Within-section synteny in *Aspergillus* is higher than between-section synteny. (A) A graphical representation of a hypothetical syntenic region between two species is demarcated by a dashed box. Arrows of the same color, linked by a line, represent homologous genes from two different species, with the arrow direction indicating the gene's orientation. (B) The heatmap shows pairwise synteny expressed as the synteny percentage based on all-versus-all comparisons of all species, arranged based on the phylogenetic tree (Figure 1). The species tree, displayed to the left and top of the heatmap, uses colors to differentiate between sections (see legend for Figure 1A for the color coding). (C) Boxplots show the quantification of synteny by the 'synteny percentage' between sections, within sections, and in each section of the *Aspergillus* genus. Numbers in the parentheses indicate the number of species in the sections, and only sections with more than one species are shown. (D) Genome alignment between two species from the same section (top) and different sections (middle and bottom) highlights the degradation of synteny when taxonomic distance increases.

In Ascomycota, synteny, or the conservation of gene order, varies across distantly related species (Hane et al., 2011). This phenomenon is categorized into micro-synteny, meso-synteny, and macro-synteny (Hane et al., 2011). Micro-synteny refers to the conservation of a small number of successive genes, typically ranging from two to ten. Meso-synteny represents larger, yet fragmented, synteny blocks compared to micro-synteny but shorter than

20 thousand base pairs (kbp). Macro-synteny, on the other hand, is characterized by large and continuous blocks extending over 20 kbp (Hane et al., 2011). Our findings align with expectations, revealing longer synteny blocks within sections than between them (Figure S2). For instance, species in the *Fumigati* section show extensive regions of shared synteny across chromosomes (Figure 3D). In contrast, species from different sections exhibit markedly reduced synteny, both in percentage and block length (Figures 3D and S2). A pattern of 'degraded macrosynteny' was previously identified in several filamentous Ascomycota fungi, including some Aspergilli (Hane et al., 2011). Our data suggest that within *Aspergillus* sections, synteny blocks with an approximate length of 150 kbp are indicative of macrosynteny. In contrast, between different sections, synteny blocks averaging 70 kbp to 150 kbp represent degraded macrosynteny, likely reflecting the divergence time among these sections.

SM backbone genes tend to reside in low-synteny and sub-telomeric regions

To investigate the genomic localizations of SM genes in Aspergilli, we analyzed four species with chromosomal-level assemblies: *A. nidulans*, *A. fumigatus*, *A. niger*, and *A. oryzae* (Figures 4 and S3-S5). In each of the four species, the gene density shows that predicted genes are evenly distributed throughout the genome, except for putative centromere and telomere regions, which are known to contain fewer genes but harbor repetitive sequences and exhibit unique structural and functional characteristics distinct from the rest of the genome (Xu et al., 2022). BUSCO genes, which are conserved across the fungal kingdom and crucial for organismal function, are significantly enriched in regions with high synteny, both within individual sections (91% of BUSCO genes) and across the *Aspergillus* genus (83%) compared with all genes (59% and 42%, respectively) (Figure 5B and 5C). In contrast, SM backbone genes are significantly enriched in low-synteny regions in all four species at the *Aspergillus* genus level (81% of backbone genes) (Figures 5B and 5C, Table S6). For the section-level synteny scores, though only 24% of SM backbone genes are found in low-synteny regions, the trend remains significant compared with all genes (14%) and clearly differs from BUSCO genes (2%) (Figures 5B and 5C, Tables S6). When examining the synteny scores at the section level, we observed that while a subset of SM backbone genes is in regions with relatively high-synteny scores, the general pattern of these scores is notably distinct from that of regions with BUSCO genes. This contrast is evident when comparing the chromosomal distribution of synteny scores for SM backbone genes against those for BUSCO genes (Figures 5B and 5C; Table S6). Only 21% of all genes are located in sub-telomeric regions, and BUSCO genes are significantly located outside of these regions (7% in sub-telomeric regions) (Figures 5D and 5E). In contrast, SM backbone genes show a trend to be located in the sub-telomeric regions (36%) (Figures 5D and 5E), aligning with previous reports in *A. nidulans* (Klejnstrup et al., 2012), *A. fumigatus* (Keller, 2019; Perrin et al., 2007), *A. oryzae* (Kjærboelling et al., 2020), as well as other fungal species such as *F. fujikuroi* (Studt et al., 2017) and *Penicillium chrysogenum* (Guzmán-Chávez et al., 2018). However, the enrichment of SM backbone genes in sub-telomeric regions is less significant than in low-synteny regions,

suggesting that association with low-synteny regions is an attribute of SM BGCs. The localization of SM backbone genes in low-synteny and sub-telomeric regions of *Aspergillus* genomes may facilitate rapid genetic rearrangement of these BGCs, thereby enabling rapid adaptation to diverse ecological niches. Noteworthy, SM backbone genes with known metabolite structures, as listed in the MIBiG database (Table S5), tend to occur more frequently in sub-telomeric areas. For instance, four out of six SM backbone genes in *A. nidulans* (Figure 4), 18 out of 27 in *A. fumigatus* (Figure S3), and seven out of eleven in *A. niger* (Figure S4) are found in sub-telomeric regions. *A. oryzae* presents a unique case, with only two out of 18 SM backbone genes with known structures located in sub-telomeric regions (Figure S5). The observation that most characterized BGCs are localized in sub-telomeric regions suggests that they are more frequently expressed than those in other regions.

Figure 4 SM backbone genes occur preferentially in low-synteny and sub-telomeric regions.

This figure illustrates the genomic localization of BUSCO genes and SM backbone genes in *A. nidulans*. Lines in black and green represent synteny density across 177 species and within the *Nidulantes* section, respectively. The gene density is shown along the chromosomes. Red bars indicate the chromosomal locations of BUSCO genes, with bar width proportional to gene length. Black and blue bars mark the positions of shared and unique SM backbone genes, respectively, with their widths corresponding to gene length. Numbers adjacent to the black bars denote SM backbone genes associated with known metabolites as listed on the MIBiG website (Table S5).

Figure 5 Analysis of SM backbone gene localization in low-synteny and sub-telomeric regions in four *Aspergillus* species. (A) Summary table of the different groups of genes considered in four *Aspergillus* species. (B) Distribution of different groups of genes in relation to synteny score analyzed across 177 species and within individual sections. (C) Summary table of the number of SM backbone genes, BUSCO genes, and all genes with high-synteny score (larger than 80%) and low-synteny score (lower than 20%) at the genus-level and section-level. Chi-square statistic tests (Virtanen et al., 2020) were performed on SM backbone genes and BUSCO genes, determining whether their distributions differ significantly from the distribution of all genes in terms of genus-level synteny and section-level synteny. (D) Distribution of different groups of genes relative to chromosomal localization, considering the terminal 10% of chromosomal regions as sub-telomeric. (E) Summary table of the number of SM backbone genes, BUSCO genes, and all genes within and outside of sub-telomeric regions. Chi-square statistic tests (Virtanen et al., 2020) were performed on SM backbone genes and BUSCO genes, determining whether their distributions differ significantly from the distribution of all genes in terms of sub-telomeric localization.

Exploring the impact of genomic localization and histone PTMs on SM gene expression variability in *Aspergilli*

It has been proposed that genomic localization of SM BGCs is important for the regulation of their expression through histone modifications as several histone PTMs were shown to influence the production of SM in *Aspergilli* (Cánovas et al., 2014; Lee et al., 2009; Li et al., 2019). Thus, we sought to explore the relationship between gene expression, histone PTMs, and genomic and syntenic conditions of SM backbone genes compared with BUSCO genes. To this end, we utilized publicly available RNA-seq from *A. nidulans*, *A. fumigatus*, *A. niger*, and *A. oryzae* and ChIP-seq data from the former two *Aspergilli* (Tables S7 and S8). We used the coefficient of variance (CV) to assess the relative variability of gene expression and histone modification of different gene groups across diverse experimental conditions. For BUSCO genes, we observed stable gene expression in all species (Figures 6, S6, and S7), which is accompanied by low variation in all histone PTMs included in this study (H3K4me3, H3K9me3, H3K36me3, and H3Kac). Compared to BUSCO and all genes, SM backbone genes exhibit greater variability in gene expression (Figures 6, S6, and S7). For histone PTMs, H3K36me3 in *A. nidulans* and H3K4me3 in both *A. nidulans* and *A. fumigatus* show higher variability at SM backbone genes in regions compared with other gene groups (Figures 6 and S8), suggesting a role for these histone modifications in regulating the expression of SM genes. The correlation between the CVs of these marks' reads and RNA-seq reads further supports this (Figure 6). Especially, SM backbone genes with known structure and variable expression in *A. fumigatus* also exhibit high CVs in H3K4me3, with four of them ranking among the top five most variable SM genes (Table S5). However, the observed gene expression variation of SM genes is not explained by H3K9me3 (in *A. nidulans* and *A. fumigatus*) nor H3ac (in *A. nidulans*) as SM genes do not differ from BUSCO genes for these PTMs (Figures 6 and S8).

When taking the chromosome localization into account, SM backbone genes within the sub-telomeric regions show slightly higher variation in gene expression in *A. nidulans*, *A. fumigatus*, and *A. niger*, but not in *A. oryzae* (Figures 6 and S6). The difference in *A. oryzae* could be due to the fact that it was domesticated for industrial purposes such as producing sake, soy sauce, and miso, and it is generally recognized for its simplified metabolic profile (Gibbons et al., 2012). However, the sub-telomeric localization does not fully explain a higher variation in both gene expression and histone PTMs because the distribution of these variations for SM backbone genes outside sub-telomeric regions is bimodal and overlap with sub-telomeric backbone genes (Figures 6, S6, and S7). Lastly, SM backbone genes with the known metabolite structures listed on the MIBiG website show various expression patterns (Table S5). In *A. fumigatus*, known SM genes show high variability as their average CV (1.20) is higher than the average CV for both all SM backbone genes (1.09) and SM backbone genes outside sub-telomeric regions (0.94) (Table S5). Two SM backbone genes responsible for sartorypyrone A are in the top five most variably expressed SM backbone genes. By contrast, in other *Aspergilli*, either no (in *A. nidulans* and *A. niger*) or only one (in *A. oryzae*) SM

backbone gene with known structure is in the top five most variable SM backbone genes (Table S5). Based on our results, SM backbone genes that are still uncharacterized but exhibit higher variation in expression deserve further attention as they are likely to produce SMs under laboratory conditions.

Figure 6 SM backbone genes in sub-telomeric regions tend to show more gene expression, H3K4me3, and H3K36me3 variation compared with BUSCO genes. We employed the coefficient of variance (CV) to assess the relative variability of all genes, BUSCO genes, and SM backbone genes in *A. nidulans*. The variability is depicted using distinct colors for dots and density lines to differentiate between the gene groups.

Conclusions

Altogether, our results highlighted that SM backbone genes are quite abundant and diverse in the fungal genus *Aspergillus*, especially between different sections. Moreover, we showed that BGCs exhibit a strong bias for low-synteny regions, and the association between BGC localization, variation in expression, and histone PTMs is restricted to H3K4me3 and H3K36me3 only. It is important to note that our study is limited to the few histone PTMs that are publicly available and other PTMs might play a more important role and need to be investigated. In particular, H3K79me is a relevant candidate as this modification was reported to localize at transition regions between heterochromatin and euchromatin, and we recently reported differences in abundances between different *Aspergilli* (X. Zhang et al., 2023).

Materials and methods

Acquisition of genomes and predicted proteomes for 177 fungal species

The genomes and predicted proteomes of 177 fungal species were retrieved from the Joint Genome Institute MycoCosm (<https://mycocosm.jgi.doe.gov/mycocosm/home>) repository (Grigoriev et al., 2014) in January 2022. These species comprise 174 *Aspergilli* as well as

three *Penicillium* species (*Penicillium brevicompactum*, *Penicillium griseofulvum*, and *Penicillium chrysogenum*) that were used as an outgroup in our analyses (Table S1).

Species tree reconstruction

To reconstruct the phylogenetic relationship between the here analyzed *Aspergillus* species, we used BUSCO (Benchmarking Universal Single-Copy Ortholog assessment tool) v4.0.1 (Simão et al., 2015) to retrieve 758 fungal single-copy genes (Table S2) that are present in the 177 genomes. For homologs of each single-copy BUSCO gene, we first generated multi-sequence alignment using MAFFT v7.271 (Katoch & Standley, 2013), then removed positions in the alignments with gaps in more than 90% of the sequences using ‘-gt 0.1’ in TrimAl v1.2 (Capella-Gutiérrez et al., 2009). We concatenated the 758 alignments into one ‘super-alignment’ and employed IQ-TREE v1.6.10 (Chernomor et al., 2016; Nguyen et al., 2015) to construct the maximum-likelihood phylogeny with partitioned model selection to allow selecting a substitution model (Table S2) for each BUSCO gene alignment, and used both ultrafast bootstrap and SH-aLRT (Shimodaira–Hasegawa approximate Likelihood Ratio Test) with 1,000 pseudo-replicates to calculate branch supports.

Identification and conservation analysis of putative SM backbone genes and orthologous groups

We used antiSMASH (antibiotics and Secondary Metabolite Analysis SHell) v6.1.0 (Blin et al., 2021) (parameters: –minimal) to identify all regions with predicted BGCs in the 177 genome assemblies, and refined the classification of SM backbone genes with our in-house tool BGCToolkit (<https://github.com/WesterdijkInstitute/BGCLib>, DOI: 10.5281/zenodo.6593238) (Figure 1 and Table S3). Then, we extracted the protein sequence of the predicted backbone enzymes or of the adenylation domains for NRPS, NRPS-like, and PKS-NRPS hybrid enzymes using BGCToolkit. For each type of backbone enzyme, protein sequences were aligned and trimmed using MAFFT and TrimAl, respectively, as mentioned above. We constructed phylogenetic trees using FastTree v2.1.11 with default parameters (Price et al., 2009). We subsequently used Newick Utilities v1.6.0 (Junier & Zdobnov, 2010) to identify orthologs *via* three steps: i) re-root the tree based on the mid-point (nw_reroot); ii) manually select the clades having more than 88 leaves and with trustworthy bootstrap value (≥ 0.99) and mark them as orthologs; iii) for the remaining leaves, automatically split the clades with fewer than 88 leaves and with trustworthy bootstrap value (≥ 0.99) (nw_ed -n -r). In the construction of the three adenylation domain trees, an extra step was undertaken to consolidate multiple domains originating from the same gene. This involved examining all leaves in the domain tree to identify the genes associated with these domains. Clades were collapsed and assigned a new clade name when the domains were found to originate from the same gene. For any remaining domains, the original clade names were retained. We built a saturation curve with the matplotlib.pyplot visualization library (Hunter, 2007) and used the function from the SciPy library (Virtanen et al., 2020) to implement a curve-fitting process,

which determines the rate of growth (β) of unique gene numbers under Heap's Law (Heaps, 1978).

We used Orthofinder v2.3.8 (Emms & Kelly, 2019) to identify orthologous groups across 177 predicted proteomes using default settings (Table S4). A saturation curve based on these orthologous groups was built as described above.

Genome synteny analysis

We employed MCSanX (Multiple Collinearity Scan Toolkit X version) (Wang et al., 2012) to conduct an all-versus-all pairwise comparison among all species to identify syntenic blocks (match size: -s 3 and max gaps: -m 15). We defined the 'synteny percentage' between a pair of species as the ratio of syntenic genes detected between two compared species to the total genes. We defined the 'between sections' synteny percentage by considering all pairs of species that are associated with different taxonomic sections, and the 'within sections' synteny percentage by considering all pairs from the same taxonomic section. For the synteny percentage of each taxonomic section, we considered all comparisons for species within that specific section. For visual representation of genome alignment between two species, we used the R package GENESPACE v1.2.3 (Lovell et al., 2022).

To calculate the average length of syntenic regions, we took all syntenic blocks identified by the MCSanX in all-versus-all pairwise comparisons and excluded the contigs with less than 50 genes. Subsequently, we employed the hypergeometric distribution (Rice, 2003) utilizing the 'hypergeom.cdf(x, M, n, N)' function from the SciPy library (Virtanen et al., 2020) to evaluate the likelihood of successfully detecting a syntenic region between two given species. In this function, 'M' denotes the total number of homologous gene pairs identified when comparing the complete genomes of species A and B, 'n' represents the count of genes on scaffold B1 with homologs in species B, and 'N' is the number of genes on scaffold A1 with homologs in species A. This cumulative distribution function aggregates the probabilities of identifying up to 'x' successful syntenic matches, thereby yielding the cumulative probability of detecting 'x' or fewer successes. The analysis considered (1) the total number of homologs between the two species, (2) the number of homologs on each contig relative to the other species, and (3) the number of homologs between the contigs themselves. Setting a p-value threshold at $1e-5$, we then computed the average length of syntenic blocks for each pair of species.

We defined the synteny score at the genus level as the synteny score for a specific gene by dividing the number of species containing that gene by the total number of species (177 species). At the section level, the synteny score for a gene is determined by the ratio of the number of species within the section harboring that gene to the total species count in that section. We used the function 'chi2_contingency' from the SciPy library (Virtanen et al., 2020)

to perform chi-square statistic tests on SM backbone genes and BUSCO genes, determining whether their distributions differ significantly from the distribution of all genes in terms of genus-level synteny, section-level synteny, and sub-telomeric localization (Table S6).

RNA-seq sample preparation

To perform RNA sequencing, we obtained the fine powder of young mycelium of *A. fumigatus* (strain: Af293, CBS 126847), *A. nidulans* (strain: Wtpaba (genotype: pabaA1)), and *A. niger* (strain: NRRL3, CBS 120.49) as described previously (X. Zhang et al., 2023). Subsequently, we extracted high-quality total RNA from each species in four replicates, following our in-house RNA extraction protocol. Briefly, we placed around 100 mg of fine powder in a 1.5 mL tube, added 1 mL TRIzol reagent (Fisher, 15596026), and incubated for 5 mins at 25°C. Following that, we added 0.2 mL chloroform-d (Sigma, 416754), mixed gently by hand 15 times, and incubated for 5 mins at room temperature. After centrifuging the samples at 10,000 RPM for 15 mins, we transferred the aqueous supernatant to a new tube. We then added 0.5 volume of 100% ethanol (BOOM, 200-578-6) and proceeded from the 5th step of the NucleoSpin RNA Kit protocol (Bioke, 740955). Finally, we eliminated DNA contamination using DNase I (Sigma, AMPD1) and sent samples to the Beijing Genome Institute (BGI, Hong Kong, China) for library construction and DNBseq (DNA NanoBall sequencing).

Acquisition and analysis of public RNA-seq and ChIP-seq datasets

To retrieve publicly available RNA-seq data (Table S7) from *A. niger*, *A. fumigatus*, *A. nidulans*, and *A. oryzae*, we utilized prefetch v2.10.0 and fasterq-dump v2.10.0 from SRA Toolkit (<https://github.com/ncbi/sra-tools>) to extract FASTQ files from the SRA database (<https://www.ncbi.nlm.nih.gov/sra>). For all reads from both our BGI sequencing projects and the public database, we used the pseudoalignment tool kallisto v0.46.0 (Bray et al., 2016) to build the index and quantify raw read counts per gene. To remove the potential batch effect, we used ComBat-seq (Y. Zhang et al., 2020) in R v3.6.1 (Team, 2010) and obtained batch-effect corrected read counts. Following this, we calculated the TPM (Transcripts Per Million) and used log-transformed TPMs to calculate the coefficient of variation (CV) to assess the variability of gene expression levels across different samples. We used seaborn (Waskom, 2021) and Matplotlib (Hunter, 2007) to plot the scatter plot and density plots.

We utilized ChIP-seq data from two studies (Colabardini et al., 2022; Gacek-Matthews et al., 2016), which included *A. nidulans* (H3ac, H3K4me3, H3K9me3, and H3K36me3) and *A. fumigatus* (H3K4me3 and H3K9me3) (Table S8). The analyses (downloading and processing) of this data were the same as the RNA-seq analysis mentioned above, yet we did not perform the batch effect removal step because the two studies were conducted in different species.

Supplementary materials

Supplementary Figure 1 The phylogeny-aware method to detect SM backbone gene diversity. We used FastTree (Price et al., 2009) to construct the phylogeny of each type of SM backbone genes and annotated the trees with iTOL. The inner colored ring indicates *Aspergillus* sections and the outer colored ring shows the splitting results by Newick Utilities (Junier & Zdobnov, 2010). (A) Manual selection is implemented first to pick up the clades larger than 88 leaves (red “*” in the tree). For remaining leaves and trees that don’t need manual trimming (B), automatic splitting was performed with a trustworthy bootstrap value of ≥ 0.99 .

Supplementary Figure 2 Longer syntenic blocks are shared within *Aspergillus* sections. The heatmap displays the all-versus-all pairwise comparisons based on the average length of syntenic blocks across all species; species were arranged according to the phylogenetic tree. The accompanying species tree, displayed to the left and top, uses colors to differentiate between sections.

Supplementary Figure 3 SM backbone genes occur preferentially in low-synteny regions.

This figure illustrates the genomic localization of BUSCO genes and SM backbone genes in *A. fumigatus*. Lines in black and green represent synteny density across 177 species and within the *Fumigati* section, respectively. The gene density is shown along the chromosomes. Red bars indicate the chromosomal locations of BUSCO genes, with bar width proportional to gene length. Black and blue bars mark the positions of shared and unique SM backbone genes, respectively, with their widths corresponding to gene length. Numbers adjacent to the black bars denote SM backbone genes associated with known metabolites as listed on the MIBiG website (Table S5).

Supplementary Figure 4 SM backbone genes occur preferentially in low-synteny regions.

This figure illustrates the genomic localization of BUSCO genes and SM backbone genes in *A. niger*. Lines in black and green represent synteny density across 177 species and within the *Nigri* section, respectively. The gene density is shown along the chromosomes. Red bars indicate the chromosomal locations of BUSCO genes, with bar width proportional to gene length. Black and blue bars mark the positions of shared and unique SM backbone genes, respectively, with their widths corresponding to gene length. Numbers adjacent to the black bars denote SM backbone genes associated with known metabolites as listed on the MIBiG website (Table S5).

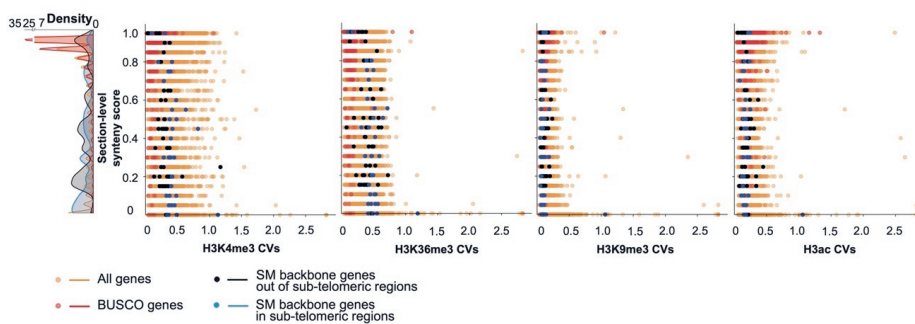

Supplementary Figure 5 SM backbone genes occur preferentially in low-synteny regions.

