Mechanisms and biogeochemical implications of the
mid-Cretaceous
global organic carbon burial events

**Mechanisms and biogeochemical implications of the mid-Cretaceous global organic carbon
burial events**

Mechanismen en biogeochemische gevolgen van wereldwijde organische koolstof begravings
episodes tijdens het midden Krijt

(Met een samenvatting in het Nederlands)

Proefschrift ter verkrijging van de graad van doctor
aan de Universiteit Utrecht
op gezag van Rector Magnificus, Prof. Dr. W. H. Gispen
ingevolge het besluit van het College voor Promoties
in het openbaar te verdedigen
op maandag 17 september des ochtends te 10.30 uur

Door
Marcel Martinus Maria Kuijpers
geboren op 6 juni 1970, te Hunsel

Promotor: Prof. Dr. J. W. de Leeuw
Co-promotor: Dr. Ir. J. S. Sinninghe Damsté

The investigations were supported by the Research Council for Earth and Life Sciences (ALW) with financial aid from the Netherlands Organisation for Scientific Research (NWO).

ISBN 90-5744-066-0

Chapter 1

Introduction and summary

Marcel M. M. Kuypers

1.1 The mid-Cretaceous oceanic anoxic events

The interval spanning the Barremian to Turonian (~125-88 Ma) is known as the mid-Cretaceous 'greenhouse' world [Barron, 1983]. As a possible analogue for future climates influenced by anthropogenically enhanced carbon dioxide emissions, the 'greenhouse' climate of the mid-Cretaceous received close attention in the last decades. Both marine and terrestrial proxies indicate that the mid-Cretaceous climate was significantly warmer with a smaller equator-to-pole temperature gradient than the modern climate (Fig. 1) [Barron, 1983; Huber *et al.*, 1995].

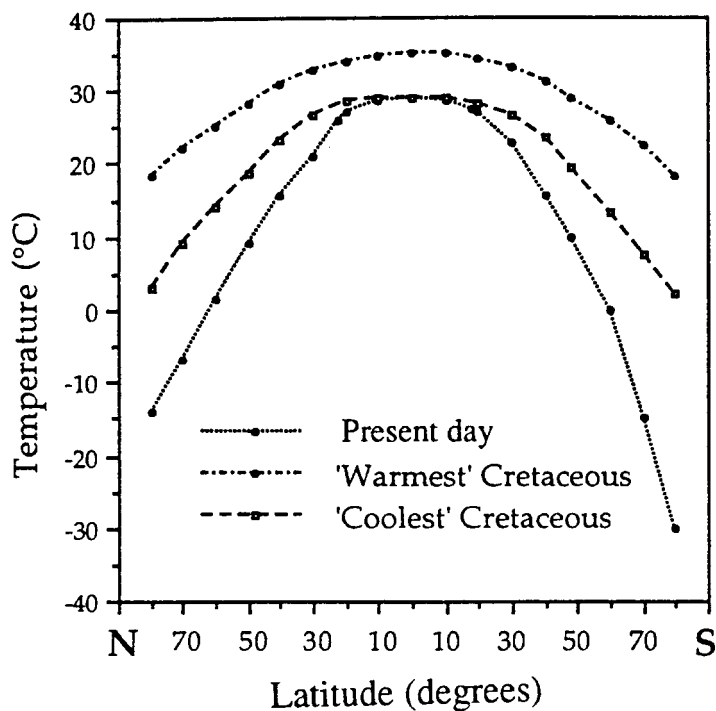

Figure 1. Estimates of latitudinal maximum and minimum temperature gradients for the mid-Cretaceous plotted for comparison against present day mean annual surface temperature [from Sellwood *et al.*, 1994].

It has been suggested that this resulted from an anomalous amount of oceanic volcanism [Arthur *et al.*, 1985; Larson, 1991], leading to 3 to 12 times higher atmospheric levels of carbon dioxide during the Cretaceous than at present (Fig. 2) [Bernier, 1992].

Figure 2. Best estimates of RCO_2 (i.e. the carbon dioxide concentration at a given time normalised to the present day value) versus time. The arrow denotes that early Paleozoic RCO_2 values may be higher. The dashed lines represent a rough estimate of errors based on sensitivity studies [from *Berner, 1991*].

Burial of organic matter (OM) in the marine realm could have provided a feedback mechanism to the enhanced volcanic outgassing of the mid-Cretaceous. As a result of carbon dioxide exchange between the atmosphere and the ocean, uptake of dissolved inorganic carbon (DIC) during photosynthesis and subsequent export of phytoplanktonic biomass to deeper water and underlying sediment act as a biological carbon dioxide pump. Organic matter (OM) degradation (i.e. respiration) and ocean circulation will eventually return most of this carbon dioxide again to the atmosphere. However, a small amount of OM escapes degradation and is buried in the sediment. This burial of sedimentary OM largely controls the carbon dioxide content of the atmosphere on geological time scales [*Berner, 1991*; *Berner, 1992*].

Oceanic anoxic events (OAEs), episodes of globally enhanced organic carbon (OC) burial rates, may have reduced CO_2 concentrations of the mid-Cretaceous 'greenhouse' atmosphere especially effectively by sequestering large amounts of carbon in the subsurface. Originally the term OAE was introduced to describe the episodic expansion and intensification of the Oxygen Minimum Zone (OMZ), which was proposed to explain the seemingly global distribution of laminated sediments rich (> 1%) in organic carbon (OC) (black shales) in pelagic sequences of Aptian-Albian and Cenomanian/Turonian (C/T) age [*Schlanger and Jenkyns, 1976*]. Since then several other time-bounded envelopes of particularly, perhaps more globally, widespread black shale deposition in marine environments have been identified [*Arthur et al., 1987*] and a total of five OAEs has been

recognised for the mid-Cretaceous (Fig. 3). In most cases the OAE black shales are devoid of or strongly impoverished in benthic faunas indicating that these sediments were deposited under

oxygen-deficient bottom-water conditions [*Summerhayes*, 1987]. The most intensely studied OAEs occurred near the Barremian/Aptian (OAE1a) and Cenomanian/Turonian (C/T OAE or OAE2) transition (Fig. 3). Both OAEs are accompanied by a significant increase in $^{13}\text{C}/^{12}\text{C}$ ratios for marine carbonates (up to 2.5‰) and organic matter (upto 6‰). This positive excursion in $\delta^{13}\text{C}$ values likely resulted from preferential removal of ^{12}C by the globally enhanced burial of ^{13}C

depleted OC into black shales [Arthur *et al.*, 1988]. Positive shifts in $\delta^{13}\text{C}$ values of marine carbonate, albeit significantly smaller, may also have been associated with other mid-Cretaceous OAEs [Erbacher and Thurow, 1997].

The OAE that occurred near the C/T boundary is the most extensive and has been considered as the type example of the the mid-Cretaceous OAEs [Wignall, 1994]. The C/T OAE was accompanied by a marine extinction event that especially affected certain reef building molluscs [i.e., rudists, Johnson *et al.*, 1996; Philip and Airaud-Crumiere, 1991], and planktonic foraminifera [Jarvis *et al.*, 1988]. In addition, evidence of a significant decrease in atmospheric CO_2 concentrations during the C/T OAE was provided by the drop in the isotope effect associated with carbon fixation (ϵ_p) by phytoplankton in the Cretaceous Western Interior Seaway (Fig. 4) of the United States [Freeman and Hayes, 1992]. This decline is also documented indirectly by oxygen isotope data, which indicate an 8-13°C cooling at high latitudes during the early Turonian [Arthur *et al.*, 1988; Jenkyns *et al.*, 1994]. Additional indications of global cooling are provided by micropaleontological data, showing an incursion of boreal fauna into low latitude seas [Kuhnt *et al.*, 1986].

1.2 Models for black shale deposition during the mid-Cretaceous OAEs

Two fundamentally different models have been used to explain the enhanced OM burial rate during the OAEs. The *preservational* model is based on decreased OM remineralisation resulting from a decreased oxygen flux. In the modern world's oceans deep ocean circulation is driven by the convective sinking of cold, dense, well-oxygenated water in polar regions (thermohaline circulation). Although enhanced oxygen consumption by OM decomposition and slow downward mixing and diffusion of dissolved oxygen from the surface waters can lead to very oxygen-deficient mid waters (i.e. the OMZs), true anoxic conditions are generally restricted to the sediments and basins isolated from oxygenated deep-sea circulation. However, in the mid-Cretaceous, anoxic water column conditions may have developed more readily as minimal equator-to-pole thermal gradients should have resulted in a decreased formation of oxygenated bottom-waters [Barron, 1983]. In addition, a halothermal mode of circulation with the formation of oxygen-poor, warm deep-water in subtropical, net evaporative regions instead of thermohaline circulation has been suggested for the mid-Cretaceous [Chamberlin, 1906; Brass *et al.*, 1982; Hay, 1988]. This could have resulted in basin-wide oxygen deficiency with the most intense dysoxia/anoxia occurring in the deepest parts of tectonically isolated basins such as the Cretaceous North and South Atlantic (Fig. 4) [Zimmerman *et al.*, 1987; De Graciansky *et al.*, 1984]. The reoccurrence of thinly laminated OM-rich sediments devoid of traces of benthic activity indicates that middle Cretaceous bottom-waters were indeed periodically anoxic [Summerhayes, 1987; Bralower and Thierstein, 1987]. Sedimentary derivatives (molecular fossils) of a pigment indicative of anoxygenic photosynthetic bacteria recovered from abyssal and shelf sites indicate that anoxic conditions extended even into the photic zone of the southern proto-North Atlantic during the C/T OAE [Sinninghe Damsté and Köster, 1998a]. Extensive denitrification in largely anoxic or suboxic mid and deep waters may have led to N_2 -fixing cyanobacteria periodically dominating phytoplankton communities during the early to middle Cretaceous [Rau *et al.*, 1987].

The *productivity* model is based on a greatly increased primary productivity that overwhelmed the oxic OM remineralisation potential of the water column. Primary productivity in the modern marine environment is largely controlled by the input of biolimiting nutrients from deeper water into the surface waters. Either enhanced vertical circulation (upwelling), or an enhanced supply of biolimiting nutrients from the terrestrial realm [Erbacher *et al.*, 1996] or from enhanced volcanism [Sinton and Duncan, 1997], could have led to increased primary productivity and thus to an expansion and intensification of the OMZs during the OAEs [Schlanger and Jenkyns, 1976]. The deposition of OM-rich sediments would have largely been confined to places where the OMZ impinged on the continental margin or other elevated portions of the sea floor, as the deepest places of the basin may have remained oxic. This model has especially been used to explain the OM-rich deposits in the Cretaceous Pacific Ocean [Schlanger and Jenkyns, 1976; Thiede and van Andel, 1977].

1.3 Biomarkers as tracers of environmental changes during the mid-Cretaceous OAEs

Unlike certain dinoflagellates, diatoms and calcareous algae, many other common pelagic algae and bacteria (e.g. cyanobacteria) do not leave behind microscopically identifiable fossilised remains in the sedimentary record. Instead, taxon specific biochemicals (i.e. biomarkers), such as membrane lipids and pigments or molecular fossils of these compounds formed upon diagenesis, can provide information about their relative abundance in ancient marine environments. Hence these biomarkers can reveal valuable insight concerning the environmental conditions during sediment deposition [Peters and Moldowan, 1993; De Leeuw *et al.*, 1995].

For example, Sinninghe Damsté and Köster [Sinninghe Damsté and Köster, 1998a] recovered molecular fossils (i.e. sulfur (S)-bound isorenieratane) of a pigment indicative of anoxygenic photosynthetic bacteria from C/T OAE abyssal and shelf sediments of the southern part of the North Atlantic Ocean. S-bound isorenieratane is formed in anoxic sediments upon sulfurisation of the polyunsaturated pigment isorenieratene in the presence of reduced inorganic S species [Sinninghe Damsté *et al.*, 1993; Koopmans *et al.*, 1996]. The pigment isorenieratene is exclusively produced by the brown strains of green sulfur bacteria [Imhoff, 1995], which require sunlight penetrating the euxinic part (i.e. containing reduced inorganic sulfur species) of an aquatic environment (Fig. 5) [van Gemerden and Mas, 1995]. Currently, these phototrophic bacteria are restricted to a few isolated euxinic basins in the marine realm such as the Black Sea. In such environments they thrive near the hydrogen sulfide/oxygen interface (i.e. chemocline) at depths of up to 150 m, where light levels are less than 1% of surface irradiance, and utilise reduced inorganic sulfur species as electron donors during photosynthesis [Repeta *et al.*, 1989; van Gemerden and Mas, 1995]. Therefore, the occurrence of S-bound isorenieratane in the C/T black shales indicates that anoxic conditions periodically reached up into the photic zone of the southern proto-North Atlantic during the C/T OAE [Sinninghe Damsté and Köster, 1998a].

The stable carbon isotopic composition of biomarkers can provide additional information concerning the paleoenvironment [e.g. Kohnen *et al.*, 1992; Hayes *et al.*, 1987; Schouten *et al.*, 2000; Hayes *et al.*, 1989; Freeman and Hayes, 1992; Jasper *et al.*, 1994; Schoell *et al.*, 1994; Pagani *et al.*, 1999]. The isotope effect associated with carbon fixation (ϵ_p) by primary producers

causes OC to be depleted in ^{13}C relative to the inorganic carbon source (i.e. DIC/atmospheric CO_2). $\delta^{13}\text{C}$ values of fresh OM of primary producers are determined by the stable carbon isotopic composition of the carbon source and ϵ_p . Heterotrophy, selective preservation, and diagenetic alteration can severely affect the stable carbon isotopic signature of bulk sedimentary OC, while the $\delta^{13}\text{C}$ values of biomarkers are largely unaffected [Grice *et al.*, 1998; Hayes *et al.*, 1989; Freeman and Hayes, 1992; Sinninghe Damsté *et al.*, 1998]. Therefore, compound-specific stable carbon isotope analysis is particularly useful in stable carbon isotope stratigraphy in settings where carbonate is absent or diagenetically affected. For example, the sharp increase in $^{13}\text{C}/^{12}\text{C}$ ratios that is observed worldwide for marine carbonates and OM at the C/T boundary [Scholle and Arthur, 1980; Arthur *et al.*, 1988] has been shown to be a powerful tool in high resolution correlation [Gale *et al.*, 1993; Hasegawa, 1997]. This positive excursion in $\delta^{13}\text{C}$ values reflects a change in the global atmospheric-oceanic pool of inorganic carbon resulting from a global increase in the burial rate of ^{13}C -depleted OC during the C/T OAE [Arthur *et al.*, 1988]. The use of molecular fossils that are specific for primary producers instead of bulk OM for stable carbon isotope stratigraphy greatly reduces the effect of heterotrophy, preservation, and diagenetic alteration on the carbon isotopic signature of OC [Grice *et al.*, 1998; Hayes *et al.*, 1989; Freeman and Hayes, 1992; Sinninghe Damsté *et al.*, 1998].

Figure 5. The habitat of green sulfur bacteria with euxinic conditions in the photic zone.

Shifts in the stable carbon isotopic composition of phytoplanktonic biomarkers can also provide important insight into changes in environmental conditions under which photosynthetic carbon fixation occurs. ϵ_p values for marine phytoplankton shows a pronounced dependence on CO_2 concentration [Rau *et al.*, 1989]. Therefore, the drop in atmospheric CO_2 concentrations resulting from enhanced OC burial rate during the C/T OAE [Arthur *et al.*, 1988; Freeman and Hayes, 1992;

Kuypers et al., 1999] should be reflected in the stable carbon isotopic composition of phytoplanktonic OC. Most terrestrial plants do not show the pronounced dependence of ϵ_p values on $p\text{CO}_2$ that is observed for marine phytoplankton [*Freeman and Hayes*, 1992] due to their ability to regulate the amount of CO_2 entering the leaf by adjusting the stomatal density of the leaves [*Farquhar et al.*, 1989; *White et al.*, 1994]. Thus, ϵ_p values of terrestrial higher plants do vary with humidity [*Farquhar et al.*, 1989; *White et al.*, 1994], but with the exception of extreme environments, such changes are expected to cause only minimal isotopic variability. Therefore, $\delta^{13}\text{C}$ values of biomarkers of terrestrial plants are expected to increase by only $\sim 2.5\%$ in response to the changes in $\delta^{13}\text{C}$ values of atmospheric/oceanic CO_2 during the C/T OAE [*Scholle and Arthur*, 1980; *Arthur et al.*, 1988; *Jenkyns et al.*, 1994].