This figure illustrates the genomic localization of BUSCO genes and SM backbone genes in *A. oryzae*. Lines in black and green represent synteny density across 177 species and within the *Flavi* section, respectively. The gene density is shown along the chromosomes. Red bars indicate the chromosomal locations of BUSCO genes, with bar width proportional to gene length. Black and blue bars mark the positions of shared and unique SM backbone genes, respectively, with their widths corresponding to gene length. Numbers adjacent to the black bars denote SM backbone genes associated with known metabolites as listed on the MIBiG website (Table S5).

Supplementary Figure 6 SM backbone genes show more variance in gene expression compared to BUSCO and all genes in four Aspergilli. We employed the coefficient of variance (CV) to assess the relative variability of all genes, BUSCO genes, and SM backbone genes within (A) *A. fumigatus*, (B) *A. niger*, (C) *A. oryzae*, and (D) *A. nidulans*. The variability is depicted using distinct colors for dots and density lines to differentiate between the gene groups. RNA-seq data was downloaded from SRA (Table S7) and ChIP-seq data is from the publication (Gacek-Matthews et al., 2016).

Supplementary Figure 7 Gene distribution of section-level synteny score in *A. nidulans*. We employed the coefficient of variance (CV) to assess the relative variability of all genes, BUSCO genes, and SM backbone genes in *A. nidulans*. The variability is depicted using distinct colors for dots and density lines to differentiate between the gene groups. ChIP-seq data is from the publication (Gacek-Matthews et al., 2016).

Supplementary Figure 8 SM backbone genes in sub-telomeric regions show more variance in H3K4me3 in *A. fumigatus*. We employed the coefficient of variance (CV) of H3K4me3 and H3K9me3 to assess the relative variability of all genes, BUSCO genes, and SM backbone genes. Data is from publication (Colabardini et al., 2022). The variability is depicted using distinct colors for dots and density lines to differentiate between the gene groups.

Supplementary Table 1 Summary of 177 *Aspergillus* and *Penicillium* species included in this study

No.	Species	JGI abbreviation	Section	Assembled length	Scaffolds	Genome completeness	Genes
1	<i>Aspergillus aculeatus</i>	Aspac1	<i>Nigri</i>	35424414	660	99.2	10845

Abstract

Chemical modifications of DNA and histone proteins impact the organization of chromatin within the nucleus. Changes in these modifications, catalyzed by different chromatin-modifying enzymes, influence chromatin organization, which in turn is thought to impact the spatial and temporal regulation of gene expression. While combinations of different histone modifications, the histone code, have been studied in several model species, we know very little about histone modifications in the fungal genus *Aspergillus*, whose members are generally well-studied due to their importance as models in cell and molecular biology as well as their medical and biotechnological relevance. Here, we used phylogenetic analyses in 94 *Aspergilli* as well as other fungi to uncover the occurrence and evolutionary trajectories of enzymes and protein complexes with roles in chromatin modifications or regulation. We found that these enzymes and complexes are highly conserved in *Aspergilli*, pointing towards a complex repertoire of chromatin modifications. Nevertheless, we also observed few recent gene duplications or losses, highlighting *Aspergillus* species to further study the roles of specific chromatin modifications. SET7 (KMT6) and other components of PRC2 (Polycomb Repressive Complex 2), which is responsible for methylation on histone H3 at lysine 27 in many eukaryotes including fungi, are absent in *Aspergilli* as well as in closely related *Penicillium* species, suggesting that these lost the capacity for this histone modification. We corroborated our computational predictions by performing untargeted mass spectrometry analysis of histone post-translational modifications in *Aspergillus nidulans*. This systematic analysis will pave the way for future research into the complexity of the histone code and its functional implications on genome architecture and gene regulation in fungi.

Introduction

Inside eukaryotic cells, the membrane-bound nucleus facilitates the storage and replication of the genetic material as well as the regulation of gene expression (Labrador & Corces, 2002). Within the nucleus, DNA is arranged as a chromatin fiber formed by repeated nucleosome units consisting of histone protein octamers (two copies of each H2A, H2B, H3, and H4 histones) that are wrapped by 145-147 bp of DNA (Luger, 2003; Luger et al., 1997). The chromatin structure is regulated by chemical modifications such as methylation of DNA on cytosines (5mC) and adenines (6mA), and different post-translational modifications (PTMs) on the histone proteins, including methylation and acetylation (Jenuwein & Allis, 2001; Peterson & Laniel, 2004). The combination of these different modifications, the histone code, influences the recruitment of diverse nucleosome-associated proteins (e.g., DNA binding proteins), which can cause dynamic transitions between the condensed and transcriptionally silent heterochromatin and the accessible and transcriptionally active euchromatin (Berger, 2007; Grewal & Jia, 2007; Santos-Rosa et al., 2002). Chromatin dynamics is therefore key for organisms to adapt gene expression patterns in response to a variety of developmental and environmental clues.

In the past decades, several enzymes involved in orchestrating chromatin dynamics have been identified and functionally characterized in diverse eukaryotes (Berger, 2007; Jenuwein & Allis, 2001; B. Xiao et al., 2003). These enzymes can be broadly classified into three distinct types: (i) writers that place modifications on nucleosomes or linker DNA; (ii) erasers that remove these modifications; and (iii) readers that first recognize specific modifications and subsequently recruit writers, erasers, or other proteins to the correct genomic location (Collemare & Seidl, 2019). Chromatin modifiers that catalyze the same type of chemical modification often harbor functionally and evolutionarily conserved catalytic domains. For instance, DNA methylation (5mC) is catalyzed by different DNA methyltransferases (DNMTs) which contain a DNA methyltransferase domain, while histone mono-, di-, and tri-methylation are nearly exclusively catalyzed by proteins containing a SET (Su (var) 3-9, E(z) and Trithorax) domain (B. Xiao et al., 2003). Next to these catalytic domains, the enzymes often contain accessory domains, which can contribute to the overall stability of the enzyme or establish interactions with other proteins (Helmlinger et al., 2021). Furthermore, these multi-domain proteins, together with other accessory protein subunits, can form multi-protein complexes to find the correct target region within the genome and modify the exact amino acid residue, collectively contributing to the specific functions of these complexes (Gates et al., 2018; Hajheidari et al., 2019). For example, the histone methyltransferase complex PRC2 (Polycomb Repressive Complex 2) is responsible for the mono-, di-, and tri-methylation of histone protein H3 on the lysine at position 27 (abbreviated as H3K27me1/2/3; the same abbreviation principle will be applied below for other histone PTMs) (Freitag, 2017; Jamieson et al., 2013, 2016; Kamei et al., 2021). Evolutionary analyses have suggested that the key enzymes responsible for chromatin modifications have evolved and significantly expanded

early in eukaryotic evolution (Weiner et al., 2020). An analysis of 94 gene families with roles in chromatin modifications reveals that 87 out of 94 gene families emerged more than one billion years ago, and 48 were already present in the last eukaryotic common ancestor (Weiner et al., 2020).

Among eukaryotes, the fungal kingdom is remarkably large and diverse, comprising an estimated 1.5-5 million species with various morphologies, life cycles, and ecological niches (Choi & Kim, 2017). The most well-studied model fungal species in respect of chromatin modifications is the unicellular yeast *Saccharomyces cerevisiae*, in which 75 histone PTMs on 43 distinct amino acid positions have been reported with histone methylation and acetylation being most abundant (Collemare & Seidl, 2019). In addition to ancient chromatin modifiers, also lineage-specific innovations such as duplications and losses were found in fungi. For example, Dim-2 and RID (Repeat-Induced Point Mutation (RIP)-Defective) are considered to be fungal-specific DNMTs, while DNMT3 that is typically found in animals and plants seems to be absent in fungi (Bewick et al., 2019; Kouzminova & Selker, 2001; Nai et al., 2021). However, *S. cerevisiae* is not representative of the complete fungal kingdom, and detailed studies on PTMs are needed for other, less studied fungal species.

The fungal genus *Aspergillus* comprises approximately 350 species, including pathogens of humans, animals, and crops, food contaminants, as well as important cell factories for industrial and medical applications (Samson et al., 2014). Chromatin dynamics influences gene expression in several *Aspergilli* and regulates growth, sexual development, secondary metabolite biosynthesis, and virulence (Cánovas et al., 2014; Collemare & Seidl, 2019; Palmer et al., 2008; Yang et al., 2016). Thus far, very few well-known chromatin modifications and their catalytic protein complexes have been identified and studied in few *Aspergillus* species (Collemare & Seidl, 2019). For example, gene knockout of the H3K9 methyltransferase *Clr4* homolog in *Aspergillus fumigatus* reduced histone H3K9me1/3 results in reduction of radial growth and conidia production, as well as delayed conidiation (Palmer et al., 2008). Similarly, *CclA*, a subunit of the COMPASS (COMplex of Proteins ASSociated with SET1) complex, is essential for H3K4me2/3 in *A. fumigatus*, and the deletion strain showed increased secondary metabolite production and decreased growth (Palmer et al., 2013). The SAGA (Spt-Ada-Gcn5 Acetyltransferase) complex, which is responsible for histone acetylation, has been functionally characterized in *Aspergillus nidulans* (Georgakopoulos et al., 2013). Notably, this complex in *A. nidulans* lacks the Sgf11 and Sus1 subunits that have been described in *S. cerevisiae*, suggesting that this complex evolves in distinct trajectories in different fungi (Georgakopoulos et al., 2013). Besides these few examples, we so far lack a complete view of the occurrence and evolution of chromatin modifiers in the *Aspergillus* genus. Here, we report the phylogenetic analyses of core enzymes involved in the deposition and removal of histone PTMs, and assess the conservation of all the subunits belonging to chromatin regulator complexes in 94 diverse *Aspergilli*. We also performed proteomics analyses to

corroborate our computational predictions and reveal a broader spectrum of histone modifications.

Results and discussion

DNA methylation, histone methylation, and histone acetylation are among the most studied chromatin modifications in animals, plants, and fungi (Binda, 2013; Wade et al., 1997; Wolffe & Matzke, 1999). Protein complexes involved in writing, reading, and erasing these modifications have been reported in few model fungal species to date (Jamieson et al., 2013; Kouzminova & Selker, 2001), but the evolution and conservation of these complexes in diverse fungal species have not been largely systematically explored. Besides some research on DNA methyltransferases (Bewick et al., 2019; Nai et al., 2021) and SET domain-containing proteins (Freitag, 2017) that have been performed throughout the fungal kingdom, we still lack the evolutionary overview of other chromatin modifiers and in depth analyses for important fungal groups. To start uncovering the occurrence and evolutionary histories of chromatin modifiers involved in these major modifications in the fungal genus *Aspergillus*, we first focused on six conserved catalytic domains reported to be involved in histone modifications: DNA methyltransferase domain for DNMTs, SET domain for histone methyltransferases (HMTs), acetyltransferase domain and MOZ/SAS FAMILY domain for histone acetyltransferases (HATs), histone deacetylase domain for histone deacetylases (HDACs), and JmjC domain for histone demethylases (HDMTs). We identified homologs harboring these conserved domains in 109 predicted proteomes; the completeness of the predicted proteomes was generally high as 97 had more than 97% complete BUSCO predicted proteins (Table S1). The 94 *Aspergilli* species cover 18 recognized sections: *Polypaecilum*, *Cremeri*, *Restricti*, *Aspergillus*, *Cervini*, *Clavati*, *Fumigati*, *Candidi*, *Circumdati*, *Janorum*, *Terrei*, *Flavi*, *Ochraceorosei*, *Bispori*, *Cavernicularum*, *Usti*, *Nidulantes*, and *Nigri* (Chen et al., 2016; James et al., 2020; Kjærboelling et al., 2020; Souza et al., 2019; Steenwyk et al., 2019; Sun et al., 2020; Vesth et al., 2018), and 15 other species were used as outgroups (Figure S1). Two of the outgroup species are Basidiomycota and the remaining species cover each class in the Ascomycota phylum, which provides a robust framework for our evolutionary analyses within *Aspergilli*. The outgroup species include well-studied model species, some of which are important for crop production, food fermentation, and antibiotics production (Grunstein & Gasser, 2013; Nielsen et al., 2017). We used the identified homologs for each catalytic domain to determine their evolutionary history using maximum-likelihood phylogenies (Figures 1-4, S2, and S3).

Figure 1. Conservation of DNA methyltransferase families in the *Aspergillus* genus and outgroup species. The maximum-likelihood phylogeny of DNA methyltransferase domain (PF00145) found in 94 *Aspergilli* and 15 outgroup species was determined using IQ-TREE (Boratyn et al., 2013; Simão et al., 2015). The black dot on the branch indicates ultrafast bootstrap values over 95 and SH-aLRT values over 80. Leaves from *Aspergilli* with trustworthy support are collapsed and shown as red triangles. The numbers of hits and species are separated by the pipe in the '#Homologs | #Species' column. The number in parentheses after * indicates the additional hits found by the TBLASTN search on NCBI. Additional conserved domains in DNA methyltransferase domain-containing proteins were identified using the PFAM database (<https://pfam.xfam.org>).

Aspergilli harbor conserved DNA methyltransferases for genome defense and methylation maintenance

The conserved DNA methyltransferase domain is the only domain known to catalyze the addition of methyl groups to DNA specifically at cytosines (5mC) (Bewick et al., 2019). Based on previous domain architecture analyses, phylogeny reconstructions, and functional experiments, five distinct protein families containing a DNA methyltransferase domain have been recognized in fungi: DNMT1, DNMT2, and DNMT5 are commonly found in eukaryotes, while Dim-2 and RID are considered to be fungal specific (Bewick et al., 2019). Among these five families, DNMT2 seems to function as a tRNA methyltransferase rather than DNA methyltransferase (Ko et al., 2021). In line with previous observation (Bewick et al., 2019; Jurkowski & Jeltsch, 2011), DNMT2 only occurs in our study in two Basidiomycota and one Ascomycota (*Schizosaccharomyces pombe*), suggesting it has been lost in most Ascomycota.

Three (DNMT1, DNMT5, and Dim-2) of the four remaining families catalyze the maintenance of DNA methylation pattern from parental DNA strand onto synthesized daughter DNA strands, while Dim-2 is also able to catalyze *de novo* methylation (Bestor, 1988; Okano et al., 1998). Based on our species selection and phylogenetic analyses, we here found *DNMT1* and *Dim-2* to be absent in all Aspergilli and only present in four or seven out of 15 outgroup species, respectively, while *DNMT5* is found in most Aspergilli and outgroup species (Figure 1). Only four outgroup species harboring *DNMT1*, the two Basidiomycota species, *Botrytis cinerea*, and *Plectania melastoma*, which corroborates previous findings (Bewick et al., 2019; Z. Zhang et al., 2021). *Dim-2* was identified only in seven Ascomycota outgroup species, and matches in *B. cinerea* and *Zyoseptoria tritici* were included after an additional TBLASTN search in NCBI (Table S6). The original *Dim-2* absence in *B. cinerea* by local Hmsearch is caused by the older version and fragmented assembly at JGI compared to NCBI. The *Z. tritici* IPO323 strain used in this study carries a non-functional *Dim-2* as previously reported (Moller et al., 2021) and no significant hit was found with Hmsearch or BLASTP searches, but several fragmented hits with TBLASTN search in NCBI. This loss of *Dim-2* function in *Z. tritici* IPO323 is very recent because other isolates harbor a functional *Dim-2* gene (Moller et al., 2021). Its loss leads to the deactivation of transposable elements (TEs) and decreased mutation rate, thus influencing genome defense and genome evolution (Moller et al., 2021). Integration of a functional *Dim-2* allele in Zt09 restores DNA methylation (Moller et al., 2021). In contrast to the *DNMT1* and *Dim-2* losses in Aspergilli, *DNMT5* is identified in 88 out of 94 Aspergilli and 10 out of 15 outgroup species (Figure 1), with a conserved domain architecture consisting of a DNA methyltransferase domain, an SNF2 family domain (PF00176), and a Helicase conserved C-terminal domain (PF00271), in which the latter two domains are involved in transcription regulation (Delmas et al., 1993). The five outgroup species without DNMT5 are *S. cerevisiae*, *S. pombe*, *Neurospora crassa*, *Fusarium graminearum*, and *Cladonia grayi*, among which the two yeast species also lack the other two DNA methylation maintaining enzymes, and thus accordingly are considered to be incapable of DNA methylation (Capuano

et al., 2014; Huff & Zilberman, 2014; Proffitt et al., 1984). Five out of the six *Aspergillus* species that lost *DNMT5* belong to a single clade within the *Nidulantes* section (*Aspergillus undulatus*, *Aspergillus olivicola*, *Aspergillus filifera*, *Aspergillus venezuelensis*, and *Aspergillus stellamaris*), and the sixth one is *Aspergillus robustus* which is assigned to the *Circumdati* section (Figure S1). In the Basidiomycota fungus *Cryptococcus neoformans*, *DNMT5* maintains DNA methylation using the same cofactors as *DNMT1* (Catania et al., 2020; Huff & Zilberman, 2014). Thus, it is most likely that *DNMT5* is similarly involved in DNA methylation maintenance in Aspergilli as in *C. neoformans*. Moreover, DNA methylation maintenance does not appear to be required for the survival of fungi as shown with the absence of all three *DNMT1*, *DNMT5*, and *Dim-2* not only within the *Nidulantes* section but also in *S. cerevisiae* and *S. pombe* (Figure 1). However, the absence of these genes could have an impact on the regulation of certain genes like secondary metabolite biosynthetic gene clusters and it would be interesting to compare species within the *Nidulantes* section in more detail to identify how such loss may have affected gene expression and genome organization.

RID is a more recently acquired single domain DNMT that specifically occurs in fungi and is involved in a fungal-specific genome defense mechanism called RIP (Repeat-Induced Point mutation) (Bewick et al., 2019). RID is a putative *de novo* methyltransferase for TEs in both CG and non-CG contexts relating to RIP during the sexual stage in *N. crassa*; however the capacity of RID to catalyze 5mC has not yet been demonstrated (Rountree & Selker, 2010). Here, we identified RID in all analyzed Aspergilli species as well as in ten outgroup species. A RID-like homolog knock-out mutant in the model filamentous Ascomycota *Podospora anserina* shows blocked sexual development, as gametes formation and fertilization can happen but dikaryotic cells cannot develop normally (Grognet et al., 2019). Interestingly, the knock-out mutant of *DmtA* (homolog of *RID* in *Aspergillus flavus*) shows altered conidiation, sclerotial production, aflatoxin biosynthesis, and virulence (Yang et al., 2016), suggesting that RID might have additional functions next to genome defense. Additionally, fungi lost the gene for *de novo* DNA methyltransferase, *DNMT3*, around 50–150 million years ago (Catania et al., 2020; Madhani, 2020), and only *DNMT5* and *RID* were consistently found in Aspergilli (Figure 1). Thus, we hypothesize that Aspergilli can only maintain DNA methylation *via* *DNMT5* but do not spur genome-wide *de novo* DNA methylation. This hypothesis seems to be corroborated as bisulfite sequencing in *A. flavus* has uncovered very little genome-wide DNA methylation (S.-Y. Liu et al., 2012). However, systematic analyses of DNA methylation patterns and experimental evidence for the roles of DNMTs in Aspergilli are still largely missing.

Aspergilli lack *SET7 (KMT6)*, but SET-domain proteins are abundant and other histone methyltransferases are conserved

Histone methylation is typically catalyzed by SET domain-containing proteins (Freitag, 2017; Spellmon et al., 2015). We identified a total of 1,548 SET domain-containing proteins and classified them into 15 groups based on their domain architecture and phylogenetic support

that contain species both from *Aspergillus* as well as from the outgroup. Among these groups, 107, 111, 109, 102, and 108 sequences represent homologs of the known histone methyltransferases (HMTs) SET9 (KMT5), Dim-5 (KMT1), SET1 (KMT2), Ash1 (KMT2H), and SET2 (KMT3), respectively (Figure 2). The remaining homologs were divided into nine groups that we broadly classified as SET domain-containing proteins. Among them, eight groups contain a SET domain but lack experimentally determined functions, and 117 sequences could be grouped as Ribosomal lysine N-methyltransferases (Figure 2). Enzymes in this group contain a SET domain together with a Rubisco LSMT substrate-binding domain (PF09273). While the homolog in plant transfers a methyl group to the large subunit of the Rubisco holoenzyme complex (Raunser et al., 2009; Trievel et al., 2003), the homolog in *S. cerevisiae* has been characterized as a ribosomal lysine N-methyltransferase (Porras-Yakushi et al., 2007).

The well-described HMTs, SET1, Dim-5, SET2, Ash1, and SET9, all contain distinct accessory domains and catalyze methylation on lysine residues at different positions of H3 or H4 tails (Freitag, 2017). SET1 is composed of the SET domain, the N-SET domain (PF11764), as well as the SET_assoc domain (PF11767), and is responsible for H3K4me1/2/3 in *S. cerevisiae* (Roguev et al., 2001). SET1 occurs in a single copy in all species (Figure 2), indicating that this enzyme and its catalyzed PTM play fundamental roles in fungal biology. Dim-5 contains a SET domain and Pre-SET domain (PF05033) and acts as an H3K9 methyltransferase inducing heterochromatin formation notably in *N. crassa* (X. Zhang et al., 2002). Dim-5 was found in all species included in this study except *S. cerevisiae* and *Aspergillus calidoustus*, among which *S. cerevisiae* is reported to lack H3K9me (Marina et al., 2013; X. Zhang et al., 2002). How such a loss has impacted gene expression in *A. calidoustus* in comparison to its closest relative *Aspergillus carlsbadensis* deserves further investigation. Both SET2 and Ash1 catalyze H3K36me in *N. crassa* and share the SET domain and the AWS domain (PF17907) (Figure 2), yet SET2 harbor one additional SRI domain (PF08236) that interacts with RNA polymerase II and links H3K36me with transcript elongation (M. Li et al., 2005; Strahl et al., 2002; T. Xiao et al., 2003). In *N. crassa*, Ash1 was shown to contribute to H3K36me at sub-telomeric regions, while SET2 acts primarily at euchromatic regions (Bicocca et al., 2018; Janevska et al., 2018). Considering the common origin of SET2 and Ash1 as well as their similar activities, an ancient duplication followed by the loss or gain of the SRI domain is likely to have contributed to their functional diversification (Figure 2). SET2 was found in all outgroup species, while Ash1 was lost in both Basidiomycota and two yeasts. False absences of Ash1 in *B. cinerea* and *F. graminearum* were corrected as they could be retrieved by TBLASTN search at NCBI (Table S6). Both enzymes are conserved in all *Aspergillus* species except in *Aspergillus carbonarius* from the *Nigri* section, suggesting that either other SET domain-containing proteins exhibit functional redundancy or that H3K36 methylation is not fully required in this species. In *Fusarium fujikuroi*, deletion of SET2 and Ash1 strongly affected vegetative growth and conidiation (Janevska et al., 2018). SET9 homologs harbor only a SET

domain, and were shown to catalyze H4K20me in *S. pombe* (Y. Wang et al., 2009). This group is well conserved in most of the species except in *S. cerevisiae* (Veerappan et al., 2008) and in the two closely related Aspergilli, *Aspergillus novoparasiticus* and *Aspergillus arachidicola* that both belong to section *Flavi* (Figures 2 and S1).