In addition, $\delta^{13}\text{C}$ values of biomarkers can also provide information about the pathway of carbon fixation used by the organism. Carbon fixation in green sulfur bacteria occurs via the reverse tricarboxylic acid (TCA) cycle [*Sirevåg et al.*, 1977; *Van der Meer et al.*, 1998] instead of the Calvin cycle that is used by algae, cyanobacteria and higher plants. The degree of carbon-isotope fractionation during carbon assimilation is much smaller for the reverse TCA cycle than for the Calvin cycle such that green sulfur bacterial lipids are typically enriched in ^{13}C by 10-15% relative to algal or cyanobacterial lipids [*Sinninghe Damsté et al.*, 1993; *Koopmans et al.*, 1996]. This isotopic difference is of great help in the recognition of diagenetic products of isorenieratene, indicative of photic zone anoxia.

1.4 Scope and framework of the thesis

The OAE that occurred near the C/T boundary is the most extensive and as such has been considered as the type example of the mid-Cretaceous OAEs [*Wignall*, 1994]. One of the main sites of carbon burial during the C/T OAE was the proto-North Atlantic Ocean, where up to 80 m thick black shales [*Kuhnt et al.*, 1990], which can contain more than 40% organic carbon [*Herbin et al.*, 1986], were deposited basin-wide. The main part of this thesis (Part I) focuses on the causes and consequences of enhanced OM burial in the proto-North Atlantic Ocean during the C/T OAE. Another objective is to determine if the apparent similarities between black shales such as enrichment in OC, lamination, absence of or impoverished benthic faunas, ^{13}C -enrichment of inorganic and/or organic carbon indicate a common cause for the mid-Cretaceous OAEs (Part II). Therefore, the early Albian (~ 112 My) OAE1b black shales were investigated using the same techniques as for the C/T black shales and the results from both studies were compared.

In Chapter 2 direct evidence is provided for a dramatic decline in $p\text{CO}_2$ during the C/T OAE occurring in only ~ 60 ky. The observed carbon isotopic shift of up to 16% for individual leaf wax components extracted from sediments from an abyssal site in the southern North Atlantic Ocean suggests a sudden change in plant communities of the north African continent. Specifically this suggests that plants using the C_3 -type photosynthetic pathway were succeeded by plants using the C_4 -type pathway. Because C_4 plants can outcompete C_3 plants only at $p\text{CO}_2$ levels below 500 p.p.m.v. [*Cerling et al.*, 1997], the observed change indicates a far larger reduction in C/T CO_2 -levels (40-80%) than previously [*Freeman and Hayes*, 1992] suggested. The 6% excursion in $\delta^{13}\text{C}$

values that is observed for molecular fossils of marine phytoplankton is consistent with this large reduction.

In Chapter 3 the C/T sections of three sites along a northeast-southwest transect from Morocco to French Guyana (Fig. 4) were correlated by stable carbon isotope stratigraphy using the characteristic ^{13}C excursion in both bulk OM and molecular fossils of algal chlorophyll and steroids. Carbon isotope stratigraphy was also used to calculate the increase in carbon accumulation rates at these sites of different palaeobathymetric setting during the C/T OAE. To test whether enhanced OM preservation resulted from reduced oxygen supply or enhanced productivity caused the increase in carbon burial in the proto-North Atlantic we reconstructed: 1) Chemocline variations using redox sensitive trace metals and molecular fossils from pigments exclusively produced by bacteria that require both light and free hydrogen sulfide; and 2) Variations in primary productivity using Ba/Al ratios and $^{13}\text{C}/^{12}\text{C}$ ratios for molecular fossils of algal chlorophyll and steroids. It is shown that enhanced productivity led to increased organic carbon burial in an euxinic North Atlantic basin during the C/T OAE. We propose that increased upwelling of nutrient-rich, proto-Atlantic deep water, resulting from the tectonically induced formation of a deep water connection between the North and South Atlantic basins enhanced primary productivity during the C/T OAE.

In Chapter 4 the C/T sections of two sites from the northwestern part of the proto-North Atlantic (Fig. 4) were correlated by stable carbon isotope stratigraphy using the characteristic ^{13}C excursion in both bulk OM and molecular fossils of algal chlorophyll. The C/T intervals at these sites show high amplitude, short-term cyclic variations in TOC content with the more pronounced changes in TOC content being accompanied by changes in lithology from green (TOC < 1%) to black claystones (TOC > 1%). We show that these cyclic variations reflect changes in the contribution of marine OM. Sedimentation rates obtained from the isotope stratigraphy and spectral analyses indicate that these changes were predominately precession controlled. To test whether enhanced marine OM preservation resulted from reduced oxygen supply or enhanced productivity caused this precession controlled variation in TOC contents we reconstructed: 1) Chemocline variations using redox sensitive trace metals and molecular fossils from pigments exclusively produced by bacteria that require both light and free hydrogen sulfide; and 2) Variations in primary productivity using Ba/Al ratios, abundance of biogenic silica and $^{13}\text{C}/^{12}\text{C}$ ratios for molecular fossils of algal chlorophyll. It is shown that periodically increased primary productivity led to euxinic conditions in the water column of the northwestern proto-North Atlantic. These euxinic conditions, which sometimes extended to at least the base of the photic zone (<150 m), led to enhanced preservation of marine OM resulting in the deposition of OM-rich black claystones. In addition, we show that the trend of continually increasing TOC content and HI values of the black claystones up section that is observed at these sites, most likely resulted from both enhanced preservation due to increased anoxia and increased production of marine OM during the C/T OAE.

In Chapter 5 the role and significance of N_2 -fixing cyanobacteria in the increase in OM burial at four proto-North Atlantic sites of different palaeobathymetric setting was determined using nitrogen isotope measurements and molecular fossils of cyanobacterial membrane lipids. The ^{15}N -depletion of OM-rich marine sediments ($\delta^{15}\text{N} = -2-0 \text{ ‰}$) typical for newly fixed N_2 and the abundance of cyanobacterial membrane lipids indicate that N_2 fixation supplied the additional nutrient N required to increase primary productivity in the proto-North Atlantic during the C/T OAE.

In Chapters 6 and 7 the source for both soluble and insoluble OM of the early Albian OAE 1b black shales of the Ocean Drilling Program (ODP) site 1049C (North Atlantic Ocean off the coast of Florida) and the Ravel section of the Southeast France Basin (SEFB) were determined using optical, chemical, stable carbon and nitrogen isotopic analyses. It is generally believed that these OAEs were caused either by decreased remineralisation or increased production of phytoplanktonic OM. Here we show that enhanced organic carbon (OC) burial during the early Albian OAE1b (~112 My) was caused by a different process. Isoprenoidal tetraether membrane lipids and free isoprenoids, diagnostic for marine planktonic archaea and archaea in general, respectively, are abundantly present in these black shales. In fact, combined biogeochemical and stable carbon isotopic analyses indicate that black shales from this period contain up to 80% of OC derived from archaea. Although there are apparent similarities (distinct lamination, ^{13}C -enrichment of OC) between the black shales of OAE1b and the C/T OAE, our detailed molecular work shows that the origin of the OM (archaeal versus phytoplanktonic) and causes for ^{13}C -enrichment of OC are completely different.

Chapter 2

A large and abrupt fall in atmospheric CO₂ concentrations during Cretaceous times

Published in *Nature*, 399, 342-345, 1999

Abstract.

Marine carbonates and organic matter (OM) show a sharp increase in their ¹³C/¹²C isotope ratios at the Cenomanian/Turonian (C/T) boundary [Scholle and Arthur, 1980; Arthur *et al.*, 1988] in the Cretaceous period. This isotopic shift resulted from an increase in the rate of sedimentary burial of ¹³C-depleted organic carbon in response to the C/T 'oceanic anoxic event' [Arthur *et al.*, 1988]. The enhanced burial rate should have led to a significant drop in the atmospheric CO₂ concentration, which could explain the apparent climatic cooling of early Turonian times [Arthur *et al.*, 1988; Jenkyns *et al.*, 1994; Kuhnt *et al.*, 1986]. Here we present stable carbon isotope data for specific compounds from terrestrial leaves and marine phytoplankton, and quantify the abruptness and magnitude of the atmospheric CO₂ concentration change. Isotope shifts in leaf-wax components extracted from abyssal sediments in the northeastern tropical Atlantic Ocean—the components are wind-delivered from Africa—indicate a sudden change in plant communities of the north African continent. Specifically, the data suggest that plants using the C₃-type photosynthetic pathway were succeeded by plants using the C₄-type pathway. If C₄ plants can outcompete C₃ plants only at atmospheric CO₂ concentrations below 500 p.p.m.v. [Cerling *et al.*, 1997], the observed vegetation change indicates a far larger reduction in C/T CO₂ concentration—some 40-80%—than previously suggested [Freeman and Hayes, 1992]. The isotopic excursion in the marine phytoplankton compounds is consistent with this estimate. We infer that this dramatic fall in the atmospheric CO₂ concentration was abrupt, occurring in just 60,000 years.

2.1 Introduction

The middle-late Cretaceous climate has been described as a ‘greenhouse climate’ with minimal Equator-to-pole thermal gradients [Barron, 1983]. It has been suggested that this climate condition resulted from extensive periods of volcanic outgassing [Arthur *et al.*, 1985; Larson, 1991] leading to increased atmospheric concentrations of the greenhouse gas carbon dioxide (estimates of the partial pressure of CO₂ ($p\text{CO}_2$) vary between 3 and 12 times modern (pre-industrial) values [Berner, 1992], that is, 900-3,300 p.p.m.v.). However, the widespread burial of organic matter in black shales during the C/T ‘oceanic anoxic event’ (OAE) probably led to a significant reduction of $p\text{CO}_2$ [Arthur *et al.*, 1988]. Such a decrease is suggested by the drop in the isotope effect associated with carbon fixation (ϵ_p) by phytoplankton in the Cretaceous Western Interior Seaway of North America [Freeman and Hayes, 1992]. This decline is also documented indirectly by oxygen isotope data, which indicate an 8-13 °C cooling at high latitudes during the early Turonian [Arthur *et al.*, 1988; Jenkyns *et al.*, 1994]. Additional indications of global cooling are provided by micropaleontological data, showing an incursion of boreal fauna into low latitude seas [Kuhnt *et al.*, 1986].

2.2 Methods

2.2.1 Bulk analyses. Total Organic Carbon (TOC) contents were determined by a LECO C/S analyser. The $\delta^{13}\text{C}$ values ($\pm 0.1\%$) ($\delta^{13}\text{C} = [({}^{13}\text{C} / {}^{12}\text{C})_{\text{sample}} / ({}^{13}\text{C} / {}^{12}\text{C})_{\text{standard}}] - 1$; the Pee Dee belemnite standard (PDB) has been used) were measured on bulk sediments using automated on-line combustion after removal of the inorganic carbonates with diluted HCl.

2.2.2 Compound specific analyses. The powdered samples (15-30 g) were Soxhlet extracted for ~24 h to obtain the total lipid fraction. An aliquot (~250 mg) of the total extract was separated into an apolar and a polar fraction using column chromatography. AgNO₃ column chromatography and urea adduction were used to obtain *n*-alkane fractions. The hydrocarbons that were released from the polar fraction by Raney nickel desulphurisation and subsequent hydrogenation were isolated using column chromatography. Samples were analysed by gas chromatography-mass spectrometry (GC-MS) for identification. Compound-specific $\delta^{13}\text{C}$ analyses were performed using GC-isotope ratio mass spectrometry (GC-IRMS). The $\delta^{13}\text{C}$ values for individual compounds are the means of duplicate runs ($\sigma = \pm 0.3$ to 0.6) expressed versus PDB.

2.3 Results and discussion

Here we present the results of a compound-specific carbon isotope study of C/T sediments deposited in the southern part of the North Atlantic Ocean off the coast of northwest Africa (Deep Sea Drilling Project (DSDP) site 367, close to the equator). The laminated black shales consist of a mixture of terrigenous silicates and clay minerals [Mélières, 1978], high amounts of organic matter

(up to 50 wt%) and some biogenic carbonate. The thermally immature organic matter is almost exclusively of marine origin, as revealed by the Rock Eval hydrogen indices [Herbin *et al.*, 1986] and the extremely low abundance of lignin pyrolysis products generated from the kerogen. The saturated hydrocarbon fractions consist mainly of short-chain *n*-alkanes (with no obvious odd-over-even carbon number predominance), isoprenoids of bacterial/algal origin, and long-chain *n*-alkanes with a strong odd-over-even carbon number predominance (Carbon Preference Index CPI = 2.7-5.1) derived from leaf waxes of higher plants [Eglinton and Hamilton, 1967]. An important mode of transport of leaf-wax *n*-alkanes is via wind, as indicated by the high relative amounts of leaf-wax components in aeolian dust collected at remote ocean sites [Gagosian *et al.*, 1981]; consequently, they are common constituents of extractable organic matter of recent and ancient abyssal plane sediments [Farrington and Tripp, 1977]. Taking into account the prevailing wind direction, the most likely candidate for the origin of these wind-transported terrestrial *n*-alkanes is the nearby north African continent. Often, the generation of *n*-alkanes from other sources during dia- and catagenesis makes carbon-isotope analyses of the leaf-wax lipids impossible. In the C/T sediments described here the leaf-wax components are still relatively abundant in the hydrocarbon biomarker fraction due to the fact that most marine biomarkers were transformed to sulphur-bound components during early diagenesis [Kohnen *et al.*, 1991].

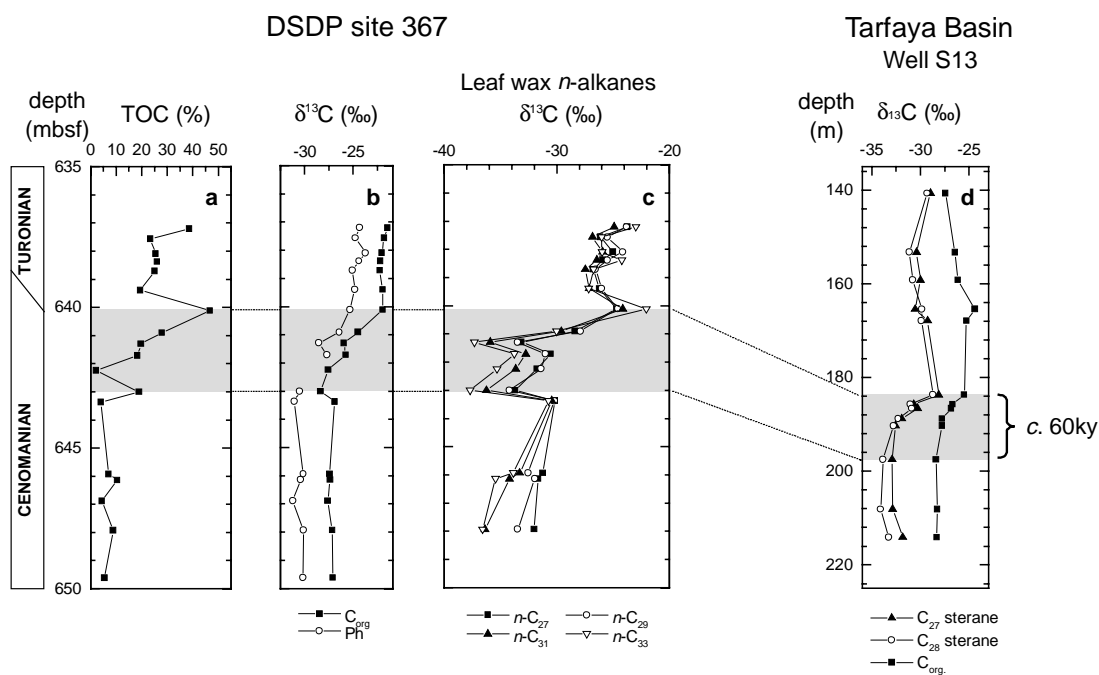

Figure 1 Bulk and biomarker data of the investigated sites; the stratigraphy is also shown. **a-c**, Data from DSDP site 367. **(a)** Total organic carbon (TOC) content; **(b)** and **(c)** carbon isotope values (in ‰ vs. PDB) of C_{org}, and S-bound phytane (Ph) derived from phytoplanktonic chlorophyll **(b)**, leaf-wax components **(c)**. **(d)** Data from shelf sediments from well S13 of the Tarfaya basin; carbon isotope values of C_{org} and free steranes (C₂₇ sterane (5 α -cholestane) and C₂₈ sterane (5 α -24-methyl-cholestane)) derived from marine algae. The time difference (estimated at ~60 kyr) between the onset of the $\delta^{13}\text{C}_{\text{org}}$ excursion and the first maximum carbon isotope-value for organic matter is indicated as a grey shaded area in the graphs. At site 367 carbonate carbon is absent, due to deposition below the carbonate compensation

depth, but carbonate $\delta^{13}\text{C}$ values for the Tarfaya shelf sediments, although affected by diagenesis, indicate a 2.5‰ excursion (W. Kuhnt, personal communication).

The isotopic compositions of the terrestrial *n*-alkanes show a remarkable shift coincident with the positive isotope-ratio excursion observed here for organic carbon ($\delta^{13}\text{C}_{\text{org}}$; Fig. 1b) and worldwide [Scholle and Arthur, 1980; Arthur et al., 1988; Jenkyns et al., 1994] for marine carbonates (~2.5‰). Most terrestrial plants do not show the pronounced dependence of ϵ_p values on $p\text{CO}_2$ that is observed for marine phytoplankton [Freeman and Hayes, 1992]; this results from the ability of plants to regulate the amount of CO_2 that enters their leaves by adjusting the stomatal density of the leaves [Farquhar et al., 1989; White et al., 1994]. ϵ_p values of terrestrial higher plants can vary with humidity [Farquhar et al., 1989; White et al., 1994] but, with the exception of extreme environments, such changes are expected to cause only minimal isotopic variability. Therefore, leaf wax *n*-alkanes are expected to increase by only ~2.5‰ in response to the changes in $\delta^{13}\text{C}$ values of atmospheric/oceanic CO_2 during the C/T OAE [Scholle and Arthur, 1980; Arthur et al., 1988; Jenkyns et al., 1994]. However, for the leaf wax *n*-alkanes a far larger shift (of 10 to 16‰) is observed (Fig. 1c). The magnitude of the isotopic shift of the sedimentary *n*-alkanes is consistent with a change in the source of these leaf wax lipids from C_3 - to C_4 -type plants. The carbon isotope effect differs between the two photosynthetic pathways, such that $\delta^{13}\text{C}$ values for bulk plant material range from -22‰ to -30‰ for C_3 and -10‰ to -14‰ for C_4 [Street-Perrot et al., 1997]. The *n*-alkanes are typically depleted in ^{13}C relative to the bulk material by 6 and 10‰, respectively [Collister et al., 1994].

In the lower part of the studied section (until 641.29 m) *n*-alkane isotopic values (-38 to -30‰) are typical for a predominately C_3 -type origin and become depleted in ^{13}C with increasing carbon number (Fig. 2). This latter trend has been previously observed for C_3 plants [Collister et al., 1994] and for sediment samples dominated by detritus derived from such plants [Rieley et al., 1991]. In the upper part of the section, *n*-alkanes exhibit $\delta^{13}\text{C}$ values (-22 to -27‰) that are indicative of mainly C_4 -type input or a mixture of C_3 -type and C_4 -type leaf-wax lipids. In marked contrast to the C_3 -dominated *n*-alkane samples, $\delta^{13}\text{C}$ values of the individual leaf-wax components in these samples are nearly constant with increasing chain length (Fig. 2), which is consistent with what has been observed for C_4 plants [Collister et al., 1994]. The different trends of $\delta^{13}\text{C}$ values versus carbon number for samples dominated by C_3 -type and C_4 -type plants results in a larger carbon-isotope shift for longer *n*-alkanes (Fig. 2).

Figure 2 $\delta^{13}\text{C}$ values of leaf lipids versus chain length. The $\delta^{13}\text{C}$ values of the individual leaf-wax components for a sample before (643.00 m), during (641.29 m) and at the first maximum of (640.11 m) the $\delta^{13}\text{C}_{\text{org}}$ excursion indicate the rapid shift in the source of these higher plant lipids from C_3 - to C_4 -

Direct evidence (that is, plant remains) for the presence of C₄-type photosynthesis in the fossil record is scarce, due to the absence of readily fossilized woody parts in most plants using the C₄ system. Instead, the ¹³C/¹²C ratios of tooth enamel of herbivorous animals, of palaeosol carbonate, and of terrestrial-derived organic matter have been used as tracers for ecosystems dominated by C₃-type and C₄-type plants, and suggest that the C₄-type system did not represent an important part of the terrestrial ecosystem until the late Miocene [Cerling *et al.*, 1997]. However, on basis of palaeo *p*CO₂ reconstructions, it was proposed that a C₄-type pathway could have evolved independently during the Carboniferous-Permian glaciation and subsequently disappeared in the Mesozoic [Cerling *et al.*, 1997], while other authors [Spicer, 1989; Bocherens *et al.*, 1994] suggest that C₄-type photosynthesis could have evolved earlier than the late Miocene. Carbon-isotope measurements provide additional evidence for the presence of C₄-type plant remains in pre-Miocene sediments. Such examples include Carboniferous calcified root mats [Wright and Vanstone, 1991], a late Cretaceous lignite sample [Bocherens *et al.*, 1994], collagen from dinosaur bones [Bocherens *et al.*, 1994], and *n*-alkanes in extracts from the Eocene Green River Formation [Collister *et al.*, 1994]. But until now, evidence for a CO₂-driven shift from a C₃-type to a C₄-type dominated ecosystem has not been observed for sediments older than late Tertiary.

The dominant photosynthetic pathway for a given ecosystem (C₃ or C₄) depends on both *p*CO₂ and temperature [Fig. 3, Ehleringer *et al.*, 1997; Collatz *et al.*, 1998]. Plants using the C₄ photosynthetic pathway use an active CO₂-concentrating mechanism that provides them with an advantage over C₃ plants at low CO₂ levels and high temperatures. But at higher CO₂ levels the C₄ pathway becomes less advantageous, due to the higher energy demand for the concentrating mechanism. Consistent with this, a 10‰ shift in δ¹³C values was reported for *n*-alkanes in Pleistocene high-altitude lake sediments and attributed to a change from C₃ to C₄ plants resulting from lower *p*CO₂ levels during glacial times [Street-Perrot *et al.*, 1997]. Assuming that equatorial temperatures were comparable to present-day temperatures, as is suggested by oxygen-isotope data for the Cenomanian [Sellwood *et al.*, 1994], and a similar response to CO₂ partial pressure for Cretaceous C₃-type/C₄-type plants, *p*CO₂ during the C/T OAE would have been no more than twice that of the modern (pre-industrial) atmosphere. In fact, Cerling *et al.* [1997] suggested that the C₄ photosynthetic pathway would not be present at atmospheric CO₂ levels of more than 500 p.p.m.v. Assuming that CO₂ levels for the middle Cretaceous ranged from 3 to 12 times modern values [Berner, 1992], this suggests that *p*CO₂ decreased by 40-80%.

In addition to low *p*CO₂, aridity can also lead to a competitive advantage for C₄ plants [Bird and Cali, 1998], as low humidity will lead to stomatal closure and a decreased intercellular CO₂ level [Collatz *et al.*, 1998]. But at the high *p*CO₂ levels suggested for the Cretaceous, C₃-type plants will predominate independent of the level of humidity [Cerling *et al.*, 1997; Ehleringer *et al.*, 1997]. Increased aridity of the north African continent could have facilitated an increase in C₄-type vegetation during the C/T OAE when *p*CO₂ was significantly lower (that is, below 500 p.p.m.v.). The presence of both marine and terrestrial biomarkers in sediments from this section provides an opportunity to compare the timing and nature of the carbon isotope excursion on land and in the marine environment. ε_p values for marine phytoplankton show a pronounced dependence

on CO₂ concentration: therefore a drop in CO₂ levels should be reflected in their δ¹³C values. For the Western Interior Seaway of North America, a geoporphyrin fraction was used to calculate a 1.5‰ decrease in ε_p values during the C/T OAE [Hayes *et al.*, 1989], and this was subsequently interpreted as a ~20% reduction in pCO₂ levels [Freeman and Hayes, 1992]. In sharp contrast, at site 367 the 6‰ increase in the δ¹³C values for sulphur-bound phytane derived from algal chlorophyll (Fig. 1b) records a 3.5‰ decrease in ε_p values, assuming a 2.5‰ excursion for inorganic carbon [Scholle and Arthur, 1980; Arthur *et al.*, 1988; Jenkyns *et al.*, 1994]. This larger decrease in ε_p values is also suggested by the 5-6‰ increase in δ¹³C values observed for a multitude of phytoplanktonic biomarkers from two other North Atlantic C/T sites (that is, the Tarfaya Atlantic coastal basin (Morocco; Fig. 1d) and DSDP site 144 off the coast of northern South America (M.M.M.K. *et al.*, unpublished results)). It is difficult to determine which marine site best records the global pCO₂ change during the C/T OAE, as physiological and environmental variables other than pCO₂ can affect ε_p values for marine phototrophs. However, the larger decrease in ε_p values observed for these three North Atlantic sites is consistent with the 40-80% decrease in pCO₂ required for a transition from C₃-type to C₄-type plants.

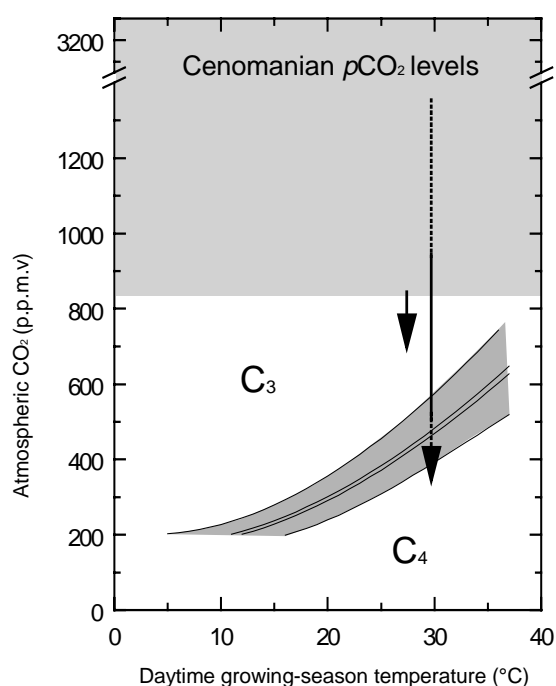

Figure 3 The C₃/C₄ crossover function. This function shows the pCO₂ dependence of the C₃/C₄ crossover temperature [after Ehleringer *et al.*, 1997]. The estimated range of Cenomanian pCO₂ levels is indicated as a grey shaded area. The drop in pCO₂ levels that is observed here (large broken arrow) and the previously [Freeman and Hayes, 1992] reported drop (small arrow) for the C/T OAE are shown. It is assumed that equatorial temperatures were comparable to present day values [Sellwood *et al.*, 1994].

There is a difference in timing of the isotope excursion between the marine-derived organic matter and phytane, and the terrestrial *n*-alkanes (Fig. 1). The magnitude of this time lag can be determined if the time difference is known between the onset of the δ¹³C_{org} excursion and the first maximum carbon-isotope value for organic matter. As the δ¹³C excursion is synchronous for all sites [Gale *et al.*, 1993], data from the expanded C/T section of the Tarfaya basin [Kuhnt *et al.*, 1997; Kuhnt *et al.*, 1990] can be used for this calculation. An accumulation rate of ~12 cm ky⁻¹ [Kuhnt *et al.*, 1997] has been derived for these sediments, leading to a calculated duration for this particular excursion interval of ~60 ky (Fig. 1). Assuming a constant accumulation rate, the

difference in timing between the onset of the carbon-isotope excursion of marine markers and the $\delta^{13}\text{C}$ shift for terrestrial markers is ~30 ky. This difference could be explained by the time needed to reach the low $p\text{CO}_2$ values that are favourable for a C_4 -type pathway through the burial of organic matter.

The enhanced burial of organic matter during the C/T OAE led to a profound decrease in $p\text{CO}_2$ [Arthur *et al.*, 1988] allowing the appearance of plants using a CO_2 -concentrating mechanism (C_4 -type) in the Cretaceous north African plant community. This shows that in addition to anthropogenic emissions, perturbations of the biogeochemical cycles may have an abrupt and dramatic effect on atmospheric CO_2 concentrations.

Chapter 3

Enhanced productivity led to increased organic carbon burial in the euxinic North Atlantic basin during the late Cenomanian oceanic anoxic event

Abstract.

Three Cenomanian/Turonian (C/T ~93.5 Ma) black shale sections along a northeast-southwest transect in the southern part of the proto-North Atlantic Ocean were correlated by stable carbon isotope stratigraphy using the characteristic excursion in $\delta^{13}\text{C}$ values of both bulk organic matter (OM) and molecular fossils of algal chlorophyll and steroids. All three sites show an increase in marine organic carbon (OC) accumulation rates during the C/T Oceanic Anoxic Event (OAE). The occurrence of molecular fossils of anoxygenic photosynthetic green sulfur bacteria, lack of bioturbation and high abundance of redox sensitive trace metals indicates sulfidic conditions, periodically reaching up into the photic zone before as well as during the C/T OAE. During the C/T OAE there was a significant rise of the chemocline as indicated by the increase in concentrations of molecular fossils of green sulfur bacteria and Mo/Al ratios. The presence of molecular fossils of the green strain of green sulfur bacteria indicates that euxinic conditions periodically even occurred at very shallow water depths of 15 m or less during the C/T OAE. However, bottom water conditions did not dramatically change as indicated by more or less constant V/Al and Zn/Al ratios at site 367. This suggests that the increase in OC burial rates resulted from enhanced PP rather than increased anoxia, which is supported by stable carbon isotopic evidence and a large increase in Ba/Al ratios during the C/T OAE. The occurrence of the productivity event during a period of globally enhanced organic carbon burial rates (i.e. the C/T OAE), points to a common cause possibly related to the formation of a deep water connection between North and South Atlantic basins.

3.1 Introduction

The interval spanning the Barremian to Turonian (~125-88 Ma) is known as the mid-Cretaceous 'greenhouse' world [Barron, 1983]. Both marine and terrestrial proxies indicate that the mid-Cretaceous climate was significantly warmer with a smaller equator-to-pole temperature gradient than the modern climate. It has been suggested that this resulted from an anomalous amount of oceanic volcanism, leading to 3 to 12 times higher atmospheric levels of carbon dioxide during the Cretaceous than at present [Bernier, 1992]. The transition from the Cenomanian to the Turonian (C/T) marks a major turning point, with globally dispersed oxygen isotope data indicating that the mid-Cretaceous warming trend ceased at the C/T boundary and was followed by a deterioration at least until the Maastrichtian [Jenkyns *et al.*, 1994]. This long-term cooling was preceded by the global deposition of sediments rich (> 1%) in organic carbon (OC) and devoid of or strongly impoverished in benthic faunas (black shales) [Schlanger and Jenkyns, 1976]. An increase in $^{13}\text{C}/^{12}\text{C}$ ratios for marine carbonates and organic matter at the C/T boundary provides evidence for an increase in the global OC burial rate. This positive excursion in $\delta^{13}\text{C}$ values likely resulted from preferential removal of ^{12}C by the enhanced burial of ^{13}C depleted OC as a response to the so-called 'C/T oceanic anoxic event (OAE)' [Arthur *et al.*, 1988]. Originally, the term OAE was introduced to describe the episodic expansion and intensification of the Oxygen Minimum Zone (OMZ), which was proposed to explain the seemingly global distribution of OC-rich sediments in pelagic sequences of Aptian-Albian and C/T age [Schlanger and Jenkyns, 1976]. The term OAE has been used by later workers more generally 'as a way of referring to time-bounded envelopes of particularly, perhaps more globally, widespread deposition of OC-rich sediments (black shales) in marine environments' [Arthur *et al.*, 1987]. In accordance with this, the term C/T OAE (i.e. OAE2) will be used in this study for the 300-500 ky period of latest Cenomanian to earliest Turonian age, during which OM burial rates were enhanced. This enhanced OM burial rate led to a significant drop in atmospheric carbon dioxide concentration [Freeman and Hayes, 1992; Arthur *et al.*, 1988; Kuypers *et al.*, 1999] and, thereby, could have triggered the early Turonian deterioration of the greenhouse climate.

Two fundamentally different models have been used to explain the enhanced OM burial rate during the C/T OAE. The *preservational* model is based on decreased OM remineralisation resulting from a decreased oxygen flux. In the mid-Cretaceous oceans, anoxic water column conditions may have developed more readily than in the modern world's oceans as minimal equator-to-pole thermal gradients and high sea surface temperatures should have resulted in a decreased formation of oxygenated bottom-waters [Barron, 1983]. This could have resulted in basin-wide oxygen deficiency with the most intense dysoxia/anoxia occurring in the deepest parts of tectonically isolated basins such as the Cretaceous North and South Atlantic [Zimmerman *et al.*, 1987; de Graciansky *et al.*, 1984]. The reoccurrence of thinly laminated OM-rich sediments devoid of traces of benthic activity indicates that middle Cretaceous bottom-waters were indeed periodically anoxic [Summerhayes, 1987; Bralower and Thierstein, 1987]. Sedimentary derivatives (molecular fossils) of a pigment indicative of anoxygenic photosynthetic bacteria recovered from abyssal and shelf sites indicate that anoxic conditions extended even into the photic zone of the southern proto-North Atlantic during the C/T OAE [Sinninghe Damsté and Köster, 1998].