SET7 is the catalytic subunit of PRC2, and is highly conserved in mammals, plants, and *N. crassa*, in which it has been well-characterized to catalyze methylation on H3K27, a PTM that is deposited at facultative heterochromatin (Jamieson et al., 2013). Even though PRC2 is considered to be a key chromatin modifier complex, its catalytic subunit *SET7* was lost in many fungal species (Freitag, 2017). *SET7* has previously been reported to be absent in *A. nidulans* and *A. fumigatus* (Freitag, 2017; Jamieson et al., 2013, 2016), and we here demonstrate that *SET7* is absent from all analyzed Aspergilli as well as from *Penicillium* (Figure 2), suggesting that this enzyme was most likely lost at or before the divergence of the last common ancestor of these two fungal genera. Thus, in line with previous reports (Bachleitner et al., 2019; Cánovas et al., 2014; Freitag, 2017; Gacek-Matthews et al., 2015), our results indicate that methylation on H3K4, H3K9, H3K36, and H4K20 are likely catalyzed by conserved enzymes in most Aspergilli, while H3K27 methylation is absent. Considering the loss of this methylation is usually reported to trigger deleterious phenotypes in the soil-borne fungus *Verticillium dahliae* (Kramer et al., 2022), humans (Sneeringer et al., 2010), and mice (Tao et al., 2011), investigating how *Aspergillus* species are able to cope with such a loss will likely provide new insights on the histone code and its evolution in fungi.

Importantly, the occurrence of a high number of uncharacterized SET domain-containing proteins opens the possibility that these contribute to not yet characterized histone modifications. Especially, four uncharacterized SET domain-containing groups with 144, 195, 113, and 113 members are conserved in Aspergilli and thus likely play important roles in different cellular processes.

Figure 2. Conservation of histone methyltransferase families in the *Aspergillus* genus and outgroup species. The maximum-likelihood phylogeny of SET domains (PF00856) found in 94 *Aspergilli* and 15 outgroup species was determined using IQ-TREE (Boratyn et al., 2013; Simão et al., 2015). The black dot on the branch indicates ultrafast bootstrap values over 95 and SH-aLRT values over 80. Leaves from *Aspergilli* with trustworthy support are collapsed and shown as red triangles. Leaves with similar protein architecture but unknown functions covering both

Aspergilli and outgroup species are collapsed and shown as grey triangles. The numbers of hits and species are separated by the pipe in the '#Homologs | #Species' column. The number in parentheses after * indicates the additional hits found by the TBLASTN search on NCBI. Additional conserved domains in SET domain-containing proteins were identified using the PFAM database (<https://pfam.xfam.org>).

Histone acetyltransferases are conserved in Aspergilli

Histone acetyltransferases (HATs) have been classified into five families: MYST (MOZ, Ybf2/Sas3, Sas2, and Tip60)-related HATs, Gcn5-related acetyltransferases (GNATs), p300/CBP HATs, general transcription factor HATs, and nuclear hormone-related HATs (Carrozza et al., 2003; Sterner & Berger, 2000; Torchia et al., 1998). We here only focused on the first two HAT families because these are known to be involved in the regulation of histone proteins and appear largely conserved in fungi (Carrozza et al., 2003). The MOZ/SAS FAMILY domain is the catalytic domain of MYST-related HATs (Roth et al., 2001). As previously reported (Kawahara et al., 2008), the three characterized MYST-related HATs, Sas3, Sas2, and Esa1, belong to distinct monophyletic clades, and these paralogues are nearly fully conserved in the here analyzed fungi (Figure 3). MOZ/SAS FAMILY domain and zf-MYST domain (PF17772) are present in Sas3, which can on its own acetylate histone H3 and H4, and H2A weakly *in vitro* (Takechi & Nakayama, 1999). Within the NuA3 (Nucleosomal Acetyltransferase of histone H3) complex, Sas3 histone acetylation activity is *in vitro* restricted on H3K14 and to a less extent on H3K23, while in *S. cerevisiae*, only H3K14ac can be detected (Taverna et al., 2006). Sas3 occurs in most of the species but is lost in *S. pombe*, as previously observed (Gómez et al., 2005; Nugent et al., 2010), and is duplicated in *A. carbonarius* (Figure 3). In addition to the two domains found in Sas3, Sas2 and Esa1 carry a PHD_4 domain (PF16866) or Tudor-knot domain (PF11717), respectively (Figure 3). Esa1 is present as a single copy in all species included in this study, and its functions is known to contribute to the acetylation of K5, K8, K12, K16 on histone H4, as well as on H2AZK14 in *S. cerevisiae* (Allard et al., 1999; Kim et al., 2018; Millar et al., 2006; Searle et al., 2017). Sas2 is similarly found in most of the species except for two Basidiomycota as well as for *A. carbonarius*. Sas2 is involved in chromatin-mediated gene regulation and H4K16 acetylation in both *S. cerevisiae* and *Candida albicans* (Kim et al., 2018; Meijnsing & Ehrenhofer-Murray, 2001; X. Wang et al., 2013). Although Esa1 and Sas2 catalyze H4K16ac, it was shown in *C. albicans* that they are differentially recruited at different stages of development (Kim et al., 2018). Because both Esa1 and Sas2 are well-conserved in the *Aspergillus* genus, we hypothesize that these two HATs may also have distinct roles during development.

Figure 3. Conservation of MOZ/SAS FAMILY domain-containing histone acetyltransferases in the *Aspergillus* genus and outgroup species. The maximum-likelihood phylogeny of MOZ/SAS FAMILY domains (PF01853) found in 94 *Aspergilli* and 15 outgroup species was determined using IQ-TREE (Boratyn et al., 2013; Simão et al., 2015). The black dot on the branch indicates ultrafast bootstrap values over 95 and SH-aLRT values over 80. Leaves from *Aspergilli* with trustworthy support are collapsed and shown as red triangles. The numbers of hits and species are separated by the pipe in the '#Homologs | #Species' column. '*In vitro*' indicates the acetylation activity of this enzyme was only observed on the substrate *in vitro*. Additional conserved domains in MOZ/SAS FAMILY domain-containing proteins were identified using the PFAM database (<https://pfam.xfam.org>).

GNATs have a acetyltransferase domain as its catalytic core, and 2,604 acetyltransferase domain-containing proteins were found in our search (Figure S2). The genes for two well-characterized GNATs, *Gcn5* and *Elp3*, occur in a single copy in every species included in our study (Figure S2). *Gcn5* harbors a Bromodomain (PF00439) in addition to the Acetyltransferase domain and is a crucial subunit of distinct histone acetyltransferase complexes such as the HAT-A2 complex, the SAGA complex, and the ADA complex in *S. cerevisiae* (Carrozza et al., 2003; Sterner & Berger, 2000). All these complexes contain two coactivator proteins, *Ada2* and *Ada3*, that directly bind to *Gcn5* (Balasubramanian et al., 2002) and the recruitment of different other subunits determines the location where they catalyze acetylation (Carrozza et al., 2003). *Elp3* is characterized by the Acetyltransferase domain, Radical SAM (PF04055), and Radical SAM C-terminal domain (PF16199), and has been shown to catalyze H3K14ac and H4K8ac in *S. cerevisiae* (Krogan & Greenblatt, 2001; Winkler et al., 2002; Wittschieben et al., 1999). *Elp3* also exhibits a dual enzymatic activity as it catalyzes demethylation in mouse zygotes (Okada et al., 2010), which is due to the Radical SAM domain that catalyzes the demethylation of methylated lysyl residues on histones (Booker & Grove, 2010).

Next to *Gcn5* and *Elp3*, we have identified 2,386 additional acetyltransferase domain-containing proteins. Because their functions remain unknown due to the lack of homology to sequences with characterized functions, they are valuable candidates that may acetylate histones or other proteins. Interestingly, it has been shown that *Gcn5* also exhibits succinyltransferase activity in humans (Y. Yuan et al., 2020) and can also function as histone crotonyltransferase to regulate gene transcription *in vitro* (Kollenstart et al., 2019). It is expected that other less common histone modifications, i.e., histone lysine butyrylation, propionylation, or malonylation, may also be catalyzed by histone acetyltransferases because these histone modifications all use acyl-Coenzyme A to complete the reactions (Jones, 2014; B. Liu et al., 2009; Papanicolaou et al., 2014). Further research is needed to determine whether these less common histone modifications are catalyzed by the known histone acetyltransferases *Gcn5* and *Elp3*, or as of yet unstudied HATs. In conclusion, all five characterized fungal HATs described above are highly conserved in the *Aspergillus* genus, showing their importance in fungal biology. Many other acetyl-transferase domain-containing proteins are encoded in *Aspergillus* genomes and may be responsible for histone acetylation or additional less common histone modifications like butyrylation, succinylation, and malonylation.

Duplication of *RpdA* histone deacetylase gene in the *Flavi* and *Janorum* sections

Five families of histone deacetylases (HDACs) can be grouped into two classes based on sequence similarity: class I (HOS1, HOS2, and *Rpd3/RpdA*) and class II (*HdaA* and HOS3) (Bernstein et al., 2000; Ekwall, 2005). They all harbor the Histone deacetylase catalytic domain, and our phylogenetic tree corroborates the HDAC classification into two distinct

classes (Figure 4). *HdaA* is found as a single copy in each species included in this study (Figure 4). It harbors the Histone deacetylase domain and C-terminal Arb2 domain (PF09757) that serves as an anchor to target centromeric heterochromatin region (Honda et al., 2016; Job et al., 2016). *HdaA* deacetylates lysine in histones H3 and H2B, but not H4 nor H2A in *S. cerevisiae* (Kurdistani & Grunstein, 2003; Wu et al., 2001), and the $\Delta hdaA$ knock-out strains show increased or reduced production of different secondary metabolites in *A. nidulans* (X. Li et al., 2019), *A. niger* (X. Li et al., 2019), and *A. fumigatus* (Lee et al., 2009). By contrast, *HOS3* is found in only 80 *Aspergillus* species, as it is lost in nine species (*Aspergillus nomiae*, *Aspergillus pseudocaelatus*, *Aspergillus tamaritii*, *Aspergillus pseudotamaritii*, *Aspergillus caelatus*, *Aspergillus sergii*, *A. novoparasiticus*, *A. minisclerotigenes*, *A. arachidicola*) in the *Flavi* section, three species (*A. desertorum*, *Aspergillus stercorarius*, and *A. multicolor*) in the *Nidulantes* section, and two species (*Aspergillus heteromorphus* and *A. carbonarius*) in the *Nigri* section. *HOS3* is well conserved in all outgroup species except *S. pombe* (Figure 4) (Brosch et al., 2008). *HOS3* has been shown to catalyze deacetylation with distinct specificity for histone H2AK7, H2BK11, H3K14 and H3K23, as well as H4K5 and H4K8 in *S. cerevisiae* cell extracts (Carmen et al., 1999). Notably, *HOS1* was only detected in three outgroup species, *S. cerevisiae* and both Basidiomycota (Figure 4). The specificity of *Hos1* in catalyzing deacetylation on histone proteins is not known yet (Pérez-Martínez et al., 2020), but it can catalyze the deacetylation of the Smc3 subunit of Cohesin and influence the regulation of chromosome segregation during mitosis in *S. cerevisiae* (S. Li et al., 2017). *HOS2* is found in 15 outgroup species and most of *Aspergilli* except *A. oryzae* (Figure 4). It is known to deacetylate lysine residues in H3 and H4 histone tails (A. Wang et al., 2002). The conservation of *HOS2* in *Aspergilli* suggests that it plays a key role, which is supported by the deletion of *HOS2* in *A. niger* where the deletion strains displays severe reduction in growth, sporulation, SM biosynthesis, and stress resistance (X. Li et al., 2019).

Figure 4. Conservation of histone deacetylase domain-containing proteins in the *Aspergillus* genus and outgroup species. The maximum-likelihood phylogeny of Histone deacetylase domains (PF00850) found in 94 *Aspergillus* and 15 outgroup species was determined using IQ-TREE (Boratyn et al., 2013; Simão et al., 2015). The black dot on the branch indicates ultrafast bootstrap values over 95 and SH-aLRT values over 80. Leaves from *Aspergillus* with trustworthy support are collapsed and shown as red triangles. The numbers of hits and species are separated by the pipe in the '#Homologs | #Species' column. '*In vitro*' indicates the

deacetylation activity of this enzyme was only observed on the substrate *in vitro*. Additional conserved domains in histone deacetylase domain-containing proteins were identified using the PFAM database (<https://pfam.xfam.org>).

Within class I HDACs, the Rpd3/RpdA clade is divided into two sub-clades (Figure 4). One is nearly fully conserved (except in *A. oryzae*) and comprises the well-characterized Rpd3/RpdA HDACs, while the other one only comprises sequences from the *Flavi* and *Janorum* sections (Figure 4). Our phylogenetic reconstruction suggests a duplication event that has occurred in the ancestor of all Aspergilli giving rise to a paralog that was retained in two sections only and could explain the *A. oryzae* loss in the conserved sub-clade. The two paralogs from the same species vary in length as they share a conserved N terminal catalytic domain but have a different C terminus (Figure 4). Follow-up studies are needed to investigate the function of both paralogues in *Aspergillus* species. Rpd3 is a crucial deacetylase in eukaryotes, as it is required for deacetylation in most locations on core histone proteins, except H4K16 *in vitro* (Suka et al., 2001) that is catalyzed by HOS2 (A. Wang et al., 2002). *S. cerevisiae* lacking *Rpd3* is sensitive to high osmolarity and shows compromised expression of osmotic stress genes (De Nadal et al., 2004). Deletion of *RpdA* in *A. nidulans* is lethal (Tribus et al., 2010), while only heterokaryon disruptants could be obtained in *A. oryzae* (Kawauchi et al., 2013), indicating its crucial role in the fungal genus *Aspergillus*. In summary, class I and class II deacetylases are well conserved in Aspergilli, and duplication events like the one observed for *RpdA* may confer new activities. While only one paralog was retained in *A. oryzae*, the presence of two paralogs in sections *Flavi* and *Janorum* may provide functional redundancy or diversification, which remains to be determined.

Lastly, we reconstructed the phylogeny of histone demethylases harboring the Jumonji C (JmjC) domain (PF02373) (Figure S3). Six groups are distinguished by their domain distribution: KDM4A/JHDM3/JMJD2, KDM5/JARID, DMM-1, JMJD6/PKDM11, KDM2/Epe1, and KDM6B/JMJD3, which also agrees with a previous study (Gacek-Matthews et al., 2015). The first five groups occur in most of the outgroup and *Aspergillus* species, but the *KDM6B/JMJD3* is only present in several outgroup species but not in any of the *Aspergillus* species. Certain JmjC domain-containing proteins were shown to catalyze the demethylation of histone proteins, e.g., KDM5/JARID for H3K4me_{2/3} and KDM4A/JHDM3/JMJD2 for H3K9me_{2/3} and H3K36me_{2/3} (Klose et al., 2006). The histone demethylase activity has not been detected for DMM-1 (Tamaru, 2010) or Epe1 (Isaac et al., 2007) in *N. crassa*, while KDM2 can demethylate H3K36me_{1/2} in mouse (Turberfield et al., 2019) and JMJD6/PKDM11 is an arginine demethylase in *Arabidopsis* (Qian et al., 2015). Interestingly, the human KDM6B/JMJD3 is responsible for the demethylation of H3K27me_{2/3} (Hong et al., 2007). As we did not find *SET7* and thus conclude that H3K27me₃ is absent, it would be tempting to speculate that H3K27 demethylase should be absent in *Aspergillus* too. However, based on the fact that other enzymes, e.g., UTX can also catalyze the demethylation of H3K27 (Agger

et al., 2007; Hong et al., 2007), we cannot unambiguously correlate the absence of *KDMB6B/JMJD3* to *SET7* loss. More studies are needed to investigate the regulation mechanism and interplay of proteins for H3K27 methylation.

Presence-absence patterns of subunits that compose histone modifier complexes

Histone PTMs are catalyzed by the conserved domains found in HMTs, HATs, and HDACs (Figure 2-4 and S2), but these chromatin modifying enzymes are often not acting alone. Instead, they are part of protein complexes that comprise accessory subunits, which are involved in the recognition and induction of specific histone modifications at the correct locations (Gates et al., 2018; Hajheidari et al., 2019). To further investigate the presence-absence patterns (PAPs) of known chromatin modifier complexes in *Aspergilli*, we focused on 15 chromatin modifier complexes with 83 subunits previously identified and studied in *S. cerevisiae* or *N. crassa* (Table S4). Forty-four subunits are present in all *Aspergillus* and outgroup species. Most of the accessory subunits are either fully conserved or absent in *Aspergilli* (Figure 5 and Table S4). Ten subunits show PAPs in both *Aspergilli* and outgroup species, while nine subunits appear specific to *S. cerevisiae* as they are not found in any other species and are likely to play a specific role in this species. Seventeen subunits show PAPs in the outgroup species, while eight are absent and nine are present in the *Aspergilli*. Lastly, three subunits are present in all outgroup species but show PAPs in *Aspergilli*.

Five histone methyltransferase complexes, COMPASS, DCDC (Dim-5/-7/-9/CUL4/DDB1 Complex), SET2 Complex, PRC2, and Dot1 (disruptor of telomeric silencing 1) (KMT4) were included in our analyses (Figure 5). Five COMPASS subunits (*SET1*, *CclA*, *Swd1*, *Swd2*, and *Swd3*) are fully conserved, suggesting an important function for H3K4 methylation. Consistent with a PAP in most outgroup species and the loss in *Aspergilli*, Spp1p is not essential for H3K4 methylation (Dehé et al., 2006). As *Sdc1* shows a PAP in *Aspergilli* and outgroup species, it is likely that this subunit also does not play a key role in H3K4 methylation. In the DCDC complex, while Dim-7 and Dim-9 seem to be dispensable for H3K9 methylation, Dim-5, Cul4, and Dim-8 are highly conserved, and we thus expect these enzymes to play key roles in the activity of this complex (Figure 5 and Table S4). However, it was shown that Dim-7 and Dim-9 are responsible for heterochromatin recognition, which leads to subsequent recruitment of the complete DCDC to induce H3K9 methylation in *N. crassa* (Lewis et al., 2010). Thus, it is very likely that other accessory subunits are involved in recruiting DCDC at specific chromatin locations in *Aspergilli*. Furthermore, the unique absence of *Dim-8* in *Aspergillus indicus* may suggest altered H3K9 methylation in this species. Consistent with the absence of *SET7* (Figure 2), all components of the PRC2 complex are lost in *Aspergilli* (Figure 5). Lastly, the interaction and crosstalk of multiple chromatin modifications in *Aspergillus* species should be further explored. For example, heterochromatin formation and regulation are done by H3K9me3, DNA methylation, and H3K27me3 in *N. crassa*. In this species, H3K9me3 is recognized by an adapter protein, HP1, to recruit DNA methyltransferase Dim-2 for DNA

methylation (Rountree & Selker, 2010), and cause the redistribution of H3K27me3 (Jamieson et al., 2016). In *Aspergillus* species, although HP1 and the writer for H3K9me3, DCDC complex, are well conserved (Figure 5), the inability for genome-wide *de novo* DNA methylation and H3K27me3 suggest different mechanisms of heterochromatin formation and regulation in Aspergilli which remain to be determined.

We included eight histone acetyltransferase complexes that differ by their distinct catalytic subunits (Figure 5). The HAT-A2, ADA, SAGA, and Elongator complexes use an acetyltransferase domain-containing protein as catalytic subunit (Eberharter et al., 1999; Georgakopoulos et al., 2013). The SAS (Something About Silencing), NuA4 (Nucleosomal Acetyltransferase of histone H4), and NuA3 complexes use a MOZ/SAS FAMILY domain-containing protein (Doyon & Côté, 2004). The NuB4 (Nuclear Hat1p-containing type B histone acetyltransferase) complex uses the histone acetyltransferase HAT1 domain-containing protein (Verzijlbergen et al., 2011). Gcn5, Ada2, and Ada3 are fully conserved in all fungi and constitute the core enzymatic module of the HAT-A2, ADA, and SAGA complexes. This catalytic module contributes to catalyzing histone acetylation, and other subunits in these complexes guide them to specific locations and link them to the transcriptional machinery (Sendra et al., 2000). Besides the catalytic module, the ADA complex also harbors the Ahc1 subunit that is found in *S. cerevisiae* only (Eberharter et al., 1999; Grant et al., 1997). Twelve additional subunits of the SAGA complex are well conserved in Aspergilli and outgroup species (Figure 5). The SAGA complex also contains a deubiquitylase (DUB) module, for which the composition differs between Aspergilli and other species. *Sgf11* is unique to *S. cerevisiae* and *Sus1* was likely lost in the ancestor of Pezizomycotina because we can only identify *Sus1* orthologs in both Basidiomycota and the yeasts (Figure 5). The Elongator complex appears more variable as four subunits are mostly conserved, but *Elp6* is specific to *S. cerevisiae*, and *Hpa2* and *Hpa3* show PAPs in both Aspergilli and outgroup species.

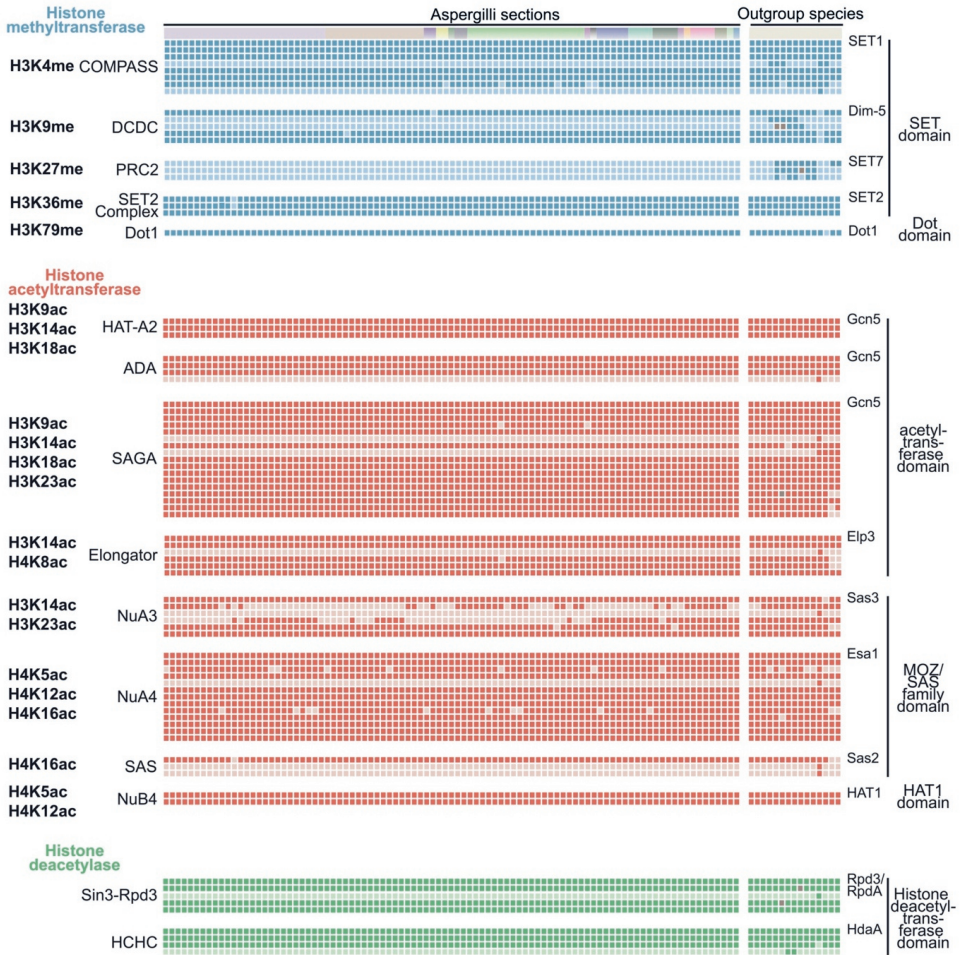

Figure 5. Presence-absence patterns of subunits that constitute characterized histone modification complexes. The top row with distinct color boxes indicates outgroup species and Aspergilli sections, the order of the species from right to left is the same as in the species tree from top to bottom (Figure S1) without *Fusarium oxysporum* and *Aspergillus kawachii* since they were excluded in the later analysis. Each row represents a subunit in the histone modification complexes, the order agrees with the summary list (Table S4). Each row shows the presence/absence of a specific complex subunit. For each complex, the first row represents the catalytic subunit. Each box in the matrix indicates the presence (dark color) or absence (light color) of a subunit (Table S4). The brown boxes indicate additional hits found with TBLASTN search on NCBI (Table S6).