The *productivity* model is based on a greatly increased primary productivity that overwhelmed the oxic OM remineralisation potential of the water column. Primary productivity in the modern marine environment is largely controlled by the input of biolimiting nutrients from deeper water into the surface waters. An enhanced supply of biolimiting nutrients could have led to increased PP and thus to an expansion and intensification of the OMZs during the C/T OAE [Schlanger and Jenkyns, 1976]. The deposition of OM-rich sediments would have largely been confined to places where the OMZ impinged on the continental margin or other elevated portions of the sea floor, as the deepest places of the basin may have remained oxic. This model has especially been used to explain the OM-rich deposits in the Cretaceous Pacific Ocean [e.g., Schlanger and Jenkyns, 1976].

In the proto-North Atlantic Ocean, black shales that can be over 80 m thick [Kuhnt *et al.*, 1990] and that can contain more than 40% OC [Herbin *et al.*, 1986] were deposited basin-wide during the C/T OAE, indicating that this was one of the main sites of carbon burial. This study focuses on the environmental conditions that led to the deposition of the especially well-developed C/T OAE black shales from the southern part of the proto-North Atlantic Ocean [de Graciansky *et al.*, 1984; Kuhnt *et al.*, 1990]. The C/T sections of three sites along a northeast-southwest transect from Morocco to French Guyana (Fig. 1) were correlated by stable carbon isotope stratigraphy using the characteristic ^{13}C excursion in both bulk OM and molecular fossils of algal chlorophyll and steroids. Carbon isotope stratigraphy was also used to calculate the increase in carbon accumulation rates at these sites of different palaeobathymetric setting during the C/T OAE. To test whether enhanced OM preservation resulting from reduced oxygen supply or enhanced productivity caused this increase in carbon burial we reconstructed: 1) Chemocline variations using redox sensitive trace metals and molecular fossils from pigments exclusively produced by bacteria that require both light and free hydrogen sulfide; and 2) Variations in primary productivity using Ba/Al ratios and $^{13}\text{C}/^{12}\text{C}$ ratios for molecular fossils of algal chlorophyll and steroids. In addition we discuss the oceanographic consequences of our findings.

3.2. Material and Methods

The samples come from Shell exploration well S13 of the Tarfaya area (Morocco), and Deep Sea Drilling Project (DSDP) holes 144 off the coast of French Guyana (leg 14) and 367 off the coast of Senegal (leg 41). Sediment slices (3-5 cm) were taken from the cores, from which sub-samples were subsequently freeze-dried and powdered in an agate mortar.

Total Organic Carbon (TOC) contents were determined using a CN analyser. The $\delta^{13}\text{C}$ values ($\pm 0.1\%$ versus Vienna Pee Dee belemnite (VPDB)) were measured on bulk sediments, after removal of the inorganic carbonates with diluted HCl, using automated on-line combustion followed by conventional isotope ratio-mass spectrometry. For analyses of the soluble OM powdered samples were Soxhlet extracted for *c.* 24 h to obtain the total extract, which was separated into an apolar and a polar fraction using column chromatography. Hydrocarbons were released from the polar fraction by Raney Nickel desulfurisation and subsequent hydrogenation [Sinninghe Damsté *et al.*, 1993]. Samples were analysed by gas chromatography-mass spectrometry

Figure 1. Palaeogeographical map of mid Cretaceous (~94 Ma) North Atlantic showing the position of the three studied cores. Light grey shaded regions represent continental plates (from GEOMAR map generator; www.odsn.de/odsn/services/paleomap/paleomap.html). Dark grey shaded regions represent land [Scotese and Golonka, 1992].

(GC-MS) for compound identification. Compound-specific $\delta^{13}\text{C}$ analyses were performed using a GC-isotope-ratio-monitoring MS. The $\delta^{13}\text{C}$ values for individual compounds are the means of duplicate runs ($\sigma = \pm 0.3$ to 0.6) expressed versus VPDB. Pyrolysis (Py)-GC was conducted on a GC equipped with a FID and a cryogenic unit. Samples were pressed onto flattened ferromagnetic wires (Curie temperature of 610°C), which were subsequently inductively heated for 10 s. The desorbed fragments were flushed into the capillary column using helium.

For major, minor and trace element analyses, samples (ca. 125 mg) were digested in 5 ml HF (40%) and 5 ml of a $\text{HClO}_4/\text{HNO}_3$ mixture at 90°C . After drying by evaporation at 190°C , the residue was dissolved in 25 ml 1 M HCl. The resulting solutions were analysed with a Perkin Elmer Optima 3000 inductively coupled plasma atomic emission spectrometer (ICP-AES). The results were checked with international and house standards, and relative standard deviations in duplicate measurements are below 4%.

3.3. Results and Discussion

3.3.1 Stratigraphy and Palaeosetting.

Our study concentrates on the C/T interval roughly between 95 and 93 My before present [Gradstein *et al.*, 1995], which spans two planktic foraminiferal zones of global significance: the late Cenomanian *Rotalipora cushmani* zone and the latest Cenomanian to early Turonian *Whiteinella archaeocretacea* zone (Fig. 2). This interval is particularly well developed in the

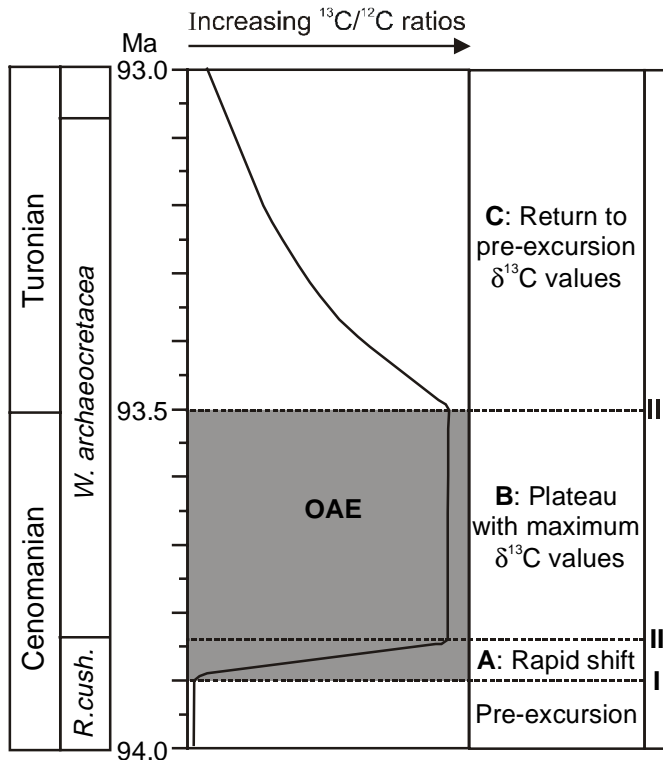

Figure 2. Idealised representation of C/T stable carbon isotope excursion showing the bio- and chronostratigraphic position of the three main phases (modified after [Gale *et al.*, 1993]). Dashed lines with roman numbers show the position of the boundaries between the different phases (pre-excursion, A, B and C) of the isotope excursion

Tarfaya basin (well S13; Morocco), where it reaches a thickness of ~150 m (Fig. 3). The C/T sequence at site S13 consists of OM-rich biogenic carbonates that were deposited in an open shelf sea with a palaeo-water depth at the depocentre (well S13) of 200-300 m [Kuhnt *et al.*, 1990]. Sedimentation rates were as high as 12 cm/ky for the *W. archaeocretacea* zone [Kuhnt *et al.*, 1997] that contains the major part of the C/T OAE.

The black shales that comprise the late Cenomanian sequence at Deep Sea Drilling Program (DSDP) Site 367 (off the coast of north-west Africa) consist of a mixture of terrigenous silicates and clay minerals, high amounts of organic carbon (total organic carbon (TOC) contents up to 50 wt. %) and minor amounts of biogenic carbonate [Herbin *et al.*, 1986]. These sediments were deposited at a water depth of 3700 m. The deposition of such extremely OM-rich sediments at this abyssal site is hard to explain by the expanding OMZ model proposed by Schlanger and Jenkyns [1976]. Therefore, it has been suggested that the deeper bottom waters (>3000 m) of the proto North Atlantic were predominately oxic and that a large part of the OC-enrichment of mid-Cretaceous black shales at site 367 resulted from redeposition of sediments deposited where the

OMZ impinged on the seafloor [Arthur *et al.*, 1984]. Indeed, thin turbidites consisting of quartz silt or clayey foraminifer sand do occur but apparently represent only a minor component of the late Cenomanian section [see also *The Shipboard Scientific Party*, 1977]. To the best of our knowledge no direct evidence has so-far been provided for a turbiditic origin of the OM-rich black shales itself [see Arthur *et al.*, 1984 and references therein], and thus, we believe that the deeper bottom waters were predominately anoxic during their deposition (see below).

Figure 3. Stratigraphy [Kuhnt *et al.*, 1997], bulk organic carbon and biomarker data of site S13 (Tarfaya basin). Carbon isotope values (in ‰ vs. VPDB) of bulk organic carbon (C_{org}) and free steranes [C_{27} sterane (5α -cholestane) and C_{28} sterane (5α -24-methyl-cholestane)] derived from marine algae, TOC content of the bulk sediment and of the residue obtained after decalcification, and concentration profile of molecular fossil (S-bound isorenieratane) of a pigment of the brown strain of green sulfur bacteria. The dashed lines with Roman numbers show the approximate position of the boundaries between the different phases of the isotope excursion (see also Fig. 2).

At site 144, the southwestern end of the transect, Cenomanian deposits consist of dark laminated carbonaceous cemented limestones and zeolitic calcareous clay [Hayes *et al.*, 1972]. These hemipelagic sediments were deposited on an ancestral Mid-Atlantic ridge at a water depth of ~1300 m [Berger and von Rad, 1972].

In sharp contrast to the Tarfaya basin section [Kuhnt *et al.*, 1990], biostratigraphically significant species are largely absent from the middle Cretaceous sediments from sites 144 and 367. Carbon isotope stratigraphy was used instead to constrain the C/T OAE interval and to correlate these abyssal sites with the Moroccan shelf site. The sharp increase in $^{13}C/^{12}C$ ratios that is observed worldwide for marine carbonates and OM at the C/T boundary [Scholle and Arthur, 1980; Arthur *et al.*, 1988] has been shown to be a powerful tool in high resolution correlation [e.g. Gale *et al.*, 1993; Hasegawa, 1997]. Although this positive excursion in $\delta^{13}C$ values consists of several spikes and nudges [Gale *et al.*, 1993], three main phases can be recognised (A to C; schematically depicted in Fig. 2). Phase A is a rapid increase in $^{13}C/^{12}C$ ratios (i.e. rapid shift) that occurred during the latest

part of the *Rotalipora cushmani* zone [Gale *et al.*, 1993; Kuhnt *et al.*, 1990]. This is followed by a plateau with maximum $\delta^{13}\text{C}$ values (phase B) mainly during the early part of the *Whiteinella archaeocretacea* zone. Finally, there is a gradual return to pre-excursion $\delta^{13}\text{C}$ values (phase C) during the early Turonian. The three boundaries (I to III) between the different phases of the isotope excursion and the pre-excursion conditions are of particular stratigraphic significance. The positive excursion in $\delta^{13}\text{C}$ values reflects a change in the global atmospheric-oceanic pool of inorganic carbon resulting from a global increase in the burial rate of ^{13}C -depleted OC [Arthur *et al.*, 1988]. By definition the C/T OAE is the main phase of enhanced carbon burial rates and, therefore, should be coeval with the interval between boundaries I and III (phases A and B, indicated as a grey shaded area in Fig. 2).

The use of molecular fossils that are specific for primary producers instead of bulk OM for stable carbon isotope stratigraphy greatly reduces the effect of heterotrophy, preservation, and diagenetic alteration on the carbon isotopic signature of OC [Hayes *et al.*, 1989; Freeman and Hayes, 1992; Sinninghe Damsté *et al.*, 1998]. At site S13 of the Tarfaya basin the stable carbon isotopic compositions of two steranes (5 α -cholestane, 24-methyl-5 α -cholestane) were used to define the C/T OAE (Fig. 3). These steranes derive from C₂₇ and C₂₈ sterols, predominantly biosynthesised by marine algae [Volkman, 1986]. Their $\delta^{13}\text{C}$ values record changes in the stable carbon isotopic composition of algae (Fig. 3). Therefore, the interval from the base of the stable carbon isotopic excursion (I) until the onset of declining $\delta^{13}\text{C}$ values (III) for these steranes (indicated as a grey shaded area in Fig. 3) should correlate to the C/T OAE. Milankovitch-derived sedimentation rates (12 cm/ky) previously reported for the *Whiteinella archaeocretacea* zone of site S13 [Kuhnt *et al.*, 1997] were used to calculate a duration of ~400 ky for the C/T OAE. By analogy phase A of the isotope excursion (Fig. 2), was estimated to be ~60 ky [Kuypers *et al.*, 1999]. Although the sample resolution introduces a significant margin of error, the ~400 ky for the C/T OAE is in good agreement with data from Western Europe [Gale, 1995] indicating ~350 ky (17 precession cycles) for the same interval. In addition a duration of ~400 ky has recently been reported for the Tunesian Bahloul formation [Caron *et al.*, 1999], which approximately coincides with phases A and B of the C/T isotope excursion [Nederbragt *et al.*, 1998]. In sharp contrast, the $\delta^{13}\text{C}$ profile for bulk OC at site S13 (Fig. 3) suggests a significantly shorter duration (~250 ky) for the C/T OAE. This illustrates the benefits of using molecular fossils specific for primary producers instead of bulk OM for stable carbon isotope stratigraphy.

At sites 144 and 367 sulfur (S)-bound phytane (Figs. 4 and 5), which mainly derives from the phytol moiety of phytoplanktonic chlorophyll [Kohnen *et al.*, 1992], was used instead of the more specific algal steranes for carbon isotope stratigraphy because of the low abundance of the latter at these sites. The $\delta^{13}\text{C}$ profiles for S-bound phytane (i.e. Ph) at sites 144 and 367 both show the rapid shift in $^{13}\text{C}/^{12}\text{C}$ ratios that marks phase A (Figs. 4 and 5). The offset of ~3‰ between $\delta^{13}\text{C}$ profiles for bulk OC and the molecular fossils of chlorophyll is well within the range reported for extant algae [Schouten *et al.*, 1998]. Assuming that the excursions in $\delta^{13}\text{C}$ values at all sites are synchronous [Gale *et al.*, 1993], data from site S13 were used to calculate an average sedimentation rate for phase A of site 367 (~3.5 cm/ky). Coring gaps obscuring the later part of phase A and the whole of phase B do not allow the calculation of sedimentation rates at site 144. Similarly a coring

gap obscuring the later part of phase B at site 367 does not allow an average sedimentation rate to be calculated for the whole C/T OAE.

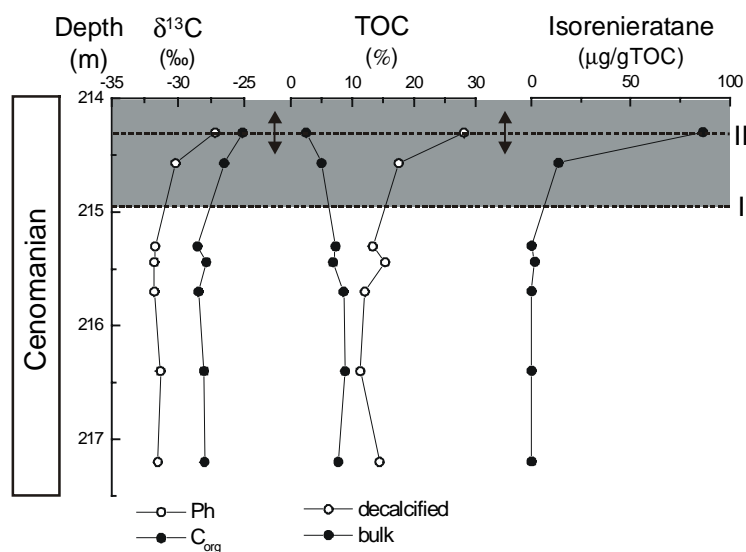

Figure 4. Stratigraphy, bulk organic carbon and biomarker data of site 144. Carbon isotope values (in ‰ vs. VPDB) of C_{org} , S-bound phytane (Ph) derived from phytoplanktonic chlorophyll, TOC content of the bulk sediment and of the residue obtained after decalcification, and concentration profile of molecular fossil (S-bound isorenieratane) of a pigment of the brown strain of green sulfur bacteria. The dashed lines with Roman numerals show the approximate position of the boundaries between the different phases of the isotope excursion (see also Fig. 2) and B indicates the sample containing benthic foraminifera.

The grey shaded areas (Figs. 4 and 5) most likely represent only a part of the total C/T OAE interval present at sites 144 and 367. However, the beginning of the rapid shift in $^{13}C/^{12}C$ ratios (earlier part of phase A) was recovered at all three sites (Figs. 3, 4 and 5) allowing a direct comparison of the changes in OC accumulation rates that occurred during the onset of the C/T OAE.

3.3.2 Organic Carbon Accumulation Rates and Organic Matter Sources

The C/T sediments of site S13 contain high amounts of OC with maximum total organic carbon (TOC) values of ~16% (Fig. 3). During the C/T OAE the average TOC content is significantly higher (~10%) than before (~5%) or after (~8%) (Fig. 3). Superimposed on these long-term trends are high-amplitude, short-term variations in TOC content throughout the investigated section. Previously reported cyclic variation in TOC content for C/T sediments from the Tarfaya basin [Kuhnt *et al.*, 1990] was attributed to fluctuations in the productivity of calcifying organisms and thus, carbonate flux [Kuhnt *et al.*, 1997]. The TOC contents for the residues obtained after decalcification (=TOC_{decalcified}) were determined in order to obtain a TOC record that is independent of these cyclic variations in carbonate flux, and which thereby better reflects relative changes in OC accumulation rate during the C/T OAE. The TOC_{decalcified} record shows an increase followed by a decrease, with maximum values within the C/T OAE interval (Fig. 3).

At site 144 the TOC content for the bulk sediment shows a decrease during the C/T OAE (Fig. 4), which co-occurs with an increase in carbonate content reflected by a change from carbonaceous marl to carbonaceous limestone. The negative correlation between TOC and carbonate content may suggest depositional dilution of OC by an increased carbonate flux [Ricken, 1993]. The TOC_{decalcified} record (Fig. 4) shows an increase during the C/T OAE for this site.

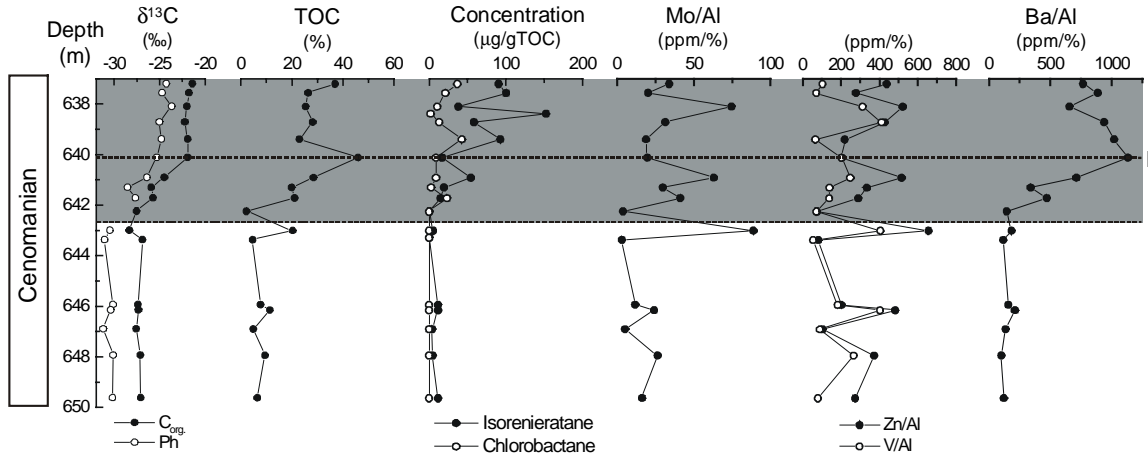

Figure 5. Stratigraphy, bulk organic carbon, biomarker, and trace metal data of site 367. Carbon isotope values (in ‰ vs. VPDB) of C_{org} , S-bound phytane (Ph) derived from phytoplanktonic chlorophyll, TOC content of the bulk sediment, concentration profiles of the molecular fossils S-bound isorenieratane and S-bound chlorobactane of green sulfur bacteria derived from members of the brown-and green-strain respectively, redox sensitive trace metals (Mo, Zn and V) normalised to Al, and the productivity proxy Ba/Al. The dashed lines with Roman numbers show the approximate position of the boundaries between the different phases of the isotope excursion (see also Fig. 2).

Extremely high OC contents (maximum TOC = 46%) exceeding the range for most if not all Holocene open ocean sediments below ~2000 m, characterise the Cenomanian sediments of site 367 (Fig. 5). Depositional dilution of OC by carbonate is insignificant for these sediments due to deposition below the carbonate compensation depth (CCD). During the C/T OAE the average TOC content is significantly higher (~25%) than before (~9%) (Fig. 5) suggesting that if sedimentation rates were constant OC accumulation rates increased significantly.

Assuming constant sedimentation rates, the average OC accumulation rates before and during the C/T OAE were determined for sites S13 and 367 using the TOC contents of the bulk (i.e. non decalcified) sediments. Prior to the C/T OAE, OC mass accumulation rates (OC MAR) for site S13 ($9 \text{ gC}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$) and site 367 ($3 \text{ gC}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$) are comparable to data for Holocene sites (Table 1) characterised by suboxic to anoxic bottom waters, high primary productivity (PP) ($140\text{-}280 \text{ gC}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$) and high bulk sediment mass accumulation rates ($125\text{-}150 \text{ g}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$). Only the OC MAR for the extremely productive (PP~ $400\text{-}500 \text{ gC}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$) Peruvian shelf is significantly higher. These values are also of the same order of magnitude as reported for Mediterranean Pliocene sapropels [i.e. $0.4\text{-}6.7 \text{ gC}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$; Nijenhuis and de Lange, 2000], which are considered younger analogues of black shales [e.g. Thomson *et al.*, 1995].

During the C/T OAE, OC accumulation rates at sites S13 and 367 (9 and $26 \text{ gC}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$, respectively) were approximately three times greater than prior to the OAE. These values exceed

those determined for most modern marine settings (Table 1) and are comparable to sites characterised by both high productivity and a high preservation potential (e.g. the Peruvian shelf). The OC accumulation rates are comparable to those determined for the OC rich interval of the *W. archaeocretacea* zone (~C/T OAE) of site CM10 off the coast of Senegal but significantly higher than values determined for the same interval of European (e.g. Gubbio) and northern North Atlantic (ODP Site 641A) sites [Table 1; *Kuhnt et al.*, 1990], confirming that the southern proto-North Atlantic was one of the main locations of OC burial during the C/T OAE.

Microscopic screening of the decalcified and sieved (>10 µm) samples reveals that the OM from both shelf (well S13) and deep sea sites (sites 144 and 367) is almost exclusively amorphous with rare vascular plant remains and pollen. High Rock Eval hydrogen indices (HI) [*Herbin et al.*, 1986; *Kuhnt et al.*, 1990] and the low abundance of lignin pyrolysis products generated from the kerogen indicate a marine origin for the thermally immature OM before, during and after the C/T OAE. This is supported by the low abundance (site 367) or even absence (sites S13 and 144) of molecular fossils of unambiguous terrestrial origin (e.g. leaf-wax lipids and oleananes) in the extractable OM. Hence the increase in OC accumulation rates observed at all three sites resulted from enhanced marine OM burial during the C/T OAE. At site S13 and site 367 this increase in OC accumulation rates could have been as large as 17 and 6 gC·m⁻²·y⁻¹, respectively. The question that remains is: did this increase in the marine OC accumulation rates mainly result from increased preservation under anoxic conditions or from increased primary productivity?

3.3.3 Water Column Redox Proxies

3.3.3.1 Molecular fossils of anoxygenic photosynthetic bacteria. Anoxic conditions periodically reached up into the photic zone as indicated by the abundance of molecular fossils (i.e. S-bound isorenieratane showing the typical 10-15‰ ¹³C enrichment relative to algal lipids [e.g. *Sinninghe Damsté et al.*, 1993]) indicative of anoxygenic photosynthetic bacteria at sites S13, 144 and 367 (Figs. 3, 4 and 5). This is in good agreement with earlier findings of *Sinninghe Damsté and Köster* [1998]. S-bound isorenieratane is formed in anoxic sediments upon sulfurisation of the polyunsaturated pigment isorenieratene in the presence of reduced inorganic S species [*Sinninghe Damsté et al.*, 1993;]. Carotenoids such as isorenieratene are generally labile compounds [*Sinninghe Damsté and Koopmans*, 1997] that do not survive transport over long distances, clearly indicating a local marine rather than allochthonous source for S-bound isorenieratane. The pigment isorenieratene is exclusively produced by the brown strain of green sulfur bacteria [*Imhoff*, 1995], which require sunlight penetrating the euxinic part (e.g. containing reduced inorganic sulfur species) of an aquatic environment [*van Gernerden and Mas*, 1995]. Currently, these phototrophic bacteria are restricted to a few isolated euxinic basins in the marine realm such as the Black Sea. In such environments they thrive near the hydrogen sulfide/oxygen interface (i.e. chemocline) at depths of up to 150 m, where light levels are less than 1% of surface irradiance [*van Gernerden and Mas*, 1995].

Molecular fossils of isorenieratene were also found in sediments predating the isotope excursion albeit in much lower concentrations, indicating that sulfide-containing water periodically penetrated the photic zone before the actual onset of the C/T OAE (Figs. 3, 4 and 5). While S-bound

isorenieratane is present throughout the interval preceding the C/T OAE at site S13 and site 367, it was only found in one sample of the same interval at site 144 (Fig. 4). This indicates that sulfide-containing water penetrated the photic zone more frequently at the southeastern side than at the southwestern side of the proto-North Atlantic Ocean, possibly reflecting a shallower average position of the chemocline (i.e. nearer to the photic zone). High amplitude short-term fluctuations in S-bound isorenieratane concentrations occur during the C/T OAE at both site S13 and site 367, although the amplitude is more pronounced at the former site (Figs. 3 and 5). The more pronounced fluctuations at site S13 could represent a sampling artefact as sample sizes are similar (~5 cm) but sedimentation rates significantly lower at site 367. As a result S-bound isorenieratane concentrations at site S13 (Fig. 3) represent an average over a much shorter time scale (~400 years) than at site 367 (Fig. 5) (~1400 years) possibly leading to a less 'smoothed' S-bound isorenieratane record at the former site. Fluctuations in S-bound isorenieratane concentrations could have resulted from changes in anoxygenic productivity. In accordance with the latter, fluctuations in the abundances of isorenieratane and its molecular fossils extracted from Holocene Black Sea sediments were attributed to changes in anoxygenic productivity related to fluctuations in the position of the chemocline [Repeta, 1993; Sinninghe Damsté et al., 1993]. The abundance of phototrophic sulfur bacteria in modern settings not only increases and decreases as euxinic conditions rise into or drop below the photic zone, respectively, but also shows a strong positive correlation with light intensity [van Gemerden and Mas, 1995]. Therefore, the short-term variations and pronounced long-term increases in S-bound isorenieratane concentrations during the C/T OAE could be produced by either the chemocline penetrating the photic zone at a similar depth but over considerably longer time scales or by relatively short excursions to much shallower depths.

The occurrence of molecular fossils of the pigment chlorobactene (i.e. S-bound chlorobactane) in the OAE sediments of sites 144 and 367 (Figs. 4 and 5) and their absence prior to the OAE interval indicates a rise of the chemocline to shallower depths during the C/T OAE. Chlorobactene is exclusively produced by the green coloured strain of green sulfur bacteria [Imhoff, 1995], which thrives at a shallower depth (less than 15 m) than the brown strain since it requires a higher light intensity [van Gemerden and Mas, 1995]. Assuming a similar light dependence for these phototrophic sulfur bacteria during the mid-Cretaceous, the occurrence of S-bound chlorobactane indicates that the upper 15 m of the photic zone of the southern proto-North Atlantic periodically contained sulfide during the C/T OAE.

3.3.3.2 Trace metals. Further information on water column redox conditions can be gained from elements (e.g. Mo, Ni and Zn) that precipitate as sulfides under euxinic conditions and certain elements (e.g. Mo and V) that are immobilised under reducing conditions. Sediments underlying a euxinic water column are often characterised by a strong enrichment of these trace metals [e.g. Arthur et al., 1990; Calvert and Pedersen, 1993]. In accordance with this, very high trace metal concentrations were previously reported for mid Cretaceous black shales of site 367 [Brumsack and Thurow, 1986] and were attributed to enhanced trace metal scavenging in a euxinic water column. The average trace metal concentrations reported here for C/T sediments (table 1) are in good agreement with the data from Brumsack and Thurow [1986].

To evaluate the variations in redox conditions, the abundances of Mo, V and Zn have been normalised to aluminium (Al) (Fig. 5). The Mo/Al, V/Al and Zn/Al profiles show strong fluctuations that could result from changes in detrital (i.e. clay minerals) sedimentation rate, the scavenging capacity of sediment and water column, and/or the trace metal abundance in the seawater. Enhanced Mo/Al ratios during the C/T OAE could have resulted from enhanced scavenging related to shoaling of the chemocline. Relatively high Zn/Al and V/Al values occur both before and during the OAE. The lack of a clear increase in V/Al and Zn/Al ratios during the C/T OAE indicates that bottom water redox conditions did not change dramatically.

3.3.3.3 Synthesis of redox proxies.

The occurrence of molecular fossils of pigments from green sulfur bacteria at sites S13, 144 and 367 indicates that the photic (<150 m) zone of the southern proto-North Atlantic Ocean periodically contained sulfide already before the C/T OAE. The deposition of predominately laminated sediments devoid of or strongly impoverished in benthic faunas at sites S13 and 144 [Berger and von Rad, 1972; Kuhnt *et al.*, 1990] suggests that these anoxic conditions periodically extended to at least 1300 m water depth. Arthur *et al.* [1984] suggested that the deeper bottom waters (>3000 m) of the proto North Atlantic were predominately oxic. This is contradicted by other workers who have described the 367 black shales from this interval as laminated and deposited under dysoxic/anoxic conditions [e.g. Bralower and Thierstein, 1987; Sinninghe Damsté and Köster, 1998]. In any case, the abundance of elements that precipitate as sulfides under euxinic conditions or that are immobilised under reducing conditions throughout the investigated interval of site 367 strongly suggests that the deeper bottom waters were anoxic for extended times [see also Brumsack and Thurow, 1986; Arthur *et al.*, 1990]. Consistent with this, very high TOC contents (up to 50%) and hydrogen indices [550-850 mg hydrocarbons/g TOC; Herbin *et al.*, 1986], the abundance of sulfur-bound compounds as well as the high preservation factors for OC are indicative of anoxic conditions during deposition of the sediments [see also Herbin *et al.*, 1986 and Sinninghe Damsté and Köster, 1998].

During the C/T OAE there was a significant rise of the chemocline as indicated by the increased concentrations of molecular fossils of green sulfur bacteria. Molecular fossils of the green strain of green sulfur bacteria (DSDP Site 144 and 367) indicate that euxinic conditions periodically even occurred above 15 m during the C/T OAE.

Decreased degradation of OM resulting from anoxic bottom water conditions would have contributed to a high OC preservation in the southern proto-North Atlantic both prior to and during the C/T OAE. Thus shoaling of the chemocline during the C/T OAE probably did not enhance OM preservation significantly since it apparently only marginally affected the exposure to oxygen. This suggests that the observed increase in OC burial rates during the C/T OAE did not result from increased preservation.

3.3.4 Productivity Proxies

3.3.4.1 Sedimentary Barium. Sedimentary Ba is generally considered as an indicator for palaeoproductivity since it originates from barite formed in decaying phytoplanktonic OM [Dymond *et al.*, 1992; Francois *et al.*, 1995]. Such barite formation has been shown to occur in the well-oxygenated open ocean [Dymond *et al.*, 1992; Francois *et al.*, 1995] as well as in the suboxic to anoxic waters of OMZs and euxinic basins [Falkner *et al.*, 1993; Dean *et al.*, 1997]. Prior to the C/T OAE the average Ba concentration at site 367 is comparable to data reported for C/T sediments and some Pliocene sapropels (Table 1). The five fold increase in Ba/Al ratios indicates enhanced export productivity during the C/T OAE (Fig. 5).