The NuA4, SAS, and NuB4 complexes are well-conserved in Aspergilli as well as in the outgroup species (Figure 5). These complexes appear slightly different in *S. cerevisiae* with the presence of specific subunits (*Eaf5* in the NuA4 complex; *Sas4* and *Sas5* in the SAS

complex). Both SAS and NuA4 complexes can catalyze H4K16ac with opposite effects during cell growth and morphogenesis in *C. albicans* (Kim et al., 2018). It would be interesting to assess whether these two complexes exhibit similar activities in Aspergilli. For the NuA3 complex, two accessory subunits are well conserved among Aspergilli while two others, *Pdp3*, and *Nto1*, show different PAPs, and *Yng1* is specific to *S. cerevisiae*. *Pdp3* and *Nto1* seem to be lost in a complementary manner, suggesting a possible functional redundancy (Figure 5). Finally, two histone deacetylase complexes, Sin3-Rpd3 and HCHC, are fully conserved (Figure 5). The Sin3-Rpd3 complex is slightly different in *S. cerevisiae* with the specific of the *Ume1* subunit. Overall, our analysis showed that the core catalytic modules of complexes involved in histone PTMs are mostly conserved in all fungi, including Aspergilli, but variability in accessory subunits could contribute to differences in the localization of histone PTMs along the genome.

Unbiased mass spectrometry captures the diverse histone modifications in *A. nidulans* and verifies the absence of H3K27 methylation

Our genomic and phylogenetic analyses have identified the presence of multiple chromatin modifiers in Aspergilli, suggesting that these species have the ability to establish a wide variety of histone modifications. To assess the presence of histone PTMs predicted in our evolutionary analyses (Figures 2-5), we extracted histone proteins from *A. nidulans* and performed unbiased mass spectrometry analyses (Figures 6A and 6B). H3 and H4 peptides with PTMs corresponding to H3K4me, H3K9me, H3K36me, and H3K79me were detected (Figure 6C), which we anticipated being catalyzed by SET1, Dim-5, Ash1 and SET2, and Dot1, respectively. H4K20me, which is catalyzed by SET9 in *S. pombe* (Y. Wang et al., 2009), was not detected (Figure 6C), which is likely due to technical reasons because the unmodified form of histone H4 peptide 20-24 containing the K20 residue, was not detected. For the acetylation on H3K9, H3K14, H3K18, H3K23, H4K5, H4K8, H4K12, and H4K16, they were confidently detected (Figure 6C). We did not observe any peptide that would indicate the presence of H3K27me in *A. nidulans*, while we did detect H3K27ac (Figure 6C and Table S3). These results corroborate our computational analysis that the PRC2 complex is absent in *A. nidulans*, as well as previous reports on the absence of H3K27me₃ in several Aspergilli (Buscaino, 2019; Erlendson et al., 2017; Freitag, 2017). Thus, the mass spectrometry results verify the occurrence of histone modifications predicted to be present based on our comparative analyses in the fungal genus *Aspergillus*. Moreover, the differences between the relative abundance of distinct histone modifications provide interesting information to investigate these abundances and identify specific conditions under which these modifications increase or decrease in abundance.

Figure 6. Mass spectrometry unlocks the histone code in *Aspergilli*. (A) Schematic presentation of the in-gel digestion method used to process histones isolated in *A. nidulans*. After SDS-PAGE separation, gel bands corresponding to histone H3 and H4 are excised and chemically acylated with propionic anhydride (which derivatizes unmodified and mono-methylated lysines). Thanks to the derivatization, trypsin cutting at lysines is impaired, and histones are cleaved only at the C-terminus of arginine. Finally, digested peptides are N-terminally derivatized with phenyl isocyanate (PIC). (B) *A. nidulans* histone H3 and H4 sequences. Cleavage sites after PRO-PIC digestion are shown. Peptides identified in this study are highlighted in light red and labeled using their starting-ending amino acids. (C) Relative abundance of post-translational modifications detected on peptides of histone H3 and H4 from *A. nidulans* using unbiased mass spectrometry analysis. unmod: unmodified peptide; me1: monomethylation; me2: dimethylation; me3: trimethylation; ac: acetylation. The term “combinations” refers to multiple modifications occurring

on the same peptide (Table S3). (D) Histone modifications are predicted by genomic and phylogenetic analyses, and/or proved by mass spectrometry in *A. nidulans*. Histone modifications verified by mass spectrometry are labeled as solid dots, while the ones that are only predicted by phylogenetic analysis are labeled as solid dots with a red outline.

Conclusion

Changes in chromatin organization play an important role in regulating the expression of genes (Brosch et al., 2008). The fungal genus *Aspergillus* is well known for its ability to thrive in a broad range of different environmental niches and the huge potential of secondary metabolite biosynthesis (Collemare & Seidl, 2019; Steenwyk et al., 2020). However, a detailed and complete overview of occurrence and evolution of chromatin modifiers in Aspergilli is a prerequisite to be able to better understand how these fungi regulate gene expression. In the future, more research is needed to uncover how the absence of *de novo* DNA methylation impacts genome evolution in Aspergilli. We demonstrate that PRC2 is lost throughout Aspergilli, a finding consistent with the lack of H3K27me detection by mass spectrometry. Although histone acetyltransferases and deacetylases are overall conserved, our study also revealed specific duplication and loss events, which require further investigation to understand their impact on chromatin and gene regulation in certain *Aspergillus* species. Moreover, other less common histone modifications like histone lysine succinylation, crotonylation, butyrylation, propionylation, and malonylation, are all likely catalyzed by HATs and HDACs as they all use Coenzyme A (CoA) to complete the reactions (Jones, 2014; B. Liu et al., 2009; Papanicolaou et al., 2014), but may require specific yet to be discovered subunits. In conclusion, our study provides a detailed overview of the evolutionary routes of chromatin modifier complex in the fungal genus *Aspergillus*, and therefore generates the necessary framework to identify targets for functional studies to understand how chromatin regulates gene expression in Aspergilli.

Material and Methods

Acquisition of predicted proteomes for 109 fungal species

The predicted proteomes of 109 fungal species were retrieved from JGI (Joint Genome Institute) MycoCosm (<https://mycocosm.jgi.doe.gov/mycocosm/home>) (Grigoriev et al., 2014) on 24th January 2020. These species comprise 94 different Aspergilli species, 13 Ascomycota species from other genera, as well as two Basidiomycota species (*Coprinopsis cinerea* and *Dendrothele bispora*) (Table S1).

Phylogenetic analyses of chromatin modifiers

Phylogenetic trees for six major chromatin modifiers were generated using their conserved catalytic domains. Catalytic domain HMMs (Hidden Markov Model) of DNA methyltransferase domain (PF00145), histone methylation SET domain (PF00856), acetyltransferase domain (PF00583), histone acetyltransferase MOZ/SAS FAMILY domain (PF01853), histone deacetylase domain (PF00850), and histone demethylase Jumonji C (JmjC) domain

(PF02373) were downloaded from the Pfam database (<https://pfam.xfam.org>). Hmsearch, which is part of the HMMER package (v3.1b2) (Eddy, 2011), with the Gathering Cut-Off threshold (-cut_ga) was used to identify occurrences of these domains in the predicted proteomes of all 109 fungal species considered here. To filter out short and incomplete fragments, we applied a cutoff calculated by 50% length coverage of the query sequence (domain) or the hit. Subsequently, the identified domain sequences were aligned using MAFFT v7.271 (Kato & Standley, 2013). TrimAl v1.2 (-gt 0.1) was used to remove positions in the alignments with gaps in more than 90% of the sequences (Capella-Gutiérrez et al., 2009). Maximum-likelihood phylogenetic trees were constructed using IQ-TREE v1.6.10 (Chernomor et al., 2016; Nguyen et al., 2015) using ultrafast bootstrap and Shimodaira–Hasegawa approximate likelihood ratio test (SH-aLRT) (Anisimova et al., 2011) with 1,000 pseudo-replicates, and standard model selection to automatically determine the best-fit model. We predicted additional domains in the analyzed proteins using Hmsearch with all Pfam domain profiles that are present in the Pfam database (v28.0) and visualized them along the phylogenetic trees using iTOL (Letunic & Bork, 2019). Lastly, additional TBLASTN searches were performed on the NCBI website (<https://blast.ncbi.nlm.nih.gov/Blast.cgi>) and checked manually to confirm dubious absences in the domain trees.

Species tree construction

To construct a species phylogeny of the here analyzed fungi, we used BUSCO v4.0.1 (Benchmarking Universal Single-Copy Ortholog assessment tool) (Simão et al., 2015) to identify the occurrence of 758 fungal single-copy genes (Table S2) within the 109 predicted proteomes (Table S1). The identified homologs of single-copy BUSCO genes were subsequently concatenated into a single super-alignment. Then, the maximum-likelihood species phylogeny was estimated using IQ-TREE v1.6.10 (Chernomor et al., 2016; Nguyen et al., 2015) by employing partitioned model selection, which allows selecting a substitution model for each BUSCO gene. Branch supports were obtained using ultrafast bootstrap and SH-aLRT (Anisimova et al., 2011) with 1,000 pseudo-replicates separately.

Chromatin modifier subunits homology search and gene tree construction

We obtained previously studied chromatin modifier complexes from literature, and the associated protein sequences were downloaded from NCBI (<https://www.ncbi.nlm.nih.gov>) (Table S4). For each subunit of the chromatin modifier complexes, homologs in the analyzed 109 predicted proteomes were detected based on sequence similarity searches. First, BLASTP (v2.2.31+) (Boratyn et al., 2013) searches were performed, and an e-value threshold of 10^{-2} was applied. Multiple BLAST matches (High-Scoring Pairs: HSPs) of the same query were concatenated if they were aligned with different non-overlapping regions. Only the non-redundant region was retained when HSPs of the same query were overlapping. For these two conditions, the highest e-value of the different matches was used to represent the merged match. Only matches with the e-value lower than 10^{-5} and covering more than 50% of query

or subject were retained for the following analyses. If we observed less than ten hits for the BLASTP search after filtering in Aspergilli, we used PSI-BLAST (Position-Specific Iterated BLAST v2.2.31+) (Boratyn et al., 2013) with five iterations (-num_iterations 5) using the best Aspergilli hit from the BLASTP as the query; if no Aspergilli match was retained, we used the same query as for the BLASTP searches. The same filter criterion as for the BLASTP selection was applied to the PSI-BLAST hits, and the results of these two homology search strategies were subsequently jointed.

To account for apparent protein absences due to erroneous gene annotation, we tested these potential losses by using TBLASTN (BLAST v2.2.31+) (Boratyn et al., 2013) to query protein sequences against the genome assemblies. Matches with e-value lower than 10^{-5} together with 4,500 nucleotides upstream and downstream were extracted, and Exonerate v2.2.0 (Slater & Birney, 2005) was used to predict the gene structure (options: protein2genome, extensive search, showtargetgff, showcigar, and showquerygff options were set as true, and ">%ti(%tcb - %tce)n%tcs\n" option was used to output the complete aligned coding sequence). Transeq v6.6.0.0 (Rice et al., 2000) was used to translate the coding sequence into protein sequences. Together with the protein sequences identified from BLASTP and PSI-BLAST, all protein sequences from each subunit were retrieved to build a phylogenetic tree (MAFFT, TrimAl, and IQ-TREE settings were the same as for the tree reconstruction using the catalytic domains above).

For each sequence included in the phylogenetic trees, the domain organization was identified and visualized as described above. When the domain organization of a *Aspergillus* protein differed from its orthologues, the corresponding gene model was manually checked in the MycoCosm genome browser (Grigoriev et al., 2014) and corrected. The presence and absence patterns of 83 subunits from 15 different chromatin modifier complexes were visualized using the Seaborn library in Python (Hunter, 2007; Waskom, 2021). Lastly, additional TBLASTN searches for dubious absences in the outgroup species were performed on the NCBI website as absences could be caused by older and more fragmented assemblies in the JGI database compared to NCBI.

Histone enrichment and mass spectrometry

Spores of 4- or 5-days old sporulating *A. nidulans* (AnWT pabaA1 veA1, kindly provided by Prof. Joseph Strauss) growing on ME (Malt Extract) agar medium were harvested with 2 mL sterile water and cultured in 50 mL ME liquid medium at 28 °C, 200 rpm for 16 hours. The sample was centrifuged at 8,000 g for 10 minutes to discard supernatant, and germinating spores were resuspended in 25 mL 0.8 M NaCl and centrifuged again. Ten mL protoplasting solution (20 mg/mL *Trichoderma* lysing enzyme and 5 mg/mL driselease in 0.8 M NaCl) were used to resuspend spores, which were then incubated at 30 °C, 100 rpm for 2-3 hours.

Protoplasts were retrieved by filtering through sterile Miracloth and were concentrated by centrifugation at 3,000 rpm, 4 °C for 5 minutes. Histone proteins were extracted according to an adapted histone protein extraction protocol (Noberini et al., 2020). Briefly, 10⁸ protoplasts were resuspended in 1 mL Nuclei Isolation Buffer (1×PBS, 0.5 mM PMSF, 5 μM Leupeptin, 5 μM Aprotinin, and 5mM Na-butyrate) with 1% Triton X-100, followed by vigorous pipetting through a 200 μL pipette several times. Then, centrifuged at 2,300 g for 15 minutes at 4 °C, discarded the supernatant, and resuspended the nuclear pellet in 200 μL Nuclei Isolation Buffer with 0.1% SDS and 250 U Pierce™ Universal Nuclease and incubated at 37 °C for 30 minutes to digest nucleic acids. The protein concentration was measured using the Bradford Protein Assay (He, 2011).

The samples were separated on a 17% SDS-PAGE gel and histone bands were excised, chemically acylated with propionic anhydride and in-gel digested with trypsin, followed by peptide N-terminal derivatization with phenyl isocyanate (PIC) (Noberini et al., 2021). Chemical acylation of lysines (which occurs on unmodified or mono-methylated residues) impairs trypsin cleavage, resulting in proteolytic cleavage at arginine residues only. This treatment allows obtaining histone peptides of proper length for MS analysis. The samples were then desalted on handmade StageTips columns (Prudhomme et al., 2021). Peptide mixtures were separated by reversed-phase chromatography on an EASY-Spray column (Thermo Fisher Scientific), 25-cm long (inner diameter 75 μm, PepMap C18, 2 μm particles), which was connected online to a Q Exactive Plus instrument (Thermo Fisher Scientific) through an EASY-Spray™ Ion Source (Thermo Fisher Scientific), as described (Noberini et al., 2021).

The acquired RAW data were analyzed using the integrated MaxQuant software v.1.6.10. The Uniprot UP000000560 database was used for identification of *A. nidulans* histone peptides. Enzyme specificity was set to Arg-C. The estimated false discovery rate (FDR) was set at a maximum of 1%. The mass tolerance was set to 6 ppm for precursor and fragment ions. Two missed cleavages were allowed, and the minimum peptide length was set to 4 amino acids. Min. score for modified peptides and min. delta score for modified peptides were set to 1. Variable modifications included lysine propionylation, monomethylation + propionylation, dimethylation, trimethylation and acetylation. N-terminal PIC labeling was set as a fixed modification (Noberini et al., 2021). To reduce the search time and the rate of false positives, with increasing the number of variable modifications included in the database search, the raw data were analyzed through multiple parallel MaxQuant jobs (Bremang et al., 2013), setting different combinations of variable modifications. Peptides identified by MaxQuant with Andromeda score higher than 50 and localization probability score higher than 0.75 were quantitated, either manually or by using a version of the EpiProfile 2.0 software (Z.-F. Yuan et al., 2018) adapted to the analysis of histones from *A. nidulans*. Identifications and retention

times were used to guide the manual quantification of each modified peptide using QualBrowser version 2.0.7 (Thermo Fisher Scientific). Site assignment was evaluated from MS2 spectra using QualBrowser and MaxQuant Viewer. Extracted ion chromatograms (XICs) were constructed for each doubly charged precursor, based on its m/z value, using a mass tolerance of 10 ppm. For each histone modified peptide, the % relative abundance (%RA) was estimated by dividing the area under the curve (AUC) of each modified peptide for the sum of the areas corresponding to all the observed forms of that peptide (Pesavento et al., 2006). The AUC values are reported (Table S3) and visualized using GraphPad Prism.

Supplementary materials

Supplementary Figure 1. A robust species phylogeny for the fungal genus *Aspergillus*. The species phylogeny was based on a maximum-likelihood phylogeny reconstructed by IQ-TREE with partitioned analysis using 758 BUSCO (Benchmarking Universal Single-Copy Orthologs) genes. The dot on the branch indicates ultrafast bootstrap values over 95 and SH-aLRT bootstraps values over 80. Species from the same section are labeled by background color with a section name. Two species, *F. oxysporum* and *A. kawachii*, are included in the species tree, but we don't use these two in the following analyses.

Supplementary Figure 2. Two known histone acyltransferase-domain containing protein groups are conserved in the *Aspergillus* genus and outgroup species together with many unknown proteins. Maximum likelihood phylogeny of Histone acyltransferase domains (PF00583) found in 94 *Aspergilli* and 15 outgroup species were determined using IQ-TREE (Chernomor et al. 2016; Nguyen et al. 2015). The black dot on the branch indicates ultrafast bootstrap values over 95 and SH-aLRT bootstraps values over 80. Additional conserved domains in histone acyltransferase domain-containing proteins were identified using the PFAM database (<https://pfam.xfam.org>).

Supplementary Figure 3. Five histone demethylase-domain containing protein groups are conserved in *Aspergillus* genus and outgroup species while KDM6B/JMJD3 is lost. Maximum likelihood phylogeny of Jumonji C (JmjC) domain (PF02373) found in 94 *Aspergilli* and 15 outgroup species were determined using IQ-TREE (Chernomor et al. 2016; Nguyen et al. 2015). The black dot on the branch indicates ultrafast bootstrap values over 95 and SH-aLRT bootstraps values over 80. Additional conserved domains in JmjC domain-containing proteins were identified using the PFAM database (<https://pfam.xfam.org>).

Supplementary Table 1. List of species included in this study.

Species name	Class	JGI abbreviation	Scaffolds	Genes	BUSCO completeness (%)
<i>Aspergillus acristatulus</i>	Eurotiomycetes	Aspacr1	311	11221	99.21
<i>Aspergillus aculeatinus</i>	Eurotiomycetes	Aspacu1	121	12027	99.47
<i>Aspergillus aculeatus</i>	Eurotiomycetes	Aspac1	660	10845	99.21
<i>Aspergillus albertensis</i>	Eurotiomycetes	Aspalbe1	473	12816	98.68
<i>Aspergillus amylovorus</i>	Eurotiomycetes	Aspamy1	462	12857	99.47
<i>Aspergillus arachidicola</i>	Eurotiomycetes	Aspara19utr	451	13895	98.94
<i>Aspergillus avenaceus</i>	Eurotiomycetes	Aspave1	1528	11293	99.08
<i>Aspergillus bertholletius</i>	Eurotiomycetes	Aspber1	443	12948	98.81
<i>Aspergillus bisporus</i>	Eurotiomycetes	Aspbisp1	244	9731	98.55
<i>Aspergillus bombycis</i>	Eurotiomycetes	Aspbom1	450	12265	97.76
<i>Aspergillus brasiliensis</i>	Eurotiomycetes	Aspbr1	105	13000	99.21
<i>Aspergillus brevijanus</i>	Eurotiomycetes	Aspbrev1	685	12832	99.34
<i>Aspergillus brunneoviolaceus</i>	Eurotiomycetes	Aspbu1	153	12075	98.68

Data Summary

The predicted proteomes used in this study are publicly available at the JGI (Joint Genome Institute) MycoCosm repository (Grigoriev et al., 2014); the species names and abbreviations are listed in Table S1. To evaluate the completeness of the predicted proteomes and to obtain a species phylogeny, 758 fungal BUSCO (Benchmarking Universal Single-Copy Ortholog) genes were used, and their names are listed in Table S2. The fasta, trimmed alignment, and maximum-likelihood phylogenetic tree files can be found in Supplementary Data 1 and 2 deposited at Zenodo (doi:10.5281/zenodo.5907090). The mass spectrometry results mentioned in Table S3 are deposited in the PRIDE database with the dataset identifier PXD033478.

Acknowledgment

The sequence data were produced by the US Department of Energy Joint Genome Institute (<http://www.jgi.doe.gov/>) in collaboration with the user community. Especially, we thank the Scott Baker, Mikael Andersen, and Joseph Spatafora for their permission to use the sequence data. We thank Jos Houbraeken for validating the *Aspergillus* species tree and Joseph Strauss for providing *A. nidulans* strain. We thank Alessandro Vai for support with analysis of mass spectrometry data for histone PTMs' identification on *Aspergillus* core histone sequences.

Funding information

Xin Zhang is funded by the Chinese Scholarship Council (CSC) (201907720028). This work has been supported by EPIC-XS, project number 823839, funded by the Horizon 2020 programme of the European Union.

Authors and contribution

Abstract

In eukaryotes, the combination of different histone post-translational modifications (PTMs) – the histone code – impacts the chromatin organization as compact and transcriptionally silent heterochromatin or accessible and transcriptionally active euchromatin. Although specific histone PTMs have been studied in fungi, an overview of histone PTMs and their relative abundance is still lacking. Here, we used mass spectrometry to detect and quantify histone PTMs in three fungal species belonging to three distinct taxonomic sections of the genus *Aspergillus* (*Aspergillus niger*, *Aspergillus nidulans* (two strains), and *Aspergillus fumigatus*). We overall detected 23 different histone PTMs, including a majority of lysine methylations and acetylations, and 23 co-occurrence patterns of multiple histone PTMs. Among those, we report for the first time the detection of H3K79me1, H3K79me2, and H4K31ac in Aspergilli. Although all three species harbor the same PTMs, we found significant differences in the relative abundance of H3K9me1/2/3, H3K14ac, H3K36me1, and H3K79me1, as well as the co-occurrence of acetylation on both K18 and K23 of histone H3 in a strain-specific manner. Our results provide novel insights into the underexplored complexity of the histone code in filamentous fungi and its functional implications on genome architecture and gene regulation.