Assuming that the mechanism for Ba enrichment in decaying OM during the Cretaceous was similar to that proposed for more recent settings [Bishop, 1988], we estimated productivity before and during the C/T OAE from Ba accumulation rates. Since under suboxic to anoxic diagenetic conditions Ba preservation may be reduced [Dymond *et al.*, 1992; Falkner *et al.*, 1993; Francois *et al.*, 1995; McManus *et al.*, 1998], the productivity values obtained here could represent underestimates of the absolute values. The amount of OC (in $\text{gC}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$) that is transported out of the photic zone (the export productivity, EP) was calculated, using equations proposed by Francois *et al.* [1995] and Dymond *et al.* [1992]. For a thorough discussion of this method see Nijenhuis and de Lange [2000]. The concentration of biogenic Ba was calculated using the Al content of the individual samples and assuming a detrital Ba/Al ratio of $6.1\cdot 10^{-3}$ [Dehairs *et al.*, 2000]. Export productivity was calculated assuming a constant sedimentation rate of 3.5 cm/ky throughout the interval and using an average dry bulk density of $1.14 \text{ g}\cdot\text{cm}^{-2}\cdot\text{ky}^{-1}$ [Hayes *et al.*, 1972]. The calculated EP prior to the C/T OAE is comparable to data for the Pliocene sapropels but considerably lower than for modern high productivity sites like the Arabian Sea (Table 1). During the C/T OAE the average EP value is five times higher than prior to the OAE and comparable to the Arabian Sea value.

In the modern ocean nitrate and phosphate formed upon remineralisation of particulate OM (POM) below the photic zone play a key role in sustaining primary productivity (=new production). Assuming this was also the case in the Cretaceous and the amount of nitrogen and phosphorus entering the photic zone was equal to the amount of nitrogen and phosphorus transported out (EP~new production), primary productivity (PP) was calculated from the EP values for site 367 using the equation of Eppley and Peterson [1979]:

$$\text{Total production} = (\text{New production} / 0.0025)^{1/2}$$

The calculated average PP (Table 1) of $70 \text{ gC}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$ before the C/T OAE is comparable to the low PP sites of the modern North Atlantic and Central Pacific (Table 1). However, a significantly higher average PP of $180 \text{ gC}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$ is calculated during the OAE, which is comparable to the high PP of the modern Arabian Sea and Black Sea. The calculated nearly threefold increase in PP ($\sim 100 \text{ gC}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$) is large enough to explain the observed increase in OC accumulation rate at Site 367 during the C/T OAE. As a consequence, preservation factors (PF= OC accumulation rate divided by the

PP) for OC before and during the C/T OAE are identical (both ~5%). This PF is comparable to what was previously suggested [Bralower and Thierstein, 1987] for mid-Cretaceous Black shales, and the maximum PF reported for the euxinic Holocene Black Sea [Arthur *et al.*, 1994] and is consistent with anoxic water column conditions during as well as before the C/T OAE.

3.3.4.2 Stable carbon isotopes. The degree of photosynthetic carbon fractionation (ϵ_p) for marine phytoplankton shows a strong negative correlation with both growth rate and cell size [e.g. Laws *et al.*, 1995; Popp *et al.*, 1998] therefore an increase in PP should be reflected in $\delta^{13}\text{C}$ values of phytoplankton-derived organic matter.]. However, ϵ_p values for marine phytoplankton also shows a pronounced dependence on CO_2 concentration [Rau *et al.*, 1989]. Therefore, the drop in atmospheric CO_2 concentrations resulting from enhanced OC burial rate during the C/T OAE [Arthur *et al.*, 1988; Freeman and Hayes, 1992; Kuypers *et al.*, 1999] should likewise be reflected in the stable carbon isotopic composition of phytoplanktonic OC.

To assess whether there is any carbon isotopic evidence for enhanced PP in the southern proto-North Atlantic during the C/T OAE changes in ϵ_p values for phytoplankton were determined. $\delta^{13}\text{C}$ values for inorganic carbon, which are needed to calculate ϵ_p , could not directly be determined due to diagenetic alteration (S13 and site 144) or absence of carbonate carbon (site 367). Since enhanced OC burial during the C/T OAE should have affected the stable carbon isotopic composition of inorganic carbon globally in a similar way, data from other sites with better preserved carbonate records are used instead. Such globally dispersed sites indicate that the positive excursion in marine carbonate $\delta^{13}\text{C}$ values was ~2.5‰ [e.g. Arthur *et al.*, 1988; Jenkyns *et al.*, 1994]. However, shoaling of the chemocline discussed previously could have introduced ^{13}C depleted recycled inorganic carbon into the photic zone causing smaller increases in $\delta^{13}\text{C}$ values for inorganic carbon in the southern proto-North Atlantic. Therefore, the estimated shift of 2.5 ‰ for inorganic carbon is likely a maximum value, and estimated shifts in ϵ_p are interpreted as minimum values. Assuming a 2.5‰ excursion for inorganic carbon, the 6‰ increase in the $\delta^{13}\text{C}$ values for S-bound phytane at site 367 (Figs. 5) records a 3.5‰ decrease in ϵ_p values. A slightly smaller decrease in ϵ_p values is suggested by the 5‰ increase in $\delta^{13}\text{C}$ values observed for steranes at site S13 (Figs. 3). Coring gaps probably obscure the later part of phase A of the carbon isotope excursion at site 144. The 2‰ decrease in ϵ_p values that was calculated from the 4.5‰ increase in $\delta^{13}\text{C}$ values for S-bound phytane at site 144 (Fig. 5) could therefore be larger. A significantly smaller decrease in ϵ_p (< 2‰) is indicated by the 4–4.5‰ increase in $\delta^{13}\text{C}$ values for S-bound phytane at site 603B [Kuypers *et al.*, unpublished results]. For the Cretaceous Western Interior Seaway (North America) geoporphyrin fractions were used to calculate a 1.5‰ decrease in ϵ_p values during the C/T OAE [Hayes *et al.*, 1989], and subsequently interpreted as a *c.* 20% reduction in atmospheric CO_2 concentration [Freeman and Hayes, 1992]. The shift in ϵ_p values has only been directly measured for the Cretaceous Western Interior Seaway; nonetheless, the shift in $\delta^{13}\text{C}$ values for the geoporphyrin fractions is smaller than for any other OC record, be it bulk or molecular fossils of phytoplanktonic origin. This prompted us [Kuypers *et al.*, 1999] to suggest that the drop in CO_2 concentrations could have been larger than the 20% suggested by Freeman and Hayes [1992]. However, sites 367 and S13 both exhibit shifts in $\delta^{13}\text{C}$ values larger than reported for any other

site indicating significantly larger ϵ_p shifts -and these are likely minimum estimates. Thus, although we can not determine the absolute effect of either decreased CO₂ concentrations or enhanced algal growth rate/average cell size on the OC isotope records, it seems likely that an increase in PP accounts for the larger shift in $\delta^{13}\text{C}$ values for molecular fossils of phytoplanktic origin at sites 367 and S13. This is entirely consistent with the increase in Ba/Al ratios for site 367 and the fact that these two sites experienced a dramatic increase in OC MAR while bottom water redox conditions did not change.

3.4. Palaeoceanographic Implications

The combined redox proxies indicate that the southern part of the proto-North Atlantic Ocean was already periodically euxinic from the bottom to at least the base of the photic (<150 m) zone before the C/T OAE. This is in good agreement with the results obtained from model simulations for the Albian and early Cenomanian proto-North Atlantic Ocean circulation [Poulsen, 1999] and probably resulted from a combination of overall sluggish circulation (possibly halothermal instead of thermohaline) and the tectonically isolated nature of the proto-North Atlantic (Fig. 1). Sedimentological and geochemical data from the proto-North Atlantic indicate that anoxic conditions persisted in the southern and southeastern part, while the northern and northeastern part was oxic during most of the Albian to late Cenomanian [de Graciansky *et al.*, 1984]. Conditions in the northwestern part were more versatile with alternating oxic and anoxic periods. The coexistence of oxic and anoxic conditions in the proto-North Atlantic could have resulted from a barrier restricting deep water exchange between the southeastern and northwestern part of the basin [de Graciansky *et al.*, 1984]. Enhanced PP as a result of wind driven upwelling in the equatorial region [Handoh *et al.*, 1999] could have further diminished the oxygen content of the southern part of the proto-North Atlantic Ocean.

During the C/T OAE there was a significant shoaling of the chemocline as indicated by the large increase in the concentrations of molecular fossils of green sulfur bacteria. The occurrence of molecular fossils of pigments specific for the green strain of green sulfur bacteria even indicates that the upper part of the photic zone (<15 m) periodically contained sulfide during the C/T OAE. However, the increase (up to $17 \text{ gC}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$) in OC accumulation rates at shallow (~300 m; site S13), intermittent (~1300 m; site 144) and deep (3700 m; site 367) water settings probably cannot be attributed to enhanced preservation as our trace metal data suggests there was no major change in bottom water redox conditions.

There is evidence (e.g. enhanced Ba accumulation rates, significantly larger shifts in $\delta^{13}\text{C}$ values for OC of phytoplanktic origin than in any other Cretaceous marine realm) for enhanced PP during the C/T OAE in the southern proto-North Atlantic. The increase in PP ($\sim 100 \text{ gC}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$) is large enough to explain the observed increase in OC accumulation rate at site 367 during the C/T OAE. In the modern ocean enhanced PP is closely linked with intensified upwelling of intermediate waters into the photic zone. In accordance with this it has been suggested that fertilisation of the surface waters by upwelling stimulated primary productivity leading to the widespread deposition of OC-rich sediments during the C/T OAE [e.g. Arthur *et al.*, 1987; Parrish, 1995]. Enhanced upwelling on a global scale has been attributed to either the initiation of a deep connection between

the proto-North and South Atlantic basins [*Tucholke and Vogt, 1979; Summerhayes, 1987*] or the increased formation of warm, saline deep water as a result of a world wide transgression [*Arthur et al., 1987*].

As alternatives to enhanced upwelling, enhanced volcanism [*Sinton and Duncan, 1997*] and leaching of flooded coastal lowlands [*Erbacher et al., 1996*] have been suggested as sources for biolimiting nutrients during the C/T OAE. Introduction of hydrothermal Fe to the surface waters could have produced large-scale plankton blooms, but only in basins where Fe was biolimiting. This was probably not the case for the small Atlantic basins where sufficient Fe could be supplied by riverine or aeolian input from the surrounding land [*Sinton and Duncan, 1997*]. Leaching of nutrients from flooded coastal areas could have enhanced PP in the southern proto-North Atlantic. Oxygen utilisation resulting from mineralisation of enhanced OM input could even have facilitated shoaling of the chemocline. However, it is hard to imagine how enhanced PP on its own could lead to euxinic conditions in the generally well mixed upper 15 m of the water column. Thus, we conclude that the co-occurrence of enhanced PP and shoaling of the chemocline in the southern part of the proto-North Atlantic was caused by enhanced upwelling providing new nutrients and sulfide-containing water to the photic zone. The enhanced production of warm, saline deep water could have led to enhanced upwelling and thereby explain the observed changes in the southern proto-North Atlantic during the C/T OAE. It is generally assumed that the rate of production of warm, saline deep water was proportional to the area of shelf flooding and that maximum flooding occurred during the C/T OAE [*Arthur et al., 1987*]. However, according to *Haq et al.* [1987] the maximum sea level high stand occurred during the early/middle Turonian rather than late Cenomanian, which would argue against a world wide transgression being the ultimate driving force for the C/T OAE.

Alternatively, influx of dense saline water from a different ocean basin could have caused the inferred upwelling. Evidence for the establishment of a deep water connection between the proto-North and South Atlantic basins through the Equatorial Atlantic Gateway may come from the widespread hiatus in the open ocean sediment record of the South Atlantic, which was attributed to an erosional event near the C/T transition [*Zimmerman et al., 1987*]. A similar unconformity has been recognised through much of the North Atlantic and western Tethyan Seaway [*de Graciansky et al., 1984*]. In addition, the sedimentary record of the Equatorial Atlantic Gateway has provided evidence for erosive deep water currents, and this has been attributed to the formation of a deep connection between proto-North and South Atlantic basins during the late Cenomanian [*Wagner and Pletsch, 1999*]. There is also evidence from Nd isotopes for invigorated exchange of water between the Atlantic basins and the Pacific at approximately the same time [*Stille et al., 1996*]. The influx into the proto-North Atlantic of large amounts of highly saline, old, oxygen deficient water from the South Atlantic would have displaced deep water towards the surface [*Tucholke and Vogt, 1979; Summerhayes, 1987*]. As a more or less stagnant anoxic basin possibly with a partly estuarine-like circulation [*Arthur et al., 1987; Thierstein and Berger, 1979*], the proto-North Atlantic could have acted as a nutrient trap [*Summerhayes, 1987*] comparable to the Holocene Black Sea and Cariaco Trench that contain high levels of dissolved nutrients such as ammonium and phosphorus [*Sarmiento et al., 1988; Fry et al., 1991*]. Thus, water brought to the surface as a consequence of the influx of South Atlantic dense water was likely extremely nutrient-rich, such

that upwelling could have globally enhanced PP and caused OC burial to increase; this would have persisted until nutrients from the proto-North Atlantic and the South Atlantic were depleted. Eventually, oxygenated deep water from the eastern Southern Ocean could have entered the proto-North Atlantic during the Turonian [Poulsen, 1999] ending the deposition of OC rich sediments.

Chapter 4

Orbital forcing of organic carbon accumulation in the proto-North Atlantic during the Cenomanian/Turonian oceanic anoxic event

Abstract.

The Cenomanian/Turonian intervals at DSDP sites 105 and 603B from the northern part of the proto North Atlantic show high amplitude, short-term cyclic variations in TOC contents. The more pronounced changes in TOC are also reflected by changes in lithology from green claystones (TOC < 1%) to black claystones (TOC > 1%). Although their depositional history was very different, the individual TOC cycles at sites 105 and 603B can be correlated using stable carbon isotope stratigraphy. Sedimentation rates obtained from the isotope stratigraphy and spectral analyses indicate that these cycles were predominately precession controlled. The coinciding variations in HI, OI, $\delta^{13}\text{C}_{\text{org}}$, and the abundance of marine relative to terrestrial biomarkers as well as the low abundance of lignin pyrolysis products generated from the kerogen of the black claystones indicate that these cyclic variations reflect changes in the contribution of marine OM. The co-occurrence of lamination, enrichment of redox sensitive trace metals and presence of molecular fossils of pigments from green sulfur bacteria indicates that the northern proto-North Atlantic Ocean water column was sometimes euxinic from the bottom to at least the base of the photic zone (<150 m) during the deposition of the black claystones. In contrast, the green claystones are bioturbated, are enriched in Mn, do not show enrichments in redox sensitive trace metals and show biomarker distributions indicative of long oxygen exposure times, indicating more oxic water conditions. At the same time there is evidence (e.g. enhanced Ba/Al ratios, abundance of biogenic silica and significant ^{13}C -enrichment for OC of phytoplanktic origin) for enhanced primary productivity during the deposition of the black claystones. We propose that increased primary productivity periodically overwhelmed the oxic OM remineralisation potential of the bottom waters resulting in the deposition of OM-rich black claystones. Because the amount of oxygen used for OM remineralisation exceeded the amount supplied by diffusion and deep-water circulation the northern proto North Atlantic became euxinic during these periods. Both sites 105 and 603B show trends of continually increasing TOC contents and HI values of the black claystones up section, which most likely resulted from both enhanced preservation due to increased anoxia and increased production of marine OM during the C/T OAE.

4.1 Introduction

During the Cenomanian/Turonian (C/T) transition laminated sediments rich ($> 1\%$) in organic carbon (OC) (black shales) were globally deposited in a variety of paleo-bathymetric settings [Schlanger and Jenkyns, 1976]. Evidence for the global nature of this organic carbon burial event is provided by a coinciding increase in $^{13}\text{C}/^{12}\text{C}$ ratios for marine carbonates and organic matter. This positive excursion in $\delta^{13}\text{C}$ values likely resulted from preferential removal of ^{12}C by the enhanced burial of ^{13}C depleted OC as a response to the so-called ‘C/T oceanic anoxic event (OAE)’ [Arthur *et al.*, 1988]. The widespread deposition of black-shales during the C/T OAE has been attributed to either decreased OM remineralisation resulting from a decreased oxygen flux (preservation model) [Bralower and Thierstein, 1987] or increased primary productivity overwhelming the oxic OM remineralisation potential of the water column (productivity model) [Schlanger and Jenkyns, 1976]. The preservation model has mainly been applied for tectonically isolated basins such as the Cretaceous North and South Atlantic [Zimmerman *et al.*, 1987; De Graciansky *et al.*, 1984]. Model simulations for the Albian and early Cenomanian ocean circulation [Poulsen *et al.*, 1999]; Bice, personal communication] show that especially the proto-North Atlantic was prone to water column anoxia due to a combination of overall sluggish circulation (possibly halothermal instead of thermohaline), high sea surface temperatures and the tectonically isolated nature of the proto-North Atlantic basin (Fig. 1).

Figure 1. Palaeogeographical map of mid Cretaceous (~94 Ma) North Atlantic showing the position of the four studied cores. Light grey shaded regions represent flooded continental plates (from GEOMAR map generator;

www.odsn.de/odsn/services/paleomap/paleomap.html). Dark grey shaded regions represent land [Scotese and Golonka, 1992].