Introduction

In eukaryotes, genetic information is stored within the nucleus as chromatin, a complex of DNA and proteins of which the basic unit is the nucleosome (Luger et al., 1997). A nucleosome is composed of a histone octamer formed by two copies of each histone protein H2A, H2B, H3, and H4 wrapped by a DNA stretch of 145-147 bp (Luger et al., 1997). Nucleosomes are linked by 30-50 bp DNA sequence and the linker histone protein H1 (Luger et al., 1997). Histone proteins are highly conserved, consistent with their fundamental roles in structuring, scaffolding, and packaging DNA (van Holde, 1989). Each histone protein contains a globular central domain that interacts with the nucleosomal DNA, and a lysine- and arginine-rich N-terminal tail that is subject to a diverse array of chemical modifications (van Holde, 1989). These histone post-translational modifications (PTMs) contribute to the regulation of chromatin accessibility by two mechanisms: first, they directly alter chromatin packaging by changing histone proteins' net charges; second, histone PTM-specific binding proteins are recruited and can influence inter-nucleosomal interactions (Henikoff & Shilatifard, 2011). The resulting chromatin changes lead to transitions between inaccessible and transcriptionally silent chromatin regions, the so-called (facultative or constitutive) heterochromatin, and the accessible and transcriptionally active regions, the so-called euchromatin (Henikoff & Shilatifard, 2011). The combination of different histone PTMs at a single genomic locus – the histone code – contributes to the accessibility of chromatin for the transcriptional machinery, thereby regulating gene expression to influence not only growth and development but also responses to environmental challenges (van Holde, 1989).

In the last decades, a plethora of different histone PTMs have been uncovered in diverse organisms from plants to humans, with an enrichment of histone mono-, di-, and trimethylation (me) and acetylation (ac) (Huang et al., 2015). Accordingly, the vast majority of studies in fungi thus far have focused on these PTMs (Collemare & Seidl, 2019). Euchromatin has been typically associated with methylations on histone protein H3 at lysine 4 (K4), K36 and K79, and acetylations on H3 at K9, K14, K18, K23, and K27 and H4 at K5, K8, K12, and K16 (Bhaumik et al., 2007; Shilatifard, 2006). For instance, in the budding yeast *Saccharomyces cerevisiae* methylation on the lysine 4 of histone protein H3 (H3K4me) and H3K36me are enriched at the 5' and 3' end of actively transcribed genes, respectively, while H3K79me has been detected at the coding regions of active genes (Farooq et al., 2016; Pokholok et al., 2005). H3K4ac is located just upstream of actively transcribed genes (Guillemette et al., 2011), and H3K9ac and H4K5ac have been shown to induce transcription elongation *in vitro* (Gates et al., 2017). In members of the filamentous Aspergilli, some of these euchromatin marks are shown to positively influence the production of secondary metabolites (SMs), including H3K4me in *Aspergillus oryzae* (Shinohara et al., 2016); H3K36me, H3K14/18/23ac (acetylation on either of these lysines), and H4K16ac in *Aspergillus flavus* (Chen et al., 2022; Zhuang et al., 2022); H3K9ac in *Aspergillus fumigatus* (Y. Zhang et al., 2021) and *Aspergillus nidulans* (Reyes-Dominguez et al., 2010); and H3K27ac in *A. fumigatus*

(Adlakha et al., 2016). Especially, the diverse functions of histone acetyltransferase complex (SAGA complex) or its crucial subunits (Gcn5 and AdaB) have been extensively studied in *A. nidulans*, in which they can influence asexual development (Cánovas et al., 2014), production of natural products in response to the interaction with bacteria (Nützmann et al., 2011), and nucleosome positioning (Reyes-Dominguez et al., 2008). Histone PTMs can also be linked to gene silencing, as first shown for H3K9me and H3K27me which are marks for heterochromatin in animals and plants (Henikoff & Shilatifard, 2011). H3K9me3 plays a similar role in fungi as this PTM is typically located at telomeres, sub-telomeres, centromeres, and transposon-rich regions in the fission yeast *Schizosaccharomyces pombe* (Yamada et al., 2005), the filamentous model fungus *Neurospora crassa* (Rountree & Selker, 2010) and many other filamentous fungi (Freitag, 2017). H3K9me can influence SM biosynthesis in *A. nidulans* (Reyes-Dominguez et al., 2010) and *A. fumigatus* (Colabardini et al., 2022), however, as H3K9me is not always found located near SM gene clusters, it remains obscure whether it is directly linked to the regulation of SM gene clusters in Aspergilli and raises the possibility of the interaction of multiple histone PTMs or the distal regulation based on a higher level of chromatin structure. Facultative heterochromatin is linked with H3K27me3, and unsurprisingly, it does generally not overlap with the euchromatin mark H3K4me in the cereal pathogens *Fusarium graminearum* (Connolly et al., 2013) and *Fusarium fujikuroi* (Wiemann et al., 2013). By contrast, SET7 (KMT6) which is responsible for H3K27me is absent in Aspergilli, and consequently, no H3K27me is detected (X. Zhang et al., 2022). Although many PTMs have been clearly associated with gene activation or repression only, their effect can also be more subtle, depending on the genomic context. In *N. crassa* and *F. fujikuroi*, H3K36me catalyzed by SET-2 drives gene expression at the euchromatic region, while H3K36me catalyzed by ASH-1 at sub-telomeric regions is associated with gene repression (Bicocca et al., 2018; Janevska et al., 2018). This complexity is even higher when considering the role of less abundant histone PTMs like histone acylation, phosphorylation, ubiquitination, and sumoylation, which thus far have been mostly reported in humans (Tan et al., 2011). In fungi, such less abundant PTMs have been only reported scarcely in *S. cerevisiae* (diverse acylations, phosphorylation, ubiquitination, and sumoylation) and *A. nidulans* (phosphorylation, ubiquitination, and sumoylation), and the phosphorylation of histone H3 serine 10 correlates with chromosome condensation (De Souza et al., 2000).

Large-scale mass spectrometry (MS) studies have been performed on bulk histones from model species such as human, yeast, and *Arabidopsis* to uncover the full pattern of histone PTMs and their interactions (Grau-Bové et al., 2022; Johnson et al., 2004). However, studies in filamentous fungi have mostly focused on quantitative changes of targeted histone PTMs in mutant strains deficient in specific histone-modifying enzymes (Gacek-Matthews et al., 2015, 2016). For instance, mutants of histone H3 demethylase gene *KdmA* or *KdmB* in *A. nidulans* show increased H3K36me3 or H3K4me3, respectively (Gacek-Matthews et al., 2015, 2016). Our previous evolutionary analysis of 16 chromatin modifier complexes across the *Aspergillus*

genus demonstrated the conservation of most of the catalytic genes responsible for a variety of histone PTMs (X. Zhang et al., 2022). However, we still lack an overview of (co-)occurrence of histone PTMs in filamentous fungi, as well as a better understanding of the quantitative diversity of histone PTMs between different species. Here, we used quantitative MS to uncover histone PTMs in three *Aspergillus* species (*Aspergillus niger*, *A. nidulans*, and *A. fumigatus*) from distinct taxonomic sections and to report their estimated quantitative intra- and inter-species differences.

Results and discussion

The study of histone PTMs in filamentous fungi has mostly been restricted to targeted analyses based on knowledge from other organisms. However, the discovery of novel histone PTMs and their potential co-occurrence on a single nucleosome requires the use of untargeted strategies. We here applied a quantitative MS approach to identify the (co-)occurrence of histone PTMs and to quantify their relative abundance in three *Aspergillus* species: *A. niger*, *A. fumigatus*, and *A. nidulans*, which belong to distinct taxonomic sections (Barrett et al., 2020). Protein sequences of histones H2A, H2B, H3, and H4 from human, yeast, and the three *Aspergilli* show very high levels of sequence conservation, especially in the core domains of all histone proteins that fold into the characteristic bulk octamer around which the DNA strand wraps, as well as in the N-terminal tails of H3 and H4 that protrude from the surface of the nucleosome and harbors most of histone PTMs (Mersfelder & Parthun, 2006) (Figure 1). The majority of well-described histone PTMs, *i.e.*, methylation and acetylation, as well as less abundant PTMs such as crotonylation and ubiquitination predominantly occur on lysine residues, but histone PTMs can also occur on other residues such as serine, threonine, and arginine (Grau-Bové et al., 2022). For histone protein H3, we observed the conservation of all lysine residues in human, yeast, and *Aspergilli*, except for two additional lysine residues at positions 121 and 125 in *S. cerevisiae* (Figure 1). On these two residues, Cul8/Rtt101, an enzyme that is thought to be specific to *S. cerevisiae* as no homolog has yet been found in human or other fungi, can introduce histone ubiquitylation and thereby regulate nucleosome assembly (J. Han et al., 2013; Young et al., 2020). We similarly observed limited variation in the N-terminal tail of histone protein H4 and the global core domains of H2A and H2B, and most of the polymorphism occurs on amino acid residues that are not known to carry any histone PTM.

Figure 1 Histone proteins are well conserved in Aspergilli. Sequence alignment of histone proteins from human (H2A: P0C0S8, H2B: P62807, H3: P84243, and H4: P62805), yeast (*S. cerevisiae*, H2A: P04911, H2B: P02293, H3: P61830, and H4: P02309), and *A. niger* (H2A: P0C953, H2B: A2QY49, H3: A2QRR5, and H4: A2QRR3), *A. fumigatus* (H2A: Q4WWC6, H2B: Q4WWC5, H3: P61832, and H4: Q7LKT3) and *A. nidulans* (H2A: P08844, H2B: P23754, H3: P23753, and H4: P23750), retrieved from UniProt database. The highly conserved globular histone core regions are highlighted by grey boxes with numbers indicating their position in human histone proteins with the symbol * showing the mismatch of the positions between human and Aspergilli histone proteins H2A and H2B caused by the poor alignment of the N-terminal tails. Peptides detected by MS in this study are labeled by black lines (Table S1), and their relative positions in Aspergilli histone proteins are indicated.

Histone protein extraction and digestion for MS-based analyses

We adapted a well-established protocol for human primary cells (Noberini et al., 2020) to specifically extract histone proteins from filamentous fungi with three additional steps (freeze drying, grinding, and homogenization) for efficient disruption of fungal cell walls and release of nuclei (X. Zhang et al., 2021, 2022) (Figure 2A). We extracted histone proteins in three biological replicates from the three *Aspergillus* species; two strains of *A. nidulans* (Wtpaba and TN02A25) were cultured on YAG medium, while *A. niger* strain NRRL3 and *A. fumigatus* strain Af293 were grown on MEA medium (Figure 2B). After visualizing the extracted histone protein on SDS-PAGE gel, bands ranging from 10,000 to 16,000 Dalton, which correspond to the size of histone proteins (Zhou et al., 2020), were cut for in-gel digestion (Figure 2C). We used lysine derivatization with propionic anhydride on unmodified and mono-methylated lysines, followed by trypsin digestion and peptide N-terminal derivatization with phenyl isocyanate (PIC) to obtain histone peptides of amino acids length required for MS analysis. This method allows performing an ‘Arg-C-like’ digestion of histone proteins directly in the gel, which is the ideal digestion pattern for histone PTM analyses (Noberini et al., 2021). In addition, because the derivatization occurs only on unmodified or monomethylated lysines, but not on di- or tri-methylated residues, it allows better discrimination of isobaric peptides (Noberini et al., 2021). The N-terminal derivatization with PIC also aids in the detection of small and hydrophilic peptides, as well as the chromatographic separation of differentially acetylated

peptides, as described previously (Maile et al., 2015; Noberini et al., 2021). After digestion of isolated histone proteins from *Aspergilli*, we detected 20 different peptides from the four core histone proteins and three peptides from the histone protein variant H2A.Z (Figure 1 and Table S1). These peptides cover most of the lysine residues that are known to harbor histone PTMs.

Figure 2. Histone proteins extraction for MS-based analysis of histone PTMs in *Aspergilli*. (A) Schematic diagram of the experimental setup and workflow applied in this work. (B) Summary of *Aspergillus* strains' genetic background and culture conditions. The number of biological replicates for each condition is indicated. (C) Histone proteins were extracted from the different *Aspergillus* species, and samples were visualized on the 17% SDS-PAGE gel. The region ranging from 10,000 to 16,000 Dalton was cut for the in-gel digestion step.

MS uncovers histone PTMs in three *Aspergillus* species

MS analyses resulted in the detection of 23 individual histone PTMs, as well as 23 distinct co-occurrence patterns of multiple histone PTMs that occur on the same peptide (Figure 3 and Table S1). We did not detect any histone PTM on histone variant H2A.Z and histone H2A, but we were able to detect acetylation on K92 and co-occurrent mono-methylations on K98 and K99 on histone protein H2B (Table S1). These PTMs correspond to histone PTMs H2BR79ac (R: arginine) and H2BK85me1R86me1 in human, yet the functions of these PTMs are unknown (Gnesutta et al., 2013). For histone PTMs on histone proteins H3 and H4 in *Aspergilli*, we successfully detected methylations on histone H3 at lysines 4, 9, 36, and 79, acetylation on histone H3 at lysines 9, 14, 18, 23, 27, and 56, and histone H4 at lysines 5, 8, 12, 16, and

31 (Figure 3). All these modifications have previously been reported in human (Barski et al., 2007; Pesavento et al., 2006), *Arabidopsis* (Scheid et al., 2022), *S. cerevisiae* (Abshiru et al., 2016), and in a few filamentous fungi (Brosch et al., 2008; Collemare & Seidl, 2019; Freitag, 2017). However, it is to our knowledge the first time that H3K79me1, H3K79me2, and H4K31ac are detected experimentally in *Aspergilli* (Figure 3). Consistently with the occurrence of these histone PTMs, their catalytic enzymes, Dot1 (Disruptor of telomeric silencing 1) for H3K79me and Gcn5 for H4K31ac were firstly identified in *S. cerevisiae* (van Leeuwen et al., 2002) and the human parasite *Toxoplasma* (Sindikubwabo et al., 2017), respectively, and then found to be conserved across the fungal genus *Aspergillus* in our previous study (X. Zhang et al., 2022). Our analysis could not differentiate between the two H4 variants found in *Aspergilli* because they only differ by two residues (Cheng et al., 2003; Grant et al., 1999) (Figure 1), which are inside the histone core domain that was not detected.

While we detected most of the known PTMs as well as a few additional ones for the first time in *Aspergilli*, we did not detect some histone PTMs which were expected to occur. Several reasons can explain these observations. First, PTMs might not be identified because they are under the detection threshold used in both the instrument and analysis pipeline. This reason likely explains why we only detected abundant histone methylations and acetylations, but not less-abundant ones, e.g., H3S10P (S: serine and P: phosphorylation) and H3R2me, which have been reported in *Aspergilli* (Cheng et al., 2003). The abundance of certain expected PTMs like H3K79me3, H3K4ac, and H3K36ac could be higher and detectable under different growth conditions or developmental stages. Second, these PTMs are true absences in *Aspergilli*. We were not able to detect any methylation on H3K27, H4K5, H4K8, and H4K12 (Figure S1), which is expected due to the absence in *Aspergilli* of their catalytic enzymes, PRC2 (Freitag, 2017; X. Zhang et al., 2022) and SET5 (X. Zhang et al., 2022) (Figure S2), respectively. Third, the mutual exclusivity of different histone PTMs on the same residue could lead to biased occupancy by only one histone PTM. For instance, apart from H3K9, either acetylation or methylation was detected on H3 lysines (Figures 3 and S1). Such an explanation would indicate very homogenous samples regarding their chromatin status and PTMs. Last, antagonistic relationships between histone PTMs might contribute to some absences. For example, H4K16ac prevents H4K20me (Nishioka et al., 2002), explaining why we could detect the former but not the latter histone PTM in *Aspergilli*.

We also detected the co-occurrence of multiple histone PTMs on the same peptide (Figure 3). For example, we observed the co-occurrence of acetylations on different residues in the same peptide such as H3K9acK14ac, H3K18acK23ac, and H4 lysines 5, 8, 12, and 16 harboring acetylations at the same time on two, three, or four residues (Figure 3). Acetylation can also co-occur with methylation, such as H3K9me1/2/3K14ac, H3K27acK36me2/3, and H3K36me1K37ac, while H3K36me1 can co-occur with another mono-methylation on H3K37 (Figure 3). The detection and functional characterization of some of these co-occurrent

patterns have been performed in several model species. For instance, in mouse, H3K9meK14ac has a role in gene silencing (Jurkowska et al., 2017). Accordingly, double replacements of K9 and K14 by arginine residues on histone H3 lead to the missing acetylations on these two locations and down-regulation of penicillin, sterigmatocystin, and orsellinic acid in *A. nidulans* (Nützmann et al., 2013). H3K18acK23ac was first reported to be acetylated by SAGA/ADA complex in *S. cerevisiae* (Grant et al., 1999) and then detected in human (X. Han et al., 2021). The investigation in *S. cerevisiae* of the combinatorial effect of acetylation on H4 lysines 5, 8, 12, and 16 showed that they are redundant and function together as a group to induce gene activation instead of forming distinct combinational patterns (Dion et al., 2005). Even though the co-occurrence of histone PTMs has not yet been systematically studied, our data as well as the results from other model systems, such as human or mouse, provide valuable clues for the possible functions of co-occurring histone PTMs in gene regulation in *Aspergilli*.

Figure 3 Identification of single and co-occurrent histone PTMs in *Aspergilli*. The red boxes show the identification of histone mono-, di-, and tri-methylation and acetylation while the black boxes show their co-occurrences in *Aspergilli*. Pie charts show the average relative abundance of unmodified peptides compared with modified peptides for each *Aspergillus* species. Unmodified peptides are shown in gray, and green, orange, as well as purple representing the proportion of modified peptides in *A. niger*, *A. fumigatus*, and *A. nidulans* (strain Wtpaba), respectively.

Although relative abundances only represent an indication of the absolute abundance of a modification as peptide detection by MS is affected by the peptide physicochemical properties and the digestion strategy (Lin et al., 2014), our data shows that the majority of detected histone H3 peptides is unmodified, while histone protein H4 exhibits a high percentage (79%-84%) of acetylated peptides in all three *Aspergilli* (Figure 3). According to a recent study, the newly synthesized histones are modified within 1.5 hours for histones H2A and H2B, and 3.5 hours for histones H3 and H4 (Flury et al., 2023). In our study, we cultured all *Aspergilli* strains at the same time and observed no difference in their growth among replicates. Different growth rates cannot explain the observed differences because one would expect the proportion of modified peptides to be consistent within a given species, which is not the case here. Indeed, the pattern we mentioned above is similar among the three species, with only a few observable differences. Fewer H3 peptides 18-26 are modified in *A. niger* (30% vs 43% in both *A. nidulans* and *A. fumigatus*), suggesting a lower abundance of H3K18ac and/or H3K23ac in this species. In contrast, *A. nidulans* exhibit more modified H3 peptides 73-83 (82% vs 49-53% in the other species), suggesting an enrichment in H3K79 methylation in this species. *A. fumigatus* differs from the two other species by having more modified H3 peptides 9-17 (53% vs 40-41%) and fewer modified H3 peptides 27-40 (19% vs 46-47%) (Figure 3). These differences suggest a higher abundance of H3K9 and/or H3K14 PTMs and a lower abundance of H3K27, H3K36, and/or H3K37 PTMs in *A. fumigatus*. These results collectively suggest that, although the same histone PTMs are detected in all three species, their abundances likely differ.

***Aspergillus* species differ in the relative abundance of histone PTMs**

To uncover quantitative differences between histone PTMs, we calculated the relative abundance of most histone PTMs in three *Aspergillus* species (*A. niger*, *A. fumigatus*, and *A. nidulans* (Wtpaba strain)). Of note, a few modified peptides could not be quantified as their chromatographic peaks were of poor quality or could not be fully resolved for accurate quantification. We plotted the figure of Principal Component Analysis (PCA) (Figure 4A) and observed that *Aspergillus* species are well separated, suggesting that the three *Aspergilli* indeed differ quantitatively in their histone PTMs. These differences could be caused by differences in growth conditions (Figure 2B). However, we observed that even though *A. fumigatus* and *A. niger* were grown on the same medium compared with *A. nidulans*, *A. fumigatus* was more distinct from *A. nidulans* and *A. niger*. These distinctions suggest that the observed differences are not related to the different media but seem to be consistent with their taxonomic relationships. Specifically, *A. fumigatus* harbors significantly more H3K9 methylations, either alone or co-occurring with H3K14ac, and it has significantly less H3K36me1 compared to the other two *Aspergilli* (Figure 4B and Table S3). *A. fumigatus* also appears to have a trend of being enriched in H3K79me1 compared to *A. nidulans* (p-value: 0.080789) and *A. niger* (p-value: 0.165426) (Figures 3 and 4B and Table S3). In contrast, H3K9me1/2K14ac showed lower abundance in *A. niger* compared to the other two species, and H4K8ac was significantly higher in *A. fumigatus* compared to *A. nidulans*. There are also

trends indicating that *A. niger* contains fewer H3K18ac and H3K23ac while *A. nidulans* appears particularly rich in H3K79me2 and poor in H3K79me1 (Figures 3 and 4B). The observed differences suggest that *A. fumigatus* exhibit more heterochromatin-linked modifications compared to the other two species as it harbors more H3K9me1/2/3 linked with constitutive heterochromatin (Lachner et al., 2001) and H3K9meK14ac associated with triggering gene silencing (Jurkowska et al., 2017). For euchromatin, *A. fumigatus* uses more H3K79me1 and the combination of acetylations on diverse lysines of histone protein H4, while *A. niger* and *A. nidulans* harbors more H3K36me1 (Figure 4B). Even though we observed no qualitative difference in histone PTMs among three Aspergilli, these species differ quantitatively in specific histone PTM abundances, suggesting that the three populations (and their replicates) were very homogenous and in a similar state and they used a mix of marks associated with gene activation and gene silencing. Yet, the absence or low abundance of histone PTMs like H3K4ac, H3K14me, or H3K36ac could indicate their important roles in gene regulation in other developmental stages.

Figure 4 Quantification of histone PTMs in three *Aspergillus* species. (A) Principal component analysis (PCA) of three *Aspergilli* based on their relative abundance of histone PTMs (Table S3). (B) Quantitative comparison of all histone PTMs detected by MS. The heatmap displays red or blue color boxes according to the $\log_2(\text{relative abundance}/\text{average of relative abundance})$ of different peptides in *Aspergilli*. 'Di-ac' indicates H4K5acK8ac, H4K5acK12ac, H4K5acK16ac, H4K8acK16ac, and H4K12acK16ac; 'tri-ac' means H4K5acK8ac12ac, H4K5acK8acK16ac, H4K5acK12acK16ac, and H4K8acK12acK16ac; and 'tetra-ac' indicates H4K5acK8ac12acK16ac. For each histone PTM between the three *Aspergilli* species, we applied an ANOVA test and Tukey HSD tests to determine significant differences. We used p-value = 0.05 as the threshold for a significant difference in the ANOVA test and p-value = 0.025 in the Tukey HSD test. Colored dots

indicate significant differences between represented species. (C) Relative abundance of histone PTMs that are significantly different. Points show the average relative abundance and lines indicate standard deviation.