The reoccurrence of thinly laminated OM-rich sediments devoid of traces of benthic activity indicates that proto-North Atlantic bottom-waters were indeed periodically anoxic during the mid Cretaceous [Summerhayes, 1987; Bralower and Thierstein, 1987]. Sedimentary derivatives (molecular fossils) of a pigment indicative of anoxygenic photosynthetic bacteria recovered from abyssal and shelf sites indicate that anoxic conditions extended even into the photic zone of the southern proto-North Atlantic during the C/T OAE [Sinninghe Damsté and Köster, 1998]. Recently we provided evidence (e.g. occurrence of molecular fossils of green sulfur bacteria, lack of bioturbation and high abundance of redox sensitive trace metals) that the southern part of the proto-North Atlantic Ocean was already euxinic up into the photic zone well before the C/T OAE [Kuypers et al., 2000 submitted to Pal.]. Sedimentological and geochemical data from the proto-North Atlantic indicates that anoxic bottom-water conditions persisted in the southern and southeastern part during most of the late Aptian to late Cenomanian [De Graciansky et al., 1987]. However, in the northwestern part conditions were more versatile with alternating oxic and anoxic periods [De Graciansky et al., 1987]. Herbin et al. [Herbin et al., 1987a] showed that the C/T OAE interval at sites 105 and 603B is not a single, homogeneous, black shale layer but rather a condensation of several black claystone layers alternating with thinner levels of green claystone. The coexistence of permanently anoxic conditions in the southern part and alternating oxic and anoxic conditions in the northwestern part of the proto-North Atlantic has been attributed to restricted deep water exchange as a result of a barrier between the southeastern and northwestern part of the basin [De Graciansky et al., 1987]. The diminished oxygen content of the southern part of the proto-North Atlantic Ocean has been suggested to result from enhanced primary productivity (PP) as a result of wind driven upwelling in the equatorial region [Handoh et al., 1999].

Here we provide evidence of precessional forcing in the C/T OAE intervals for these northwestern proto-North Atlantic sites using isotope-stratigraphy and spectral analysis. In addition, changes in geochemical parameters of two green-black-green claystone cycles were studied in high resolution and the results are used together with the data obtained from an overall geochemical analyses for the C/T OAE interval to reconstruct precessional forced chemocline variations and variations in primary productivity.

4.2. Material and methods

4.2.1 Material. The sediment samples used in this study were obtained from the Deep Sea Drilling Project (DSDP) sites 105 (leg 11) and 603B (leg 93) off the coast of North America. One to five cm thick sediment slices were taken from the cores. Sub-samples were taken from these slices and subsequently freeze-dried and powdered in an agate mortar.

4.2.2 Organic matter analyses. Analyses of soluble and insoluble organic matter were performed as described previously by Kuypers et al. [2000; submitted to Paleocyanography]. Briefly, Total Organic Carbon (TOC) contents were determined using a CN analyser. The $\delta^{13}\text{C}$ values ($\pm 0.1\%$

versus Vienna Pee Dee belemnite (VPDB)) were measured on bulk sediments, after removal of the inorganic carbonates with diluted HCl, using automated on-line combustion followed by conventional isotope ratio-mass spectrometry. For analyses of the soluble OM powdered samples (15 to 30 g) were Soxhlet extracted for c. 24 h to obtain the total extract. The total extract was separated into an apolar and a polar fraction using column chromatography. The hydrocarbons that were released from the polar fraction by Raney Nickel desulfurisation and subsequent hydrogenation [Sinninghe Damsté *et al.*, 1990] were isolated using column chromatography. Samples were analysed by gas chromatography-mass spectrometry (GC-MS) for compound identification. Compound-specific $\delta^{13}\text{C}$ analyses were performed using a Finnigan Delta C GC-isotope-ratio-monitoring MS. The $\delta^{13}\text{C}$ values for individual compounds are the means of duplicate runs ($\sigma = \pm 0.3$ to 0.6) expressed versus VPDB.

4.2.3 Inorganic analyses. For major, minor and trace element analyses, a 125 mg sample was digested in 5 ml HF (40%) and 5 ml of a $\text{HClO}_4/\text{HNO}_3$ mixture at 90°C . After evaporation to dryness on a sand bath at 190°C , the residue was dissolved in 25 ml 1 M HCl. The resulting solutions were analysed with a Perkin Elmer Optima 3000 inductively coupled plasma atomic emission spectrometer (ICP-AES). The results were checked with international and house standards. For all ICP analyses, relative standard deviations in duplicate measurements are below 4%.

X-ray powder diffraction (XRD) was carried out on a home-built (NIOZ, Texel) high accuracy θ - θ diffractometer to determine the mineralogical composition of the sediments. $\text{CuK}\alpha$ radiation (40 kv, 40 mA) from a long fine focus tube was applied in combination with variable divergence and antiscatter slits, and an energy dispersive Si/Li detector (Kevex). The measuring slit was set at 0.2 mm and the counting time was 1 sec./ $0.02^\circ 2\theta$. The samples were Ca exchanged prior to analysis. The samples were measured at 50% relative humidity [Kühnel and van der Gaast, 1993] The patterns were corrected for the Lorentz and polarisation factor and for the irradiated specimen volume.

4. 2.4 Spectral analyses. Power spectra for the TOC and HI data from site 603B were obtained by using the AnalySeries 1.0 software. The Blackman-Tukey method was used for the spectral analysis of the high-resolution data set that was reported previously by Herbin *et al.* [1987]. The data sets were prepared by removing the linear trends of continually increasing TOC contents and HI values of the black claystones up section by determining and subsequently subtracting the linear regression between TOC contents or HI values and depth before using the Fourier technique.

4.3. Results and discussion

4.3.1 Stratigraphy and palaeosetting

Our study concentrates on the sediments of DSDP sites 105 and 603B that have been assigned a late Cenomanian to early Turonian age based on biostratigraphy [Herbin *et al.*, 1987a; Thurow, 1988]. Although these sites are only ~125 km apart, their depositional history was very

different with 603B located nearer to the coast and being influenced by coastal oceanic events, whereas Site 105 showed mainly pelagic influences [Herbin *et al.*, 1987a]. Both sites, however, show the OM-enrichment that characterizes C/T sediments worldwide [Herbin *et al.*, 1987a]. The C/T sequences at DSDP sites 105 and 603B consist of an alternation of OM-poor green claystones and OM-rich (TOC 1-25%) black claystones [Herbin *et al.*, 1987a]. Carbonate contents are low (<10%) which suggests that deposition took place below CCD. The hemipelagic sediments of site 603B as well as the pelagic sediments of site 105 were deposited at a water depth of ~4000 m [Chénet and Francheteau, 1979].

Figure 2. Idealised representation of C/T stable carbon isotope excursion showing the bio- and chronostratigraphic position of the three main phases (modified after [Gale *et al.*, 1993]). Dashed lines with roman numbers show the position of the boundaries between the different phases (pre-excursion, A, B and C) of the isotope excursion

Carbon isotope stratigraphy was used to constrain the C/T OAE interval and to correlate these abyssal sites with the Moroccan shelf site S13, a site with good bio- and chronostratigraphic control [Kuhnt *et al.*, 1997a]. For a more thorough discussion of this method see Kuypers *et al.* [2000]. The horizontal dotted lines with Roman numbers (I-III) in the idealised representation of C/T stable carbon isotope excursion (Fig. 2) indicate the boundaries between the pre-excursion conditions (i.e. pre-excursion $\delta^{13}\text{C}$ values) and the three main phases of the isotope excursion (i.e. rapid positive shift in $\delta^{13}\text{C}$ values, plateau with maximum $\delta^{13}\text{C}$ values and return to pre-excursion $\delta^{13}\text{C}$ values). Of particular stratigraphic significance is boundary II that nearly coincides with the last occurrence of the planktonic foraminifer *Rotalipora cushmani* [Kuhnt *et al.*, 1990] and boundary III, which approximately coincides with the C/T boundary [Gale *et al.*, 1993]. The positive excursion in $\delta^{13}\text{C}$ values reflects a change in the global atmospheric-oceanic pool of inorganic carbon resulting from a global increase in the burial rate of ^{13}C -depleted OC [Arthur *et al.*, 1988]. By definition the C/T OAE is the main phase of enhanced carbon burial rates and, therefore, should be coeval with the interval between boundaries I and III (phases A and B, indicated as a grey shaded area in Fig. 2).

Milankovitch cyclicity-derived sedimentation rates (12 cm/ky) previously reported for the *Whiteinella archaeoetacea* zone of site S13 [Kuhnt *et al.*, 1997b] were used to calculate a duration of ~400 ky for the C/T OAE [Kuypers *et al.*, 2000 submitted to *Paleoceanography*]. In a similar way phase A of the isotope excursion (Fig. 2), was estimated to be ~60 ky [Kuypers *et al.*, 1999]. Although the sample resolution introduces a significant margin of error, the ~400 ky for the C/T OAE is in good agreement with data from Western Europe [Gale, 1995] indicating ~350 ky (17 precession cycles) for the same interval. In addition, a duration of ~400 ky has recently been reported for the Tunesian Bahloul formation [Caron *et al.*, 1999], which approximately coincides with phases A and B of the C/T isotope excursion [Vonhof, 1998; Nederbragt *et al.*, 1998].

The use of molecular fossils that are specific for primary producers instead of bulk OM for stable carbon isotope stratigraphy greatly reduces the effect of heterotrophy, preservation, and diagenetic alteration on the carbon isotopic signature of OC [Hayes *et al.*, 1989; Freeman and Hayes, 1992; Sinninghe Damsté *et al.*, 1998]. At DSDP site 603B the stable carbon isotopic composition of the acyclic isoprenoid phytane released upon desulfurisation of the polar fraction (e.g. S-bound phytane) was used for carbon isotope stratigraphy (Fig. 3). This S-bound phytane mainly derives from the phytol moiety of phytoplanktonic chlorophyll [Kohnen *et al.*, 1992a] and, thus, reflects the changes in the stable carbon isotopic composition of phytoplankton [Kohnen *et al.*, 1992b]. The $\delta^{13}\text{C}$ profile for S-bound phytane (i.e. Ph) at DSDP site 603B shows the rapid shift in $^{13}\text{C}/^{12}\text{C}$ ratios that marks phase A as well as at least a part of phase B (the plateau with maximum $\delta^{13}\text{C}$ values) (Fig. 3). The isotopic record of TOC indicates that samples with a TOC < 1% are generally 1-3‰ enriched in ^{13}C relative to adjacent samples with a TOC > 1% (Fig. 3). This indicates that preservation may have affected the bulk OC $\delta^{13}\text{C}$ record. However, there is a general similarity in trend between the molecular fossil and bulk OC records for the C/T OAE interval (phases A and B) at DSDP site 603B if we exclude the $\delta^{13}\text{C}$ values of samples with a TOC < 1%. The offset of ~3‰ between $\delta^{13}\text{C}$ profiles for bulk OC and the molecular fossils of chlorophyll in this interval is well within the range reported for extant algae [Schouten *et al.*, 1998]. This offset is significantly larger (4-5‰) in the pre-excursion interval, which we also attribute to selective preservation (see below). As a consequence, the $\delta^{13}\text{C}$ excursion is ~1‰ smaller for bulk OC than for S-bound Ph (Fig. 3). The $\delta^{13}\text{C}$ excursion for bulk OC at DSDP site 105 is comparable in magnitude (~3 ‰) to site 603B (Fig. 4). At DSDP site 105 phase A and part of phase B can be distinguished. Assuming that the excursions in $\delta^{13}\text{C}$ values at all sites are synchronous [Gale *et al.*, 1993], data from site S13 was used to calculate average sedimentation rates for phase A of DSDP sites 105 and 603B of 1.8 cm/ky and 2.5 cm/ky, respectively. A coring gap obscuring the later part of the phase B (plateau with maximum $\delta^{13}\text{C}$ values) at DSDP site 603B does not allow an average sedimentation rate to be calculated for the whole C/T OAE. Although no coring gap occurs at DSDP site 105, an average sedimentation rate could not be calculated for the whole C/T OAE because phase C (return to pre-excursion $\delta^{13}\text{C}$ values) could not be distinguished (Fig. 4). However, assuming a maximum duration of 400 ky for the remainder of the OAE interval we calculated minimum sedimentation rates for DSDP sites 105 and 603B of 0.6 cm/ky and 1.4 cm/ky, respectively.

Figure 3. Stratigraphy, biomarker and bulk organic carbon data of DSDP site 603B. Carbon isotope values (in ‰ vs. VPDB) of C_{org} , S-bound phytane (Ph) derived from phytoplanktonic chlorophyll, TOC contents and HI indices of the bulk sediment (own data and data previously reported by Herbin *et al.* [1987a]). The dashed lines with Roman numbers show the approximate position of the boundaries between the different phases (i.e. rapid positive shift in $\delta^{13}C$ values, plateau with maximum $\delta^{13}C$ values and return to pre-excursion $\delta^{13}C$ values) of the carbon isotope excursion.

4.3.2 Cyclic Variations in Abundance and Source of the Sedimentary OM

4.3.2.1 Cyclic Variations in TOC content and Rock Eval hydrogen and oxygen indices. The late Cenomanian sediments of DSDP sites 105 and 603B contain high amounts of OC with maximum TOC values of ~26% (Figs. 3 and 4). During the C/T OAE the average TOC contents at both sites are significantly higher (5-6%) than before (~2%) (Fig. 3). At both sites this increase in TOC content is accompanied by a significant increase in Rock Eval hydrogen indices (HI) from ~150 mg hydrocarbons/g TOC before to ~270 mg hydrocarbons/g TOC during the C/T OAE [Herbin *et al.*, 1987a]. Superimposed on these long-term trends are high amplitude, short-term cyclic variations in both TOC content and HI values throughout the investigated sections (Fig. 3 and 4). The more pronounced changes in TOC and HI are also reflected by changes in lithology from green claystones, with low TOC and HI values, to black claystones, with high TOC and HI values. HI values are generally <100 mg hydrocarbons/g TOC and oxygen indices (OI) high (OI > 100) for the OM-lean green claystones, which has been attributed to a terrestrial source for the OC [Herbin *et al.*, 1987a]. In sharp contrast, high HI values and low OI values [Herbin *et al.*, 1987a] indicate a predominately marine origin for the thermally immature OM for the OC-rich black claystones. In

order to resolve the sources of the sedimentary OM, both the extractable and insoluble OM were also investigated on a molecular level.

Figure 4. Stratigraphy and bulk organic carbon data of DSDP site 105. Carbon isotope values (in ‰ vs. VPDB) of C_{org} , TOC contents and HI indices of the bulk sediment (own data and data previously reported by Herbin et al. [1987a]). The dashed lines with Roman numbers show the approximate position of the boundaries between the different phases (i.e. rapid positive shift in $\delta^{13}C$ values, plateau with maximum $\delta^{13}C$ values and return to pre-excursion $\delta^{13}C$ values) of the carbon isotope excursion.

4.3.2 2 Cyclic variations in organic matter composition at the molecular level. Only small amounts of total extracts were recovered from the OM-lean sediments outside the black shale interval (1.0 to 2.0 mg/g dry sediment), while higher amounts (4.0 to 8.0 mg/g dry sediment) were recovered from the black shales. The extractable OM was separated into apolar and polar fractions.

The apolar hydrocarbon fractions from the OM-rich black claystones consist mainly of short-chain *n*-alkanes (C_{16} - C_{22}) with no odd-over-even predominance, long-chain (C_{25} - C_{35}) *n*-alkanes with a moderate odd-over-even carbon number predominance (CPI ~1.8), hopanoids, steroids and acyclic isoprenoids (Fig. 5a). Steroids and hopanoids strongly dominate these apolar fractions. In sharp contrast, the apolar fractions from the OM-lean green claystones (Fig. 5b) are strongly dominated by short-chain *n*-alkanes (C_{16} - C_{22}) with no odd-over-even predominance and long-chain (C_{25} - C_{35}) *n*-alkanes with a moderate odd-over-even carbon number predominance (CPI ~1.8). The steroids in the black claystones derive from cholesterol, 24-methyl-cholesterol and 24-ethyl-cholesterol or their unsaturated derivatives, which are predominately biosynthesized by marine algae [Volkman, 1986]. However, zooplankton could be a significant source for the C_{27} steroids because cholesterol and its derivatives (C_{27} sterols) are also indirectly formed by dealkylation of ingested C_{28} and C_{29} sterols [Goat, 1981] by zooplankton heterotrophically living

on algal biomass. The sedimentary hopanoids are likely diagenetic products of hopanols such as bacteriohopanopolyol derivatives (C_{35}) or diplopterol (hopanes $< C_{30}$) and may derive from numerous bacterial taxa such as cyanobacteria, heterotrophic bacteria and methanotrophic bacteria [Rohmer *et al.*, 1992]. The odd-over-even predominance (CPI ~ 1.8) of the n - C_{25} to n - C_{35} suggests that leaf waxes of terrestrial plants are a significant source for the long-chain n -alkanes [Eglinton and Hamilton, 1967], while the short-chain n -alkanes (C_{16} - C_{22}) with no odd-over-even predominance are non-specific and could derive from a wide variety of algae and bacteria.