A. *nidulans* strains differ quantitatively in euchromatin marks

To evaluate the intra-species variation in the relative abundance of histone PTMs, we compared the MS data of another *A. nidulans* strain (TN02A25) to Wtpaba (Figure 5). In general, we observed that TN02A25 spurs the same type of histone PTMs as we observed in the other strains (Figure 4B and 5C), indicating all *Aspergilli* tested in this study used the same histone code. However, the two strains show a few differences, already when only considering the percentage of unmodified versus modified peptides. The vast majority of detected histone H3 peptides were unmodified (> 50%) and histone H4 peptides were highly acetylated in TN02A25 like the other strains (Figures 4 and 5A). However, TN02A25 differs from Wtpaba in H3 peptides 27-40 (11% vs 47% modified peptides in Wtpaba) and 73-83 (46% vs 82% modified peptides in Wtpaba). These proportions in TN02A25 are similar to those found in *A. fumigatus* or *A. niger* and *A. fumigatus*, respectively (Figure 3), and suggest that the two *A. nidulans* strains differ in histone PTM abundance on those peptides.

The quantitative comparison of histone PTMs between the two *A. nidulans* strains shows good separation in the PCA analysis (Figure 5B). Consistent with previous results and analyses, TN02A25 exhibit significantly less H3K36me1 compared to the Wtpaba strain. We also observed a trend of enrichment in H3K79me2 and lower abundance in H3K79me1 in Wtpaba, which contributes to the difference between both strains (Figure 5). In addition, H3K4me2, H3K9ac, H3K36me1, and H4di-ac (H4K5acK8ac, H4K5acK12ac, H4K5acK16ac, H4K8acK16ac, and H4K12acK16ac) exhibited significantly higher abundance in Wtpaba than TN02A25 (Figure 5C-D, Table S4) and they are all related to regulation of euchromatin.

Moreover, we observed that intra-species variability can be as high as the inter-species variability as the histone PTM abundances of Wtpaba and TN02A25 are more related to *A. niger* and *A. fumigatus*, respectively (Figure S3A and Table S5). Four single or co-occurrent histone PTMs, H3K36me1, H3K79me1, H3K9me3K14ac, and H3K9me1K14ac displayed the most distinct abundant patterns among the four strains, followed by H3K9me1, H3K9me2, and H3K18acK23ac being less abundant in *A. niger* compared to the other three strains (Figure S3B). These marks showing distinct relative abundance agreed with the marks we pinpointed from both species and strain comparisons. Thus, the observed differences between species are likely a 'strain effect' and highlight the importance of including several strains in the study of histone PTMs.

Figure 5 Quantification of histone modifications in two *A. nidulans* strains. (A) The average relative abundance of unmodified peptides compared with modified peptides. Grey represents the unmodified peptide percentage in the pie chart, while pink and purple represent the modified peptide percentage of TN02A25 and Wtpaba *A. nidulans* strains, respectively. (B) Principal component analysis (PCA) of two strains based on their relative abundance of histone PTMs. (C) Quantitative comparison of all histone PTMs detected by MS. The heatmap displays red or blue color boxes according to the $\log_2(\text{relative abundance}/\text{average of relative abundance})$ of different peptides in two *A. nidulans* strains. 'Di-ac' indicates H4K5acK8ac, H4K5acK12ac, H4K5acK16ac, H4K8acK16ac, and H4K12acK16ac; 'tri-ac' means H4K5acK8ac12ac, H4K5acK8ac16ac, H4K5acK12acK16ac, and H4K8acK12acK16ac; and 'tetra-ac' indicates H4K5acK8ac12acK16ac. ANOVA test and Tukey HSD test were performed to show the significance of the difference of one histone modification between two strains when p-value < 0.05 in the ANOVA test and p-value < 0.025 in the Tukey HSD test. Red stars indicate significant differences. (D) The relative abundance of the top four histone modifications that are significantly different. Points are average relative abundance and lines are standard deviations.

The use of MS spectrometry is powerful to detect and quantify histone PTMs in filamentous fungi and this approach is needed to understand the chromatin status at different developmental stages. The present study focused on fungal mycelium cultured for 16 hours in liquid medium, a particular stage that requires the expression of a specific set of genes and is expected to not favor the production of SMs. Similar future studies in *Aspergilli* at different developmental stages and different culture conditions will fully uncover quantitative variations in histone PTMs and might lead to identifying key PTMs for certain applications, such as the

controlled activation of SM production. Finally, while this work has revealed quantitative differences between species and strains, it remains to determine whether they are due to different PTM abundance at the same loci, or whether they reflect a different number of loci covered by these PTMs, which would reflect activation or repression of different sets of genes. These future studies will contribute to understanding how single and co-occurring histone PTMs regulate gene expression in *Aspergilli* and more broadly in other filamentous fungi.

Materials and methods

Fungal strains and culture

A. niger (wild type strain: NRRL3, CBS 120.49) and *A. fumigatus* (wild type strain: Af293, CBS 126847) were grown on MEA (Malt Extract Agar; Malt Extract Agar Oxoid 50 g/L) medium at 30 °C and 25 °C, respectively, while *A. nidulans* (strains: Wtpaba (genotype: pabaA1) and TN02A25 (genotype: pyrG89 argB2 pabaB22 riboB2), kindly provided by Prof. Joseph Strauss) was grown on YAG (Yeast Agar Glucose; 5 g/L yeast extract, 15 g/L agar, 20 g/L D-glucose, 1 mL/L trace elements (Solution A: dissolve 10 g EDTA and 1 g $\text{FeSO}_4 \times 7\text{H}_2\text{O}$ in 80 mL water and adjust pH to 5.5; solution B: dissolve 4.4 g $\text{ZnSO}_4 \times 7\text{H}_2\text{O}$, 1 g $\text{MnCl}_2 \times 4\text{H}_2\text{O}$, 0.32 g $\text{CuSO}_4 \times 6\text{H}_2\text{O}$, and 0.22 g $(\text{NH}_4)_6\text{Mo}_7\text{O}_{24} \times 4\text{H}_2\text{O}$ in 80mL water; combine solutions A and B, adjust pH to 6.5) medium at 37 °C.

Fungal spores of the four *Aspergilli* strains were harvested from 4- or 5-day-old sporulating plates with a spreader in 12.5 mL ice-cold ACES (1.822 g/L N-(2-Acetamido)-2-aminoethanesulfonic acid, 0.2 mL/L Tween 80) buffer at the same time. The spore suspension was centrifuged at 2,500 xg at 4 °C for 5 minutes. The supernatant was discarded, and spores were resuspended in 25 mL ice-cold ACES buffer. The spore suspension was centrifuged at 2,500 xg at 4 °C for 5 minutes, and the supernatant was discarded. Spores were resuspended in 10 mL ice-cold ACES buffer, and spore concentration was determined with a hemocytometer (Marienfeld, 0.0025mm²) or spore counter, and adjusted to 10⁷ spores/ mL. For the overnight culturing, 10⁷ to 10⁸ spores were inoculated in 50 mL liquid medium in a 250 mL flask and incubated at the same temperature as plate culture, 200 rpm, for 16 hours. Mycelium were centrifugated at 4,000 xg for 10 minutes and the supernatant was discarded. The mycelium pellet was washed with 25 mL 0.8 M NaCl, followed by centrifugation at 4,000 xg for 10 minutes to collect them for histone protein extraction. No obvious difference in regard to growth was observed.

Histone protein extraction

Histone proteins were extracted according to an adapted histone protein extraction protocol (X. Zhang et al., 2021). Briefly, the fungal material was freeze-dried, ground with a mortar and pestle, and further disrupted by TissueLyser II (QIAGEN, C.0659). 100 mg ground sample was first resuspended in 1 mL lysis buffer (1×PBS, 0.5 mM PMSF, 5 μM Leupeptin, 5 μM Aprotinin, and 5mM Na-butyrate) with high (10%) Triton X-100 concentration and incubated

on an orbital shaker at 4 °C for half an hour. Then 10 mL lysis buffer with low (1%) Triton X-100 concentration was added and the sample was incubated for another half an hour. The samples were subsequently sonicated for 30 seconds with 10 repeats and 30-second break in between each repeat. The crude histone proteins were dissolved in 0.4 N H₂SO₄ and then precipitated in four volumes of acetone. Protein concentration was measured with the Bradford Protein Assay (He, 2011).

LC-MS/MS analysis of histone PTMs

Samples were separated on a 17% SDS-PAGE gel and histone bands were excised and in-gel digested using a double derivatization protocol that involves propionylation of lysines and N-terminal derivatization with phenyl isocyanate (Noberini et al., 2021). Chemical propionylation of lysines (which occurs on unmodified or mono-methylated residues) impairs trypsin cleavage, resulting in proteolytic cleavage at arginine residues only and the generation of histone peptides of proper length for MS analysis. Peptide mixtures were separated by reversed-phase liquid chromatography and analyzed by MS on an Orbitrap instrument, as previously described (X. Zhang et al., 2022).

The acquired RAW data were analyzed using the integrated MaxQuant software v.1.6.10. The Uniprot UP000000560, UP000006706, and UP000002530 databases were used for the identification of *A. nidulans*, *A. niger*, and *A. fumigatus* histone peptides, respectively. Enzyme specificity was set to Arg-C. The estimated false discovery rate was set at a maximum of 1% at both peptide and protein levels. The mass tolerance was set to 4.5 ppm for precursor and fragment ions. Two missed cleavages were allowed, and the minimum peptide length was set to four amino acids. The second peptide search was enabled. Variable modifications include lysine propionylation (+56.026215 Da), monomethylation-propionylation (+70.041865 Da), dimethylation (+28.031300 Da), trimethylation (+42.046950 Da), acetylation (+42.010565 Da), malonylation (+86.000394 Da), and succinylation (+100.016044 Da). N-terminal PIC labeling (+119.037114 Da) was set as a fixed modification (Noberini et al., 2021). To reduce the search time and the rate of false positives, which increases with a higher number of variable modifications included in the database search, the raw data were analyzed through multiple parallel MaxQuant jobs (Bremang et al., 2013), setting different combinations of variable modifications. Peptides identified by MaxQuant with Andromeda score higher than 50 and localization probability score higher than 0.75 were quantitated, either manually or by using a version of the EpiProfile 2.0 software (Yuan et al., 2018) adapted to the analysis of histones from *Aspergillus* strains. Identifications and retention times were used to guide the manual quantification of each modified peptide using QualBrowser version 2.0.7 (Thermo Scientific). Site assignment was evaluated from MS2 spectra using QualBrowser and MaxQuant Viewer. Extracted ion chromatograms were constructed for each doubly charged precursor, based on its *m/z* value, using a mass tolerance of 10 ppm. For each modified histone peptide, the

relative abundance was estimated by dividing the area under the curve (AUC) of each modified peptide by the sum of the areas corresponding to all the observed forms of that peptide (Pesavento et al., 2006). The MS proteomics data have been deposited to the ProteomeXchange Consortium (Vizcaino et al., 2014) *via* the PRIDE partner repository with the dataset identifier PXD033478.

PCA figures were generated by `sklearn.decomposition.PCA` of Sklearn (Pedregosa et al., 2011) in Python, heatmap and point plots were made using Seaborn (Waskom, 2021) in Python. To compare the relative abundance of each histone PTM among different species/strains, we first used `'bioinfokit.stat.oanova'` to perform the one-way ANOVA test, then used `'bioinfokit.analys.stat.tukey_hsd'` to perform the post-hoc Tukey HSD (Honestly Significant Difference) test in python (Bedre, 2020). We used $\alpha = 0.05$ and $\alpha/2 = 0.025$ as thresholds for a significant difference in the ANOVA and Tukey HSD tests, respectively.

Supplementary materials

Supplementary Figure 1 Comparison of experimentally detected histone PTMs in human, yeast, and Aspergilli. The summary of histone PTMS in human and yeast is adapted from a recently published paper (Grau-Bové, Xavier, et al., Nature Ecology & Evolution, 2022) with a few corrections: 1) H3K64ac can be detected in human (Pradeepa, Madapura M., et al., Nature genetics, 2016); 2) H3K9me1 is lost in yeast (Zhang, Xing, et al., Cell, 2002 and Marina, Diana B., et al., Genes & development, 2013); 3) H4K5me1 (Green, Erin M., et al., Nature structural & molecular biology, 2012) and 4) H4K8ac (Magraner-Pardo, Lorena, et al., BMC genomics, 2014) can be detected in yeast. The detection of histone PTMs in Aspergilli comes from this study.

Supplementary Figure 2 SET5 was lost in Aspergilli. (A) The phylogeny of the SET domain-containing proteins in 94 Aspergilli and 15 outgroup species (Zhang X, et al., Microbial Genomics, 2022). The red circle indicates SET5 in *S. cerevisiae*. (B) Zoom-in of *S. cerevisiae* SET5 and its homologs. Black, pink, and red boxes indicate outgroup species, *Penicillium*, and Aspergilli, respectively.

Supplementary Figure 3 Distinct abundant patterns of several histone PTMs differ in different *Aspergillus* species/strains. (A) Principal component analysis (PCA) according to $\log_2(\text{relative abundance/average of relative abundance})$ uncovers the separation of four strains based on their histone PTMs. (B) Quantitative comparison of all histone PTMs detected via mass spectrometry. The heatmap displays red or blue color boxes according to the $\log_2(\text{relative abundance/average of relative abundance})$ of different peptides in four *Aspergilli*. 'Di-ac' indicates H4K5acK8ac, H4K5acK12ac, H4K5acK16ac, H4K8acK16ac, and H4K12acK16ac; 'tri-ac' means H4K5acK8ac12ac, H4K5acK8acK16ac, H4K5acK12acK16ac, and H4K8acK12acK16ac; and 'tetra-ac' indicates H4K5acK8acK12acK16ac.

Data availability

Data statement: All supporting data, code, and protocols have been provided within the article or through supplementary data files. Supplementary material is available with the online version of this article. The MS results are deposited in the PRIDE database with the dataset identifier PXD033478.

Acknowledgments

We thank Jos Houbraken for providing *A. fumigatus* strain and Joseph Strauss for providing two *A. nidulans* strains.

Funding information

Xin Zhang is funded by the Chinese Scholarship Council (CSC) (201907720028). This work was supported by EPIC-XS, project number 823 839, funded by the Horizon 2020 programme of the European Union.

Author contributions

X.Z. formal analysis, investigation, methodology, visualization, writing original draft; R.N. and A.V. formal analysis, investigation, methodology; T.B. funding acquisition, supervision, resources; J.C. conceptualization, funding acquisition, methodology, project administrations, supervision, visualization, writing original draft; M.F.S. conceptualization, funding acquisition, methodology, project administrations, supervision, visualization, writing original draft.

Abstract

Mass spectrometry is a powerful technique to uncover histone post-translational modifications (PTMs) in an unbiased and quantitative manner (Noberini et al., 2021). Yet, such analyses require good-quality protein samples, a challenge when working with fungi. Here, we present a protocol based on the work by Noberini and colleagues (Noberini et al., 2020) to extract histone proteins from filamentous fungi for applications like mass spectrometry-based analyses of histone PTMs. Several modifications were made: 1) additional cell disruption and homogenization steps using freeze-drying and TissueLyser II; 2) increased Triton X-100 concentration in the lysis buffer; and 3) prolonged incubation time in the lysis buffer. This protocol is reproducible, and the proteins extracted from three *Aspergillus* species (*Aspergillus niger*, *Aspergillus fumigatus*, and *Aspergillus nidulans*) were of good quality for mass spectrometry.

Guidelines

1. Use the proper medium to culture fungal strains.
2. Germinated spores from overnight cultures are the ideal starting material.
3. Disruption by TissueLyser II and sonication are necessary steps because fungal cells are protected by the cell wall which prevents efficient lysis.
4. 100 mg ground starting material per sample of *Aspergillus* ends up with enough yield (around 20 µg) for Bradford Protein Assay (He, 2011), SDS-PAGE (Sodium dodecyl sulfate polyacrylamide gel electrophoresis) visualization (Simpson, 2006), and mass spectrometry-based analysis (which ideally requires 3-4 µg of histones). Different fungal species may vary.

Materials

Solutions and reagents

- ACES buffer (1.822 g/L N-(2-Acetamido)-2-aminoethanesulfonic acid, 0.2 mL/L Tween 80)
- Solid medium and liquid medium depending on the strain (*A. niger* and *A. fumigatus* are cultured in MEA (Malt Extract Agar Oxoid 50 g/L) medium at 30 °C and 25 °C, respectively; *A. nidulans* is cultured in YAG medium (5 g/L yeast extract, 15 g/L agar, 20 g/L D-glucose, 1 mL/L trace elements (Solution A: Dissolve 10 g EDTA and 1 g FeSO₄ × 7H₂O in 80 mL water and adjust pH to 5.5; Solution B: Dissolve 4.4 g ZnSO₄ × 7H₂O, 1 g MnCl₂ × 4H₂O, 0.32 g CuSO₄ × 6H₂O, and 0.22 g (NH₄)₆Mo₇O₂₄ × 4H₂O in 80 mL water; Combine Solution A and B, adjust pH to 6.5) at 37 °C)
- PBS (Phosphate Buffered Saline) buffer (8.0 g/L NaCl, 0.2 g/L KCl, 1.44 g/L Na₂HPO₄ × 2 H₂O, 0.2 g/L KH₂PO₄, 1.32 g/L CaCl₂ × 2H₂O, and 0.5 mM MgCl₂ × 6H₂O)
- Lysis buffer (1× PBS, 0.5 mM PMSF, 5 µM Leupeptin, 5 µM Aprotinin, 5 mM Na-butyrate, and 1% or 10% Triton X-100)
- Aprotinin bovine (Sigma, A6103)
- Leupeptin (Sigma, L2884)
- Sodium butyrate (Sigma, B5887)
- Phenylmethylsulfonyl fluoride (PMSF; Fluka, 78830)
- Triton X-100 (Sigma, T8787)
- Acetone (Biosolve, 1046021)
- Coomassie protein assay reagent (Thermo, 1856209)

Equipment

- Centrifuge (Eppendorf, 5810R)
- Centrifuge (Eppendorf, 5430R)
- Hemacytometer (Marienfeld, 0.0025mm²)
- Freeze dryer (Christ, Alpha 1-4 LSCbasic)

- TissueLyser II (QIAGEN, C.0659)
- Orbital shaker (Grant-bio, PS-3D)
- Incubator (Yourtech, C.0663)
- Vortex (IKA, S000)
- Ultrasonic Cleaner (Branson 2510)

Before start instructions

1. Set centrifuges at 4 °C beforehand.
2. Acetone has strong flammability, always operate it inside a fume hood.
3. PBS buffer should be kept on ice.
4. Prepare lysis buffers with different Triton X-100 concentrations fresh and add PMSF last. PMSF stock solution in isopropanol can be stored at -20 °C for several months, but it can be inactivated within 35 minutes once it is added to the aqueous solution.

Method

Sample collection and disruption

1. Harvest fungal spores from 4- or 5-day-old sporulating plates with a spreader in 12.5 mL ice-cold ACES buffer.
2. Centrifuge the spore suspension at 2,500 xg at 4 °C for 5 minutes.
3. Discard supernatant and resuspend spores in 25 mL ice-cold ACES buffer.
4. Centrifuge the spore suspension at 2,500 xg at 4 °C for 5 minutes and discard the supernatant.
5. Resuspend spores in 10 mL ice-cold ACES buffer, and count spore concentration with a hemacytometer or spore counter. Ideally, the spore concentration is around 1×10^7 spores/ mL.
6. Inoculate 50 mL of liquid medium with $1 \sim 10 \times 10^7$ spores in a 250 mL flask, and incubate at 30 °C, 200 rpm, for 16 hours.
7. Collect germinated spores by centrifugation at 4,000 xg for 10 minutes and discard the supernatant.
8. Resuspend germinated spore pellet in 25 mL 0.8 M NaCl.
9. Centrifuge at 4,000 xg for 10 minutes and discard supernatant to get rid of liquid medium.
10. Freeze germinated spores in liquid nitrogen.
11. Freeze dry overnight.
12. Grind freeze-dried samples with a mortar and pestle, and then with TissueLyser II using two \varnothing 5 mm metal beads at 30 Hz for 30 seconds, which is repeated twice.

Histone protein extraction

1. Resuspend 100 mg ground sample in 1 mL lysis buffer with high Triton X-100 concentration (1×PBS, 0.5 mM PMSF, 5 μM Leupeptin, 5 μM Aprotinin, 5mM Na-butyrate, and 10% Triton X-100).
2. Incubate on an orbital shaker for 30 minutes at 4 °C.
3. Add 10 ml lysis buffer with low Triton X-100 concentration (1×PBS, 0.5 mM PMSF, 5 μM Leupeptin, 5 μM Aprotinin, 5mM Na-butyrate, and 1% Triton X-100), mix by vortexing, and incubate on the orbital shaker at 4 °C for another 30 minutes.
4. Centrifuge at 3,250 xg for 30 minutes at 4 °C, and discard supernatant.
5. Resuspend in 1 mL ice-cold PBS buffer.
6. Sonicate for 30 seconds; this process is repeated 10 times with 30 seconds break in between.
7. Add 9 mL ice-cold PBS buffer and mix by vortexing.
8. Centrifuge at 3,250 xg for 20 minutes at 4 °C, and discard supernatant.
9. Resuspend the pellet in 2 mL 0.4 N H₂SO₄ and incubate at 4 °C for 4 hours on an orbital shaker.
10. Centrifuge at 16,000 xg for 10 minutes at 4 °C. The supernatant contains soluble core histone proteins.
11. Add 4 volumes of acetone to the sample and keep at -20 °C overnight to precipitate histone proteins.
12. Centrifuge at 16,000 xg for 25 minutes at 4 °C to pellet proteins, then dissolve in 100 μL water.

Protein quantity and quality measurement

1. Measure protein concentration with the Bradford Protein Assay.
2. Check protein quality via 16% SDS-PAGE gel.

Chapter 5

General discussion

Fungal secondary metabolites (SMs) are small bioactive molecules with complex structures. They are not essential for normal fungal growth or reproduction but play critical roles in the interactions of fungi with other organisms or in response to environmental stimuli (Keller, 2019). Thanks to the biochemical versatility of SMs, humankind has utilized SMs for centuries in medicine, agriculture, food, and cosmetics (Mosunova et al., 2021). With the increasing accessibility of fungal genome sequences due to the development of next-generation sequencing (NGS) technologies, researchers have started to uncover an immense diversity of biosynthetic pathways that are predicted to synthesize SMs (Lind et al., 2017). However, only a limited number of these SMs have been discovered, studied, and extensively used to date (Mosunova et al., 2021). This discrepancy between the SMs experimentally discovered and the high number of biosynthetic pathways encoded in fungal genomes is due to our inability to accurately and efficiently express genes involved in the biosynthesis of SMs in the laboratory (Brakhage, 2013).

To address this bottleneck and to enable humankind to harness the as-of-yet largely untapped diversity of fungal SMs, it is therefore important to understand the regulatory mechanisms governing the expression of genes responsible for the biosynthesis of SMs. In **chapter 1**, I explained that the genes responsible for SM biosynthesis are often physically co-localized and co-regulated, an arrangement referred to as biosynthetic gene clusters (BGCs). The biosynthesis of SMs is regulated by a multi-tier regulatory mechanism, including both local and global transcription factors (TFs), and histone post-transcriptional modifications (PTMs). Several studies focused on a limited number of histone PTMs have shown that they are involved in the regulation of the biosynthesis of SMs in a few, well-known model fungal species (Yang et al., 2022). However, we still lack a complete understanding of how histone PTMs regulate SM biosynthesis in both well- and less-studied fungal species. In this thesis, I employed a combination of computational analyses (**chapters 2 and 3**) and wet-lab experiments (**chapters 3 and 4**), focusing on the fungal genus *Aspergillus*, an ensemble of diverse species that are known to be prolific producers of SMs (Soltani, 2016), with the overall aim to provide broader and deeper insights into genes involved in the biosynthesis of SMs and the roles of histone PTMs in regulating the expression of these genes.

In the last decade, studies have investigated the abundance and diversity of BGCs within a few so-called taxonomic sections of the *Aspergillus* genus (Kjærboelling et al., 2020; Vesth et al., 2018). For example, a study comparing 32 *Aspergilli* in the *Nigri* section revealed over 400 predicted BGCs, of which 49% are species-specific (Vesth et al., 2018). Similarly, another computational study in the *Flavi* section, which included 23 *Aspergilli*, uncovered 308 BGCs, with 150 being considered to be species-specific (Kjærboelling et al., 2020), suggesting that BGCs are numerous and diverse in *Aspergilli*. The *Aspergillus* genus is an ancient and large taxonomic group with an estimated 350 species, which diversified from the common ancestor shared with *Penicillium* species around 82 million years ago (Steenwyk et al., 2019). To obtain

a complete overview of BGC diversity, it is therefore crucial to explore and compare BGCs in more species and across diverse *Aspergillus* sections. In **chapter 2**, I provided a systematics exploration, employing computational approaches, to assess the BGC diversity and abundance in 174 *Aspergillus* species across 22 sections. I specifically focused on the SM biosynthetic backbone genes as these catalyze the crucial step of SM biosynthesis from primary precursors to the first stable intermediate (Mosunova et al., 2021). Interestingly, we found a high abundance and diversity of SM backbone genes across the *Aspergillus* genus, with notable diversity increases between sections. Moreover, it has been shown that SM backbone genes are often regulated by histone PTMs, and studies in a few fungal species indicated an enrichment of SM backbone genes in sub-telomeric regions (Keller, 2019; Klejnstrup et al., 2012; Perrin et al., 2007; Yang et al., 2022). Leveraging publicly available RNA-seq and ChIP-seq (*Chromatin ImmunoPrecipitation* assays followed by next-generation sequencing) data, I studied the correlation between SM backbone genes' genomic localization, gene expression, and histone PTMs. We found that SM backbone genes showed a strong bias for being localized in low synteny regions, regardless of their position in chromosomes or being unique or conserved across many species. Using chromosome-level genome assemblies, we also confirmed a significantly biased localization in sub-telomeric regions. Notably, SM backbone genes in sub-telomeric regions and about half of those in other low-syntenic regions exhibit higher gene expression variability, likely linked to similar higher variability in specific histone PTMs.

Most studies on histone PTMs in Aspergilli have solely focused on the well-characterized modifications of methylation and acetylation (Collemare & Seidl, 2019). Considering that other histone PTMs have been identified in different model species (Ahringer & Gasser, 2018; Boros, 2012; Jiang et al., 2007; Kimura, 2013) and that diverse combinations of PTMs can lead to distinct regulatory outcomes (Mosunova et al., 2021), our understanding of histone PTMs' roles in SM biosynthesis is not yet complete. To obtain an overview of different histone PTMs that can occur in Aspergilli, I performed both computational and experimental research. First, I conducted a systematic phylogenetic analysis of genes related to histone modifiers that mainly regulate histone PTMs (**chapter 3**). I investigated known genes involved in the establishment, maintenance, and readout of histone PTMs from well-studied fungal species and systematically assessed whether they are also present in the genomes of Aspergilli, which provides a proxy for the presence and function of the associated histone PTMs. Based on these results, I proposed that Aspergilli have the ability to perform most of the known histone PTMs as the genes responsible for these PTMs are encoded in their genomes. I subsequently provided experimental evidence for these computational predictions using mass spectrometry (**chapter 4**), which was facilitated by an experimental protocol, originally developed for human primary cells, that I optimized for filamentous fungi. The absence of detection of H3K27me (methylation on histone protein H3 at lysine 27) is consistent with my prediction of the loss of genes encoding enzymes involved in the deposition of H3K27me in the *Aspergillus* genus

(**chapters 3 and 4**). Mass spectrometry is an unbiased and quantitative method that allows for the detection and quantification of different types of histone PTMs among various species. In **chapter 4**, to my knowledge, I reported for the first time the detection of H3K79me1, H3K79me2, and H4K31ac in *Aspergilli*. Moreover, I discovered quantitative differences in the relative abundance of H3K9me1/2/3, H3K14ac, H3K36me1, and H3K79me1, and the co-occurrence of acetylations on both K18 and K23 of histone H3 in a species- and/or strain-specific manner. This suggests that the *Aspergilli* tested in this study utilize the same types of histone PTMs, albeit in a distinct manner. In this final chapter, I will further discuss the implications of my work and highlight promising developments that may affect our views on the regulation of SM biosynthesis.

The 'histone code' in *Aspergilli*

Chromatin organizes DNA within the eukaryotic nucleus and is mainly formed by DNA that is wrapped around a histone protein octamer composed of two copies of each of the histone proteins H2A, H2B, H3, and H4 (Baldi et al., 2020). PTMs of histone proteins can occur on the core fold of the proteins but predominantly occur on the N-terminal tails that protrude from the DNA-histone complex, the nucleosome (Luger et al., 1997). These modifications include not only well-studied PTMs such as mono-, di-, and tri-methylation, acetylation, phosphorylation, and ubiquitylation, but also less-studied modifications such as crotonylation, malonylation, succinylation, or propionylation (Bowman & Poirier, 2014). Studies have shown that both individual histone PTMs and distinct combinations of these modifications on the same histone proteins can influence the chromatin structure, allowing transitions between a 'loose' and transcriptionally active state and a 'compact', transcriptionally silent state (Collemare & Seidl, 2019). Histone PTMs at a genomic locus can synergistically or antagonistically act with other chromatin-associated proteins, which in turn are thought to drive these dynamic transitions that regulate gene expression to cope with developmental and environmental challenges (Jenuwein & Allis, 2001). The term 'histone code' was coined more than 20 years ago as an extension of the 'genetic (DNA) code' concept (Jenuwein & Allis, 2001), and since then has been further refined by studies in a few model eukaryotic species such as plant (Loidl, 2004), nematode (Ahringer & Gasser, 2018), fruit fly (Boros, 2012), and yeast (Jiang et al., 2007). Beyond these model species, the histone code in other organisms, including *Aspergilli*, remains largely unexplored. In this thesis, I provide substantial evidence that *Aspergilli* possess a histone code that shows remarkable conservation across various species and strains (**chapter 4**). Interestingly, the histone code in *Aspergilli* is also quite different compared to other model fungal species such as the filamentous fungus *Neurospora crassa*, the plant pathogen *Fusarium graminearum*, or the budding yeast *Saccharomyces cerevisiae* (**chapter 3**) (Zhang et al., 2022). For example, *S. cerevisiae* is known to have lost several genes encoding enzymes involved in histone PTMs including H3K9me, H3K27me, and H4K20me (Freitag, 2017), while *N. crassa* harbors all of them (Navarro-Mendoza et al., 2023; Zhang et al., 2022). This highlights the importance of recognizing that histone codes can differ across

species, necessitating careful considerations when extrapolating knowledge from one model species to another less studied species. In fact, both computational predictions and wet-lab experiments are likely needed to be certain of the histone code in any specific species of interest.

My research revealed that in Aspergilli, genes related to both facultative and constitutive heterochromatin (transcriptionally inactive) have largely been lost, while those associated with euchromatin (transcriptionally active) remain conserved (**chapters 3 and 4**). For instance, H3K27me₃ is associated with facultative heterochromatin, and it plays crucial roles in the timely and accurate gene expression regulation in other organisms (Ridenour et al., 2020). In *F. graminearum*, it regulates fungal development and the biosynthesis of SMs (Connolly et al., 2013), and in the plant pathogen *Verticillium dahliae*, local rather than global H3K27me₃ regulates gene expression in different culture conditions (Kramer et al., 2022). Interestingly, all genes of the catalytic complex PRC2 (Polycomb Repressive Complex 2) and the readers associated with H3K27me₃ such as EPR-1 or BP1 (Tang et al., 2021; Wiles et al., 2020; Zhang et al., 2023) are lost throughout the *Aspergillus* genus (**chapters 3 and 4**) as well as in three *Penicillium* species that we considered in our study. Given the important function of H3K27me₃ in facultative heterochromatin formation in other species (Moser Tralamazza et al., 2022), Aspergilli might rely on other histone PTMs to play a similar role to H3K27me₃. Possible candidates could be H3K36me_{2/3} and H4K20me₃, which we identified using mass spectrometry (**chapter 4**). H3K36me_{2/3} is catalyzed by Ash-1, a paralog to the conserved SET2 (**chapter 3**). In the plant pathogen *Fusarium fujikuroi*, H3K36me_{2/3} is catalyzed by Ash-1 that co-occurs with H3K27me₃ at facultative heterochromatic regions (Janevska et al., 2018). Moreover, this histone modification is known to induce the formation of H3K27me in *N. crassa* (Bicocca et al., 2018). In chapters 3 and 4, I found that *Ash-1* is present in most Aspergilli, and I also detected the presence of H3K36me_{2/3} on histone proteins. To test whether Ash-1 catalyzed H3K36me_{2/3} is directly related to facultative heterochromatin in Aspergilli, however, necessitates future experiments. For instance, ChIP-seq can identify genes marked by H3K36me_{2/3}, and ATAC-seq (Assay for Transposase-Accessible Chromatin using sequencing) can reveal the chromatin accessibility of these genes. For the other candidate, H4K20me₃, a recent paper on wheat pathogen *Zymoseptoria tritici* indicated that this mark can introduce and co-occur with H3K36me₃ catalyzed Ash-1 and H3K27me₃ catalyzed SET7 (Möller et al., 2023). The gene encoding its catalytic enzyme, *SET9 (KMT5)* is conserved in most of the *Aspergillus* species tested in my study (**chapter 3**), but I did not detect the presence of this histone PTM *via* mass spectrometry (**chapter 4**). This could be caused by the fact that the abundance of H4K20me in the conditions tested was too low to be detected. Moreover, as it has been shown that H4K20me and H4K16ac are competitive *in vitro* (Nishioka et al., 2002), and we indeed detected H4K16ac *via* mass spectrometry, and thus it is conceivable that H4K16ac inhibited H4K20me. More conditions need to be tested to see whether H4K20me is indeed present in Aspergilli and its specific roles will need to be tested

in mutants lacking *Ash-1* and *SET2*. With this evidence, we will gain more understanding of the roles of H3K36me_{2/3} and H4K20me in facultative heterochromatin formation in *Aspergilli* and whether they regulate SM biosynthesis. In regard to BGC expression, of the most studied histone PTMs, H3K4me₃ and H3K36me₃ indeed appear to be important (**chapter 2**). In contrast, H3K9me₃ and H3Kac are very stable PTMs that do not appear to explain variation in gene expression (**chapter 2**).

Chromatin modifications related to constitutive heterochromatin have been shown to be linked with methylations on the DNA cytosine and also on H3K9 (Grewal & Jia, 2007). In *N. crassa*, constitutive heterochromatin is formed by the deposition of H3K9me₃, followed by the recognition by the adapter protein HP1 that then recruits the DNA methyltransferase Dim-2 to perform *de novo* DNA methylation at the H3K9me₃-rich regions to further entrench the heterochromatin state (Rountree & Selker, 2010). In *Aspergilli*, even though two subunits that are part of the catalytic complex DCDC introducing H3K9me are lost in *Aspergilli* (**chapter 3**), I detected H3K9me_{1/2/3} *via* mass spectrometry (**chapter 4**). Moreover, in *Aspergilli*, the genes encoding HP1, and the DNA methyltransferase related to the maintenance of DNA methylation (DNMT5) are conserved, but not the ones for *de novo* DNA methylation (Dim-2 and DNMTX) (**chapter 3**). A study in the pathogenic fungus *Cryptococcus neoformans* shows that *DNMTX* was lost in an ancestral species around 50-150 million years ago (Catania et al., 2020). Dim-2 is a more recently derived *de novo* DNA methyltransferase across several groups in the fungal kingdom except the *Aspergillus* genus (Bewick et al., 2019). It is very likely that *Aspergilli* can only maintain DNA methylation but cannot introduce *de novo* DNA methylation to heterochromatin labeled by H3K9me. Thus, the heterochromatin state in *Aspergilli* is likely limited to the methylations on H3K9. Interestingly, it has been shown that genomic regions with high coverage of H3K9me are not associated with SM gene clusters in *Aspergillus fumigatus*, as only two out of 33 BGCs have H3K9me peaks within the clusters and only five BGCs have H3K9me peaks nearby (Colabardini et al., 2022). Consistently, we observed that H3K9me₃ does not regulate the expression of SM backbone genes in *Aspergillus nidulans* and *A. fumigatus* (**chapter 2**). Given these insights, future research should explore alternative epigenetic factors that operate constitutive heterochromatin independently of H3K9me₃ in controlling SM gene expression in *Aspergilli*.

In contrast to the dispensability of histone PTMs related to heterochromatin, modifications linked to euchromatin in *Aspergilli* are generally well conserved (**chapters 3 and 4**). Besides the typical euchromatin marks such as H3K4me_{1/2/3} catalyzed by SET1, H3K36me_{1/2/3} catalyzed by SET2, and acetylation on histone proteins H3 and H4 (Strauss & Reyes-Dominguez, 2011), I also detected the presence of H3K79me₁ and H3K79me₂ for the first time in *Aspergilli*. The catalytic gene encoding the enzyme that deposits H3K79me_{1/2/3}, *Dot1* (disruptor of telomeric silencing 1), was first found in *S. cerevisiae* and its overexpression disrupted telomeric silencing (Singer et al., 1998). Further study in *S. cerevisiae* shows it

marks the boundaries between heterochromatin and euchromatin, which acts together with acetylation on H4K16 to prevent the spreading of the SIR (Silent Information Regulator) complex with the function of heterochromatin formation (Farooq et al., 2016). In filamentous fungi, the knowledge of the potential roles of H3K79me remains limited. In *Aspergillus flavus*, the Δ *Dot1* mutant exhibits severely impaired aflatoxin production, but the effect on other genes related to SM production and the changes in H3K79me were not systematically explored (Liang et al., 2017). In my study, I observed significant differences in the relative abundance of H3K79me1 in different *Aspergillus* species (**chapter 4**). To further reveal the function of H3K79me in the regulation of SM biosynthesis, ChIP-seq needs to be performed in Aspergilli to check whether SM genes are decorated by this mark and how it changes under distinct conditions. Specifically, it is essential to determine the chromosomal localization of H3K79me in Aspergilli. It is particularly interesting to investigate whether H3K79me is enriched at the boundaries between heterochromatin and euchromatin, similar to observations in *S. cerevisiae* (Farooq et al., 2016), near or within sub-telomeric regions where some SM genes are located (**chapter 2**), or within low-syntenic regions that were found to be enriched in SM backbone genes (**chapter 2**). Understanding the spatial distribution of H3K79me will provide valuable insights into its functional roles in regulating SM biosynthesis in Aspergilli.

Scale matters

In the realm of high-throughput analyses, both the scale and the conditions under which data is collected influence our interpretation of biological processes. In my studies, I employed techniques such as RNA-seq, ChIP-seq, and mass spectrometry, which generated data from bulk *Aspergillus* cell populations (**chapters 2, 3, and 4**). These methods provide an averaged view of biological signals and mask the intricate heterogeneity and unique patterns present at the single-cell level. Moreover, by investigating SM backbone genes' genomic localization, I demonstrated that these genes preferentially locate at the low-syntenic regions and seem to locate at the sub-telomeric regions. However, it is important to note that this is based on the four chromosome-level assemblies available to date (**chapter 2**), and consequently, it currently remains unclear how these broad patterns are conserved throughout the genus – a question that can only be addressed once additional genomes with sufficient quality will become available. Similarly, I only cultured Aspergilli in a single condition to obtain the pattern of histone PTMs in three *Aspergillus* species (**chapter 4**), yet it is important to acknowledge that different cultural conditions will most likely yield distinct patterns. For example, the production of aflatoxin or penicillin can be significantly influenced by the substrate used, the pH of the environment, or the temperature during cultivation (Keller et al., 2005). For studying SM gene expression regulation, I utilized publicly available RNA-seq data that had been collected under various conditions (**chapter 2**). Future studies should track gene expression changes by comparing conditions of SM induction medium with normal growth medium, thereby investigating the gene regulation mechanisms of SM genes more thoroughly.

When studying *Aspergilli*, the genetic and phenotypic diversity among different strains, species, and taxonomic sections introduces multiple layers of complexity. We observed that the differences in relative abundances of histone PTMs are as pronounced within species as it is between species (**chapter 4**). This finding echoes research on the rice and wheat blast fungus *Magnaporthe oryzae* where machine learning methods revealed that different strains exhibit distinct H3K27 methylation and expression levels (Joubert & Krasileva, 2024). Consequently, a model trained on one strain proved inapplicable to another strain (Joubert & Krasileva, 2024). Coupled with our discovery that SM diversity is pronounced across sections but diminishes within individual sections, these insights underscore the importance of carefully defining the scope of comparison when drawing biological conclusions. Such consideration ensures that the inherent diversity of *Aspergilli* is accurately reflected and accounted for in research findings.

Concluding remarks

In this thesis, I have investigated histone PTMs as key regulatory mechanisms in SM biosynthesis within the *Aspergillus* genus. This study employed an integrative approach, combining computational analysis with wet-lab experiments. Initially, I revealed the high abundance and diversity of SM backbone genes across distinct *Aspergillus* sections. I also showed that SM backbone genes are preferentially located in low-syntenic regions and that their gene regulation is governed by specific histone PTMs. Furthermore, I analyzed the occurrences and quantitative differences of histone PTMs across various *Aspergillus* species and strains, identifying several marks with potential critical roles in SM biosynthesis regulation. For future investigations, I suggest scientists focus more on SM genes located at the low-syntenic regions and sub-telomeric regions because BGCs in these regions are more likely to be expressed and many remain uncharacterized. When comparing different *Aspergillus* strains, species, or sections, it is important to consider that they exhibit distinct patterns and vary in their scope. Three histone PTMs, H3K36me_{2/3} catalyzed by Ash-1, H4K20me₃, and methylations on H3K79 could be pivotal for the regulation of SM biosynthesis in *Aspergilli*. The anticipated future results combining ChIP-seq, ATAC-seq, and single-cell sequencing are likely to provide a deeper understanding of this regulation mechanism. This knowledge could unlock the vast potential of SMs for human benefit, advancing our understanding of epigenetic regulation in fungal biology.

Appendix

Summary

Secondary metabolites (SMs) are small bioactive molecules that are produced by diverse groups of organisms. These complex biochemicals are not essential for normal growth and reproduction but play crucial roles in interactions with other organisms and responding to environmental challenges. Fungal SMs have been invaluable treasures to humankind for centuries, being exploited across a myriad of applications, including medicine, agriculture, food, and cosmetics. Their biochemical versatility not only contributes to the development of novel pharmaceuticals but also promotes sustainable farming practices, enhances food preservation, and provides colorful pigments in various products. However, despite the immense diversity and complexity of SMs and their biosynthetic pathways encoded in fungal genomes, only a limited number of SMs have been discovered, extensively researched, and widely utilized to date. This extensive gap, at least in part, stems from our inability to express the enzymes responsible for biosynthesis accurately and efficiently in the laboratory. These enzymes are tightly regulated, as these metabolites are produced only under very specific conditions in nature, conditions that often prove difficult to emulate in laboratory settings. Consequently, the rich repertoire of SMs encoded in fungal genomes and their biochemical activities are not yet fully harnessed.

In **chapter 1** of this book, I introduce the concept of SM and biosynthesis gene clusters (BGCs) that are responsible for the production of SMs. BGCs are distinct groups of co-localized genes that are responsible for the regulation of expression, biosynthesis, and transport of SMs. Subsequently, I delineate the three-tier regulatory mechanisms that govern the expression of SM-BGCs, with a particular emphasis on histone post-translational modifications (PTMs). These chemical modifications affect histone proteins, which are crucial components of the DNA-protein complex called chromatin that organizes the genetic information within the eukaryotic nucleus. Histone modifiers, enzymes responsible for 'writing', 'erasing', and 'reading', regulate the occurrence and alterations of PTMs, thereby orchestrating distinct chromatin organizations within the nucleus. Broadly, chromatin can be divided into an 'open' and 'closed' state, and these conformations are thought to influence gene expression. In the last decade, a few PTMs have been demonstrated to play crucial roles in providing a global level of transcriptional regulation that also controls the biosynthesis of SMs in a handful of extensively studied fungal species. Here, I propose that PTMs, in general, are key to unlocking the as-of-yet largely unharnessed treasure chest of SMs. I suggest investigating this hypothesis in the *Aspergillus* genus because it is among the most prolific producers of SMs in the fungal kingdom, and such research could provide the basis for a better understanding of the control of SM biosynthesis, which ultimately might provide access to novel biochemistry for the benefit of humankind.

Initially, I explored the abundance and diversity of SM BGCs across the genus *Aspergillus* in **chapter 2**. I first reconstructed a species tree to establish a robust phylogenetic framework for 174 diverse *Aspergillus* species. Subsequently, utilizing a phylogenetic approach, I unveiled the diversity of SM backbone genes, which code for key biosynthetic enzymes. I found that SM backbone genes are abundant in the fungal genus *Aspergillus*, and additionally, I observed marked differences between taxonomic sections. Furthermore, I explored the genomic localizations of SM backbone genes and found that these genes show a strong bias for being localized in low-synteny regions. In chromosome-level genome assemblies of four *Aspergilli*, I revealed that some SM backbone genes are also located at the sub-telomeric regions. Finally, I probed the relationship between the localization of SM backbone genes and their expression and histone PTMs. With publicly available high-throughput sequencing data, I showed that SM backbone genes in sub-telomeric regions and about half of those localized in other low-synteny regions exhibit higher gene expression variability, likely linked to dynamics in specific histone PTMs.

To enhance our understanding of the evolutionary history of genes responsible for PTM formation and regulation across the *Aspergillus* genus in **chapter 3**, I summarized known histone modifiers from model species in the literature and conducted detailed phylogenetic analyses of these well-characterized protein complexes on a diverse selection of *Aspergilli* to unravel their evolutionary trajectories involved in the establishment or maintenance of PTMs. The protein complexes contain both catalytic subunits that catalyze the chemical modifications and accessory subunits. The latter contributes to the overall stability of the complex and establishes interactions with other proteins, thereby facilitating coordinated regulation and context-dependent fine-tuning of PTMs. I demonstrated that overall, these complexes are highly conserved in *Aspergilli*, suggesting that *Aspergillus* species, like other eukaryotes, harbor a complex repertoire of PTMs. Most genes encoding catalytic subunits are conserved, with the exception of *SET7*; additionally, next to *SET7*, genes encoding other subunits of the PRC2 complex are absent in *Aspergilli* and *Penicillium* species. PRC2 catalyzes the methylation of histone protein H3 at lysine position 27 (H3K27me₃), a modification that is typically associated with facultative 'closed' chromatin throughout most eukaryotes to timely and accurately regulate gene expression (Ridenour, Möller, and Freitag 2020). The absence of PRC2 suggests that *Aspergilli* and closely related taxa might have evolved a different mechanism to regulate chromatin conformation and, subsequently, gene expression. In genes encoding accessory subunits in other protein complexes, I discovered both recent gene losses and duplications, underscoring the potential for functional diversification within protein complexes regarding their biochemical or genomic targets. Collectively, these analyses provide an overview of the conservation of key genes related to PTMs in the genus *Aspergillus*, laying the foundation for understanding the mechanistic underpinnings of PTMs in this important fungal genus.

Thus far, most research on PTMs has focused on a small subset of chemical modifications. To confirm the presence of PTMs revealed in **chapter 3** and further explore the occurrence of additional yet unknown PTMs in *Aspergilli*, I conducted an unbiased and quantitative proteomics study. Utilizing mass spectrometry, this research aims to uncover PTM patterns in three diverse *Aspergillus* species; *Aspergillus niger*, *Aspergillus fumigatus*, and *Aspergillus nidulans*, which belong to three distinct taxonomic sections and exhibit varied lifestyles, pathogenicity, and industrial usage. First, I optimized an experimental protocol to extract high-quality histone proteins from filamentous fungi for mass spectrometry (see Appendix, **chapter 4**). Using this approach, in **chapter 4**, I provided an overview of the occurrence and relative abundance of PTMs. I detected 23 different PTMs, mostly lysine methylations and acetylations. Importantly, I corroborated my computational predictions regarding the presence and absence of PTMs from **chapter 3**. Specifically, I found that the absence of *SET7* leads to non-detectable levels of H3K27me in *Aspergilli*. For the first time, I reported the detection of H3K79me1, H3K79me2, and H4K31ac in *Aspergilli*, as well as the co-occurrence of multiple PTMs on the same histone proteins, offering new insights into the complexity of PTMs within these species. Although all three species harbor the same types of PTMs, I discovered significant differences in the relative abundance of H3K9me1/2/3, H3K14ac, H3K36me1, and H3K79me1, as well as the co-occurrence of acetylation on both K18 and K23 of histone H3 in a species and/or strain-specific manner. My exploration of PTMs in *Aspergilli* not only fortifies existing knowledge but also provides more understanding related to the enigmatic interplay of PTMs and genomic regulation in fungi.

To conclude and provide a perspective for further studies, **chapter 5** introduces the concept of the 'histone code in *Aspergilli*.' In this chapter, I highlight three different histone PTMs that I have uncovered in my research. I propose that H3K36me2/3, catalyzed by Ash-1, and H4K20me3 may perform analogous functions in compensating for the absence of the facultative heterochromatin mark H3K27me3 in *Aspergilli*. Additionally, methylation on H3K79, which marks euchromatin, is a promising candidate to play a role in regulating SM biosynthesis due to significant differences in relative abundances among different *Aspergillus* species and strains. These histone modifications might co-localize with SM backbone genes in regions of low synteny. For the discovery and characterization of SM genes, I propose that future researchers pay closer attention to low-synteny and sub-telomeric regions in *Aspergilli*. Based on my findings, it is conceivable that BGCs in these areas are more likely to be expressed, yet many remain uncharacterized. With the anticipated advancements in research, we now stand on the brink of unlocking the immense potential of SMs and significantly enhancing our understanding of epigenetic regulation in fungal biology.

Samenvatting

Secundaire metabolieten (SM's) zijn kleine bioactieve moleculen die door verschillende groepen organismen worden geproduceerd. Deze complexe biochemische stoffen zijn niet essentieel voor normale groei en voortplanting, maar spelen een cruciale rol in de interacties met andere organismen en in het reageren op ecologische uitdagingen. Schimmel-SM's zijn al eeuwenlang van onschatbare waarde voor de mensheid en worden benut in een breed scala aan toepassingen, waaronder in geneeskunde, landbouw, voeding en cosmetica. Hun biochemische veelzijdigheid draagt niet alleen bij aan de ontwikkeling van nieuwe farmaceutica, maar bevordert ook duurzame landbouw, verbeterde voedselconservering en levert kleurrijke pigmenten voor verschillende producten. Echter, ondanks de immense diversiteit en complexiteit van SM's en hun bio-synthetische pathways gecodeerd in schimmelgenomen, tot op heden is slechts een beperkt aantal SM's ontdekt, uitgebreid onderzocht en breed ingezet. Deze aanzienlijke kloof is ten dele te wijten aan onze onvermogen om de enzymen verantwoordelijk voor de biosynthese nauwkeurig en efficiënt in het laboratorium tot expressie te brengen. Deze enzymen worden strikt gereguleerd omdat deze metabolieten alleen onder zeer specifieke omstandigheden in de natuur worden geproduceerd. Deze omstandigheden zijn vaak moeilijk na te bootsen in een laboratorium. Bijgevolg is het rijke repertoire van SM's gecodeerd in schimmelgenomen en hun biochemische activiteiten nog niet volledig benut.

In **hoofdstuk 1** van dit boek introduceer ik het concept van SM en biosynthese gene clusters (BGC's) die verantwoordelijk zijn voor de productie van SM's. BGC's zijn duidelijke groepen van co-gelocaliseerde genen die verantwoordelijk zijn voor de regulatie van expressie, biosynthese en transport van SM's. Vervolgens schets ik de drie laags reguleringsmechanismen die de expressie van SM-BGC's beheersen, met bijzondere nadruk op de histon post-translationele modificaties (PTM's). Deze chemische modificaties beïnvloeden histon eiwitten, die een cruciale component zijn van het DNA-eiwitcomplex genaamd chromatine, welke de genetische informatie binnen de eukaryotische kern organiseert. Histon modificerende eiwitten, enzymen verantwoordelijk voor het 'schrijven', 'wissen' en 'lezen', reguleren de aanwezigheid en de veranderingen van PTM's, waardoor ze verschillende chromatineorganisaties binnen de kern orkestreren. In grote lijnen kan chromatine worden verdeeld in een 'open' en een 'gesloten' staat, en van deze conformaties worden verondersteld dat ze de genexpressie beïnvloeden. In het afgelopen decennium is er aangetoond dat enkele PTM's een cruciale rol spelen in de globale transcriptieregulatie die ook de biosynthese van SM's regelt in een handvol uitgebreid bestudeerde schimmels. Hier stel ik voor dat PTM's in het algemeen de sleutel zijn om de tot nu toe grotendeels onbenutte schatkist van SM's te openen. Ik stel voor deze hypothese te onderzoeken in het geslacht *Aspergillus* omdat deze tot de meest productieve producenten van SM's in het schimmelrijk behoort. Dergelijk onderzoek zou de basis kunnen vormen voor een beter begrip over van de

controle van SM-biosynthese, wat uiteindelijk toegang zou kunnen bieden tot nieuwe biochemie ten behoeve van de mensheid.

Aanvankelijk onderzocht ik in **hoofdstuk 2** de overvloed en diversiteit van SM BGC's in het geslacht *Aspergillus*. Ik reconstrueerde eerst een soortenboom om een robuust fylogenetisch kader te vestigen voor 174 verschillende *Aspergillus*-soorten. Vervolgens onthulde ik, gebruikmakend van een fylogenetische benadering, de diversiteit van fundamentele SM-genen, die coderen voor sleutel biosynthetische enzymen. Ik ontdekte dat fundamentele SM-genen overvloedig aanwezig zijn in het schimmelgeslacht *Aspergillus*, en daarnaast observeerde ik opvallende verschillen tussen taxonomische secties. Verder onderzocht ik de genomische lokalisaties van de fundamentele SM-genen en ontdekte dat deze genen een sterke voorkeur hebben om gelokaliseerd te zijn in regio's met lage synteny. In chromosoomniveau-genoomassemblages van vier *Aspergilli* onthulde ik dat sommige fundamentele SM-genen ook gelegen zijn in de subtelomere regio's. Ten slotte onderzocht ik de relatie tussen de lokalisatie van fundamentele SM-genen, hun expressie en histon PTM's. Met publiekelijk beschikbare high-throughput sequencing data toonde ik aan dat fundamentele SM-genen zich bevinden in subtelomere regio's, waarvan ongeveer de helft gelokaliseerd is in andere regio's met lage synteny en een hogere variabiliteit in genexpressie vertoont, waarschijnlijk gekoppeld aan de dynamiek in specifieke histon PTM's.

Om ons begrip van de evolutionaire geschiedenis van genen verantwoordelijk voor PTM-vorming en -regulatie door het geslacht *Aspergillus* in **hoofdstuk 3** te verbeteren, heb ik bekende histonmodificeerders uit modelsoorten in de literatuur samengevat. Daarnaast heb ik gedetailleerde fylogenetische analyses uitgevoerd op deze goed gekarakteriseerde eiwitcomplexen in een diverse selectie van *Aspergilli* om hun evolutionaire trajecten te ontrafelen en te kijken of ze betrokken zijn bij de oorsprong of het onderhoud van PTM's. De eiwitcomplexen bevatten zowel katalytische subeenheden die de chemische modificaties katalyseren als accessoire subeenheden. Laatstgenoemden dragen bij aan de algehele stabiliteit van het complex en faciliteren interacties met andere eiwitten, waardoor gecoördineerde regulatie en contextafhankelijke afstemming van PTM's wordt gefaciliteerd. Ik heb aangetoond dat, over het algemeen, deze complexen sterk geconserveerd zijn in *Aspergilli*, wat suggereert dat *Aspergillus*-soorten, net als andere eukaryoten, een complex repertoire van PTM's herbergen. De meeste genen die katalytische subeenheden coderen zijn geconserveerd, met uitzondering van *SET7*; daarnaast zijn, naast *SET7*, genen die andere subeenheden van het PRC2-complex coderen afwezig in *Aspergilli* en *Penicillium*-soorten. PRC2 katalyseert de methylering van histoneiwit H3 op lysinepositie 27 (H3K27me3), een modificatie die doorgaans geassocieerd wordt met facultatief 'gesloten' chromatine door de meeste eukaryoten om genexpressie tijdig en nauwkeurig te reguleren (Ridenour, Möller, en Freitag 2020). De afwezigheid van PRC2 suggereert dat *Aspergilli* en nauw verwante taxa mogelijk een ander mechanisme hebben geëvolueerd om chromatineconformatie en

vervolgens genexpressie te reguleren. In genen die accessoire subeenheden in andere eiwitcomplexen coderen, ontdekte ik zowel recent verlies als duplicatie van genen. Dit benadrukt de potentie voor functionele diversificatie binnen deze eiwitcomplexen met betrekking tot hun biochemische of genomische functies. Collectief bieden deze analyses een overzicht van de conservering van sleutelgenen gerelateerd aan PTM's in het geslacht *Aspergillus*, en leggen de basis voor het begrijpen van de mechanistische basis van PTM's in dit belangrijke schimmelgeslacht.

Tot dusver heeft het meeste onderzoek naar PTM's zich gericht op een kleine subset van chemische modificaties. Om de aanwezigheid van de in **hoofdstuk 3** onthulde PTM's te bevestigen en verder de voorkomst van aanvullende nog onbekende PTM's in *Aspergilli* te verkennen, heb ik een onbevooroordeelde en kwantitatieve proteomica-studie uitgevoerd. Met behulp van massaspectrometrie heeft dit onderzoek als doel PTM patronen in drie diverse *Aspergillus*-soorten te onthullen; *Aspergillus niger*, *Aspergillus fumigatus*, en *Aspergillus nidulans*, die tot drie verschillende taxonomische secties behoren en variëren in levensstijl, pathogeniciteit en industrieel gebruik. Eerst heb ik een experimenteel protocol geoptimaliseerd om hoogwaardige histoneiwitten uit filamentaire schimmels te extraheren voor massaspectrometrie (zie Bijlage, **hoofdstuk 4**). Met deze aanpak heb ik in **hoofdstuk 4** een overzicht gegeven van de aanwezigheid en relatieve aanwezigheid van PTM's. Ik detecteerde 23 verschillende PTM's, voornamelijk lysinemethyleringen en -acetyleringen. Belangrijk is dat ik mijn computationele voorspellingen met betrekking tot de aanwezigheid en afwezigheid van PTM's uit **hoofdstuk 3** heb bevestigd. Specifiek vond ik dat de afwezigheid van *SET7* leidt tot niet-detecteerbare niveaus van H3K27me in *Aspergilli*. Voor de eerste keer rapporteerde ik de detectie van H3K79me1, H3K79me2, en H4K31ac in *Aspergilli*, evenals het gelijktijdig voorkomen van meerdere PTM's op dezelfde histoneiwitten, wat nieuwe inzichten biedt in de complexiteit van PTM's binnen deze soorten. Hoewel alle drie de soorten dezelfde soorten PTM's herbergen, ontdekte ik significante verschillen in de relatieve aanwezigheid van H3K9me1/2/3, H3K14ac, H3K36me1, en H3K79me1, evenals het gelijktijdig voorkomen van acetylering op zowel K18 als K23 van histon H3 op een soort- en/of stamspecifieke manier. Mijn verkenning van PTM's in *Aspergilli* versterkt niet alleen bestaande kennis, maar biedt ook meer inzicht in de raadselachtige interactie van PTM's en genetische regulatie in schimmels.

Om af te sluiten en een perspectief voor verdere studies te bieden, introduceert **hoofdstuk 5** het concept van de 'histoncode in *Aspergilli*.' In dit hoofdstuk benadruk ik drie verschillende histon-PTM's die ik in mijn onderzoek heb ontdekt. Ik stel voor dat H3K36me2/3, gekatalyseerd door Ash-1, en H4K20me3 mogelijk analoge functies vervullen in het compenseren voor de afwezigheid van het facultatieve heterochromatinekenmerk H3K27me3 in *Aspergilli*. Daarnaast is methylering op H3K79, dat euchromatine markeert, een

Appendix

veelbelovende kandidaat om een rol te spelen bij het reguleren van SM-biosynthese vanwege significante verschillen in relatieve aanwezigheid tussen verschillende *Aspergillus*.

Acknowledgements

Wageningen is certainly the starting point of my research life. My special appreciation goes to **Zhao Zhang**, you are the very first person who introduced Wageningen University & Research to me around 10 years ago. You showed me the door to the world of scientific research. Luckily, in 2017, I started my dream journey at Wageningen, and more connections began to develop. First, I want to thank **Bart Thomma**. Your excellent courses on plant-microbe interactions inspired me a lot. I am also endeared and inspired by the Verticillium group you lead. From there, I met two of the most important people for my PhD journey: **Michael** and **Jerome**. You are the perfect combination of supervisors I could have imagined, guiding me through all the ups and downs in the unforgettable PhD life. Thank you, Michael, for the encouragement on my switch to Bioinformatics, for the guidance that helped me keep things in order and under control, and for the inspiring conversations on work and life. Thank you, Jerome, for your insights on fungal metabolites, for your caring and suggestions on my career, and for the mushroom book you gave me, which sparked my hobby of reading cookbooks. Thank you for the magic reactions between you two, providing me with the perfect balance and support to complete my PhD. I also appreciate a lot of other connections from Wageningen. **Martin**, you are an amazing supervisor, guiding me step-by-step throughout an entire research project. I learned a lot from you on how to plan and conduct experiments, how to give presentations, and scientific writing, thank you! **Hui** and **Bart**, thank you for all the chats we had and all the common emotions we shared. I wish you success in returning to the Netherlands. Thank you, **Nick**, **Gabriel**, and **David**, I am deeply impressed by your diverse and charming characteristics; Talking to you always provokes a lot of thoughts and empathy. I wish all of you all the best. Now, **Tangtang** and **Jiahui**, I'm very glad that we have so much in common in our personal growth paths, I have enjoyed all our long and cheerful chats, and I wish you two big successes in conquering the last part of your PhD. I look forward to joining your defenses soon.

The network continued to grow as I moved to the lovely city of Utrecht to start my PhD at Utrecht University in 2019. I am particularly grateful to my PhD promoter **Berend**. Thank you for accepting me as a member of the Theoretical Biology & Bioinformatics group! Thank you for all your enlightening questions and suggestions! Moreover, I want to thank all the members of the Microbial Genome Evolution team, we are such a nice and warm family. Special appreciation to **Iseult**, my first Master student. Thanks for your contributions to one chapter of this book, and I wish you all the best for your PhD journey in Spain. To **Anouk** and **Petros**, I really enjoyed my time with you in Innsbruck. More appreciation to **Anouk** for being my paranymp! To **Josje**, thank you for translating the summary of this book into Dutch. You and **David** are the youngest generation of Michael's PhD candidates, I wish you two a lot of success. Moreover, thank you, **Laura** and **Max**, my office mates. We had so many good

conversations in the office and so many relaxing walks around campus. Special thanks to **Laura** for your contributions to the translation of the summary. **Sarah** and **Tina**, thank you for the chats about plant breeding companies and fun activities at Utrecht. Lastly, I want to thank the rest members of TBB, **Monica**, **Bram**, and **Lingyi**, for organizing all kinds of group activities; **Bas**, for answering all my questions on PhD defence quickly and clearly; and **Chrats**, for all the intriguing discussions we had!

Besides the computational life at TBB, I also had a wet-lab life in the Fungal Natural Products (FNP) group at the Westerdijk Fungal Biodiversity Institute. I want to thank **Roya** and **Olga**. Thank you for your company during the last and most challenging phases of our PhD journey. Thank you for your great kindness and for sharing all the encouragement, bravery, and persistence. Special appreciation to **Roya** for being my paranymph; I wish you and Javad a lovely life in the Netherlands. To **Yanfang**, I am sure you will finish your PhD as planned soon, good luck to you! Thank you, **Caroline** and **Elske**, for making a comfortable lab environment and arranging many potluck gatherings. To the other members of FNP, **Jorge**, **Khyati**, **Lhais**, **Zaneta**, **Chendo**, and **Tim**, thank you for your company, you made FNP feel like home to me. Also, I want to thank the other members at Westerdijk. Thank you, **Jos**, **Martin**, and **Bart**, for helping me prepare the *Aspergillus fumigatus* strains; **Michel**, for assisting with the ChIP-seq experiment; and **Dianne** and **Manon**, for helping me arrange the printing. Thank you, **Jiajia** and **Yabin**, for all the chats we had in the hallway and all your encouragement; I hope you enjoy your post-doc journey. To **Dujuan**, **Li**, **Lin**, and **Raquel**, thank you for all the company and I wish you much success in wrapping up your PhD theses.

I could not have finished my PhD without my lovely friends. **Yan** and **Jingjing**, thank you so much for all the time we spent together. The museums and parks we visited, the delicious food we cooked, and the easy, fun conversations we had are all treasures of my life. I truly believe that you will complete your PhD as planned and continue to harvest the beauty of life. Thank you, **Tao**, for all the company, sharing, and discussions since high school; it's been a great pleasure growing up with you. Thank you, **Yitong**, for all the catchups we've had since our bachelor's days, and I wish you much success in your scientific endeavors. **Zhiyi**, thank you for adding so much joy and adventure to our trip. I enjoyed the beauty we saw and taking pretty pictures of you. I wish you continued enjoyment in exploring the world.

In addition, I would like to extend a heartfelt thank you to my family. To my **grandparents**, thank you for taking care of me during my childhood in Liaoning. Thanks to my **uncle** and **aunt**. Your bravery and hard work in Beijing have always been an inspiration to me. A special thanks to my

最后，我要由衷感谢我的家人。感谢**爷爷奶奶、姥姥姥爷**，照顾年幼的我在东北黑土地上快乐成长。感谢**舅舅舅妈**，你们在北京打拼闯荡的勇敢精神一直都是我的榜样。特别感谢我的**姐姐**在

sister for drawing the cover of my thesis during your pregnancy. This thesis is our 'joint' baby, and I sincerely hope your lovely baby grows up healthy and happy! I want to express my deepest gratitude to my **parents**. Thank you for your love and support throughout my life. Your belief in me gives me the courage to pursue whatever I want; I know that you are always my solid support. Lastly, I want to thank my **boyfriend Liang**. You are so warm and kind, with a boundless curiosity and spirit of exploration. Meeting you has been the most wonderful thing in my life. The time we have spent together has been so colorful and fulfilling. Now, more than ever, I am determined to walk hand in hand with you through the vastness of life, from the present into the future!

怀孕期间为我绘制毕业论文封面，这本书是我们共同的“宝宝”；同时祝愿姐姐的龙宝宝健康快乐地成长！**老爹妈妈**，感谢你们一直以来对我无穷无尽的爱和支持。你们的信任让我有勇气去追求我想要的一切，因为我知道你们永远是我最坚实的后盾。最后最后，感谢我的**男朋友**，我的“**耿同学**”。你是如此明亮温暖，充满好奇心，永怀探索精神。与你相遇是我生命里最美好的缘分，与你相处总是丰富多彩又充实。我愈发坚定，与你一同携手漫步人生路，从现在到未来！

Curriculum vitae

Xin Zhang was born in Liaoning province, China, on 24 December 1994. In 2013, she started studying Agronomy at China Agricultural University (CAU). From 2015 to 2016, she completed a national-level training program under the supervision of Prof. Zhao Zhang at the Horticultural College of CAU, aiming to boost the resistance of roses to powdery mildew disease. She then joined Prof. Qingchang Liu's group at the Agronomy College of CAU, where she studied sweet potato breeding. In 2017, she began her master's studies at Wageningen University & Research (WUR). Her first Master's internship was supervised by Prof. Bart Thomma at the Phytopathology group of WUR, where she investigated the chromatin-based regulation of *Verticillium dahliae* effector gene expression *in planta*. Her second internship was supervised by Dr. Michael Seidl, during which she built a bioinformatics pipeline to study the evolutionary trajectories of chromatin modifiers across the fungal kingdom. In 2019, she began her PhD at Utrecht University (UU) under the supervision of Dr. Michael Seidl (Theoretical Biology & Bioinformatics group, UU) and Dr. Jérôme Collemare (Westerdijk Fungal Biodiversity Institute), with Prof. Berend Snel as the promoter. During her PhD journey, she focused on studying histone modifications and their roles in the regulation of secondary metabolite biosynthesis in the *Aspergillus* genus.