Figure 5. Typical reconstructed total mass chromatogram [i.e. total ion count (TIC)] of apolar fractions of black claystones (**a**), and of green claystones (**b**), of DSDP Site 603B. Filled circles, open squares and filled triangles indicate *n*-alkanes, hopanes and saturated acyclic isoprenoids, respectively. Abbreviations are: is, internal standard; 23, *n*-C₂₃; 35, *n*-C₃₅; C, contaminant; ?, compound of unknown structure.

Since functionalised lipids and carotenoids may become sulfurised during early diagenesis in anoxic, sulfide-rich sediments [Kok *et al.*, 2000], the polar fractions were desulfurised. The apolar fractions obtained after desulfurisation of the polar fractions from the black claystones are mainly dominated by phytane of phytoplanktonic origin and bacterial derived extended (i.e. >C₃₀) hopanoids. These hopanoids are typically dominated by the C₃₃ and C₃₅ 2-desmethyl-17 β ,21 β (H)-hopanes and their coeluting 2 β -methyl-17 β ,21 β (H)-isomers. On average these hopanoids together make up 60 to 80% of the extended hopanes present in the black claystones. The abundance of 2-methylhopanoids relative to desmethylhopanoids indicates that cyanobacteria are an important source of these molecular fossils [Summons *et al.*, 1999; Kuypers *et al.*, in prep]. In contrast, the apolar fractions obtained after desulfurisation of the polar fractions from the green claystones are mainly dominated by *n*-alkanes with no obvious odd-over-even predominance.

In conclusion the low abundance of molecular fossils of unambiguous terrestrial origin (e.g. leaf-wax lipids and oleananes) relative to biomarkers of marine origin (e.g. algal steroids and hopanoids derived from cyanobacteria) supports a predominately marine phytoplanktonic source for the OM of the black claystones. The higher relative abundance of leaf-wax *n*-alkanes on the other hand is in good agreement with a mainly terrestrial source for the OM of the green claystones

Thermal degradation (flash pyrolysis) in combination with gas chromatography was used to investigate the sources of the insoluble OM, representing >90% of the TOC. In accordance with the extremely low (< 100 mg HC/ gTOC) Rock Eval HI indices, no detectable amounts of hydrocarbons were released from the green claystones. Pyrolysis of the decalcified black claystone samples, however, released considerable amounts of hydrocarbons with *n*-alkenes/*n*-alkanes, alkylbenzenes and alkylthiophenes as the main products. These compounds also dominate the pyrolysates from the C/T OAE black shales of the southern part of the proto-North Atlantic [Kuypers *et al.*, unpublished results] and from ancient marine kerogens in general [e.g. Sinninghe Damsté *et al.*, 1989; Eglinton *et al.*, 1990; Larter and Horsfield, 1993; Hartgers *et al.*, 1994]. The extremely low abundance of lignin thermal degradation (pyrolysis) products generated from the kerogen supports a predominately marine origin for the OM from the black claystones of DSDP sites 105 and 603B.

4.3.2.3 The effect of cyclic variations in the OM source on $\delta^{13}\text{C}_{\text{org}}$. There is a significant difference in $\delta^{13}\text{C}$ values for bulk OM between adjacent OM-lean green and OM-rich black claystones, with the former being enriched in ^{13}C (up to 2‰) relative to the black claystones (Figs. 3 and 4). In the late Cenomanian interval preceding the isotope excursion, the $\delta^{13}\text{C}_{\text{org}}$ values even show a moderate negative correlation with TOC ($r^2=0.78$). This dependence of $\delta^{13}\text{C}_{\text{org}}$ on TOC ($r^2=0.78$) is also observed during and after the C/T OAE carbon isotopic excursion after ‘detrending’ the $\delta^{13}\text{C}_{\text{org}}$ values for the isotope excursion by subtracting the $\delta^{13}\text{C}$ values for the marine biomarker S-bound phytane. A similar negative correlation has previously been observed for

$\delta^{13}\text{C}_{\text{org}}$ and HI for early and middle Cretaceous marine sediments, and was attributed to variations in the relative contribution of refractory terrestrial and marine OM [Arthur *et al.*, 1985]. In modern marine environments $\delta^{13}\text{C}$ values for marine OM are commonly more positive than for terrestrial OM. However, during most of the Cretaceous elevated $p\text{CO}_2$ levels resulted in an increase in the isotope effect associated with carbon fixation (ϵ_p) by phytoplankton, leading to values for marine OM that were generally more negative than for terrestrial OM. The negative correlations between TOC and $\delta^{13}\text{C}_{\text{org}}$ at sites 105 and 603B, therefore, most likely can be attributed to an increased terrestrial contribution to the green claystones relative to the black claystones.

4.3.3 Sedimentary Cycles and Orbital Forcing

The cyclic variation in TOC content and HI indices of the C/T sediments strongly reminds of the rhythmical bedding related to the Milankovitch periodicity that is often observed for Pleistocene to Mesozoic sediments [Berger *et al.*, 1992].

The most reliable tests for Milankovitch forcing in a pre-Pleistocene set of data is the detection of sinusoids with ratios similar to the modern orbital periods [Park and Herbert, 1987]. Three distinct peaks are visible at 40, 70 and 200 cm in the power spectrum for the TOC record for site 603B (fig. 6A). The ratio obtained for these wavelengths (1 : 1.8 : 5) corresponds well with the ratio for respectively a ~21 ky precession, a ~40 ky obliquity and a ~100 ky eccentricity signal (1 : 1.9 : 4.8). The best-developed maximum has a wavelength of 40 cm (~21 ky), suggesting that the TOC record is mainly precession controlled. The power spectrum for the HI record of DSDP site 603B shows the same three peaks but there is no particular dominance of the 40 cm cycle (Fig. 6B). Additional evidence for a predominantly precession controlled cyclicity comes from the sedimentation rates for DSDP site 603B. Assuming a minimum sedimentation rate of 1.4 cm/ky for the C/T OAE interval, the maximum duration for the 40 cm cycle is 28 ky, excluding an obliquity (~40 ky) and eccentricity (100 ky) origin.

A minimum of two and a maximum of three cycles in the TOC/HI record between boundaries I and II (~60 kyr) at DSDP site 603B (Fig. 3) is consistent with a precession (~21 kyr) origin. In total ~17 cycles are visible in the TOC and HI record of the C/T section of DSDP site 603B of which not all are expressed as green/black claystone cycles. We attribute this to the TOC content predominately determining the color of the sediment with sediments containing more than 1-2% TOC being black. Because the TOC content remains above 1-2% in some cycles (e.g. black layers (BL) 6 and 8, Fig. 3) only ~14 major black claystones can be recognised (i.e. BL 0-13). Using isotope stratigraphy a comparable number of major black claystones was identified for the same interval at DSDP site 105 (Fig. 4). In fact the ~17 cycles in the TOC record of DSDP site 603B can be correlated with cycles of similar amplitude at DSDP site 105. These cycles are, however, significantly thinner (10-20 cm) than at DSDP Site 603B indicating a lower sedimentation rate at site 105. This is consistent with a two times lower minimum sedimentation rate for the C/T OAE interval obtained by carbon isotope stratigraphy.

We therefore suggest that the high amplitude cyclic variations in TOC content at both DSDP sites 105 and 603B were predominately precession controlled. The coinciding variations in HI, OI, $\delta^{13}\text{C}_{\text{org}}$, and the abundance of marine relative to terrestrial biomarkers as well as the low abundance

of lignin pyrolysis products generated from the kerogen of the black claystones indicate that these cyclic variations resulted predominantly from changes in the contribution of marine OM. Did the precessional-forced changes in the marine OC accumulation rates of sites 105 and 603B mainly result from increased preservation under anoxic conditions or from increased primary productivity?

Figure 6. Power spectra of TOC contents (A), and HI indices (B) of Cenomanian sediments of DSDP site 603B (TOC and HI data from [Herbin *et al.*, 1987a]).

4.3.4 Preservation vs productivity

The presence of precession cycles in the sediment record is often attributed to productivity changes, resulting from climatic changes such as monsoonal intensity. However, the strong variations in HI values and TOC contents of C/T sediments from sites 105 and 603B were attributed to fluctuations in redox conditions of the bottom waters [Herbin *et al.*, 1987a]. To test whether enhanced OM preservation resulting from reduced oxygen supply or enhanced productivity caused this variation in TOC/HI values, two OM-poor green to OM-rich claystone couplets (i.e. the visual expression of the precession cycles) of DSDP site 603B were studied in greater detail (i.e. BL 2 and 7, Fig. 3). The C_{org} (%) data for BL2 and BL7 is comparable to what has been reported by Herbin *et al.* [1987a] for these particular intervals (Fig. 3).

4.3.4.1 Water Column Redox Proxies. The deposition of laminated sediments and the absence of benthic foraminifers at site 603B indicates predominantly suboxic to anoxic bottomwater conditions during the deposition of both green and black claystones [Herbin *et al.*, 1987a; Kuhnt, 1992]. However, the occurrence of thin (10-20 cm) bioturbated layers in the green claystones [Fig. 3; Herbin *et al.*, 1987a] indicates the periodic occurrence of oxic bottom water conditions during the deposition of green claystones.

Further information on water column redox conditions can be gained from chalcophilic elements (e.g. Mo, Ni and Zn) that precipitate as sulfides under euxinic conditions and certain redox sensitive elements (e.g. Mo and V) that are immobilised under reducing conditions [Nijenhuis and De Lange, 2000]. In a similar way Mn, which is mobilised under reducing (anoxic) conditions and precipitates as oxyhydroxides under oxic conditions, can provide information about redox

conditions of the bottom waters [Thomson *et al.*, 1995]. To evaluate the variations in redox conditions, the abundances of Mn, Mo, V and Zn have been normalised to aluminium (Al) (Fig. 7). Al is mainly present in clay minerals and although the Al content in clay minerals can vary, normalisation to Al is frequently used [Calvert and Pedersen, 1993] to correct for fluctuations in detrital contribution. The low abundance of Mn in BL 2 and 7 relative to the adjacent OM-lean intervals indicates that the OM-rich intervals were deposited under generally more reducing suboxic/anoxic conditions (Fig. 7). The difference in Mn/Al ratios between green and black claystones could have been further enhanced by Mn mobilisation in the reducing anoxic OM rich intervals and subsequent reprecipitation as Mn oxyhydroxides on re-encountering oxygen at the ancient oxidation front [Thomson *et al.*, 1995]. The abundance of Mo/Al, V/Al and Zn/Al (BL 2 and 7; Fig. 7) indicate more reducing anoxic bottom water conditions during the deposition of the black claystones [Arthur *et al.*, 1990; Calvert and Pedersen, 1993].

Additional evidence for different redox conditions of the bottom water during the deposition of the green and black claystones, may come from the sedimentary biomarker record. Oxygen exposure time significantly affects the biomarker distribution, with an increasing contribution of more refractory biomarkers like terrestrial *n*-alkanes relative to more labile biomarkers like steroids with increasing exposure to oxygen [Hoefs *et al.*, 2001; Sinninghe Damsté *et al.*, 2001]. The green claystones are dominated by the refractory terrestrial *n*-alkanes, while the labile hopanoids, steroids and lycopane are only present in trace amounts (Fig. 5b). This is indicative of long oxygen exposure times and hence oxygenated bottom waters [Hoefs *et al.*, 2001; Sinninghe Damsté *et al.*, 2001]. The dominance of labile steroids and hopanoids in the apolar fractions of the black claystones (Fig. 5b) on the other hand indicates relatively short oxygen exposure times, which is in good agreement with more anoxic bottom waters.

To investigate whether these anoxic conditions extended into the photic zone, the samples from DSDP Site 603B were checked for fossil derivatives of specific pigments (isorenieratene) of the brown coloured strain of green sulfur bacteria (Chlorobiaceae). These photosynthetic bacteria require both light and H₂S for carbon fixation and are, therefore, indicators for photic zone anoxia. At the present day the habitat for green sulfur bacteria is restricted to a few euxinic basins such as the Black Sea [Repeta *et al.*, 1989; Sinninghe Damsté *et al.*, 1993; van Gemerden and Mas, 1995]. Sinninghe Damsté and Köster [1998] showed that during the mid Cretaceous C/T OAE these organisms were also present in the proto North Atlantic Ocean. More recently we showed that green sulfur bacteria were already present in the southern part of the proto North Atlantic well before the C/T OAE [Kuypers *et al.*, 2000 submitted to *Paleoceanography*]. Molecular fossils of isorenieratene (e.g. isorenieratane) were found in the apolar fraction of several black claystones (BL 0-2, 4, 5, 7, 10, 12) of DSDP site 603B in concentrations of 7-300 ng/g sediment. This indicates that sulfide-containing water sometimes penetrated the photic zone before as well as during the C/T OAE. We calculated accumulation rates for isorenieratane in order to compare the abundance of isorenieratane at site 603B to its abundance in sediments from the southern proto North Atlantic [Kuypers *et al.*, 2001 submitted to *Paleoceanography*]. Assuming an average duration of ~21 ky for the ~40 cm precession cycles (i.e. an average sedimentation rate of 1.9 cm/ky), accumulation rates of up to 9 µg isorenieratane m⁻²·y⁻¹ were calculated for DSDP site 603B. The accumulation rates obtained for the southern proto North Atlantic are much higher (e.g. up to 1400 and 2600 µg isorenieratane m⁻²·y⁻¹ at

sites S13 and 367, respectively). These differences in isorenieratane accumulation rates could have resulted from significantly higher anoxygenic productivity in the water column of the southern proto North Atlantic. In accordance with this, fluctuations in the abundances of isorenieratane extracted from Holocene Black Sea sediments were attributed to changes in anoxygenic productivity related to fluctuations in the position of the chemocline [Repetta, 1993]. The abundance of phototrophic sulfur bacteria in modern settings shows a strong positive correlation with light intensity [van Gemerden and Mas, 1995]. Therefore, the 100 to 300 times higher abundance of isorenieratane at sites S13 and 367 relative to site 603B suggests that sulfide-containing water penetrated the photic zone much more frequently and/or at much shallower depths at the southern side than at the northern side of the proto North Atlantic Ocean. In fact the low abundance of isorenieratane at site 603B suggests that sulfide-containing water only occasionally penetrated the photic zone at the northern side of the proto North Atlantic Ocean.

Isorenieratane was found in all investigated samples from within BL7 with highest concentrations in the center of this black claystone while isorenieratane concentrations were below the detection limit in the overlying green claystone (Fig. 7). The latter is in good agreement with the green claystones being deposited under oxic conditions. The apparent positive correlation between TOC content and abundance of isorenieratane within BL7 could indicate that enhanced OM accumulation was accompanied by a rise of the average position of the chemocline (i.e. nearer to the photic zone) during its deposition. This seems to be supported by a co-occurring increase in Mo/Al ratios (Fig. 7).

Intriguingly, small amounts of isorenieratane (21 ng/g sediment) were found in one green claystone of site 603B, which was likely deposited under more oxic conditions. Based upon the available data it can not be excluded that these are not truly autochthonous molecular fossils but were transported over longer distances. Such an allochthonous source was previously suggested for aryl isoprenoids derived of isorenieratane of green sulfur bacteria extracted from North Atlantic deep-sea sediments deposited during 'Heinrich' events [Rosell-Melee et al., 1997].

4.3.4.2 Productivity Proxies. Sedimentary Ba is generally considered as an indicator for palaeoproductivity since it originates from barite formed in decaying phytoplanktonic OM in surface waters [Dymond et al., 1992; de Lange et al., 1994; Francois et al., 1995]. Such barite formation has been shown to occur in the well-oxygenated open ocean [Dymond et al., 1992; Francois et al., 1995] as well as in the suboxic to anoxic waters of OMZs and euxinic basins [Falkner et al., 1993; Dean et al., 1997].

The Ba/Al ratios are significantly higher (1.6 times) in BL 7 than in the adjacent OM-lean green claystones, indicating enhanced export productivity during the deposition of this OM-rich interval (Fig. 7). The Ba/Al ratios within BL 2 are comparable to BL 7 (Fig. 7). However, Ba/Al ratios in the adjacent green claystones are higher than in the green claystones above and below BL7, which could have resulted from bioturbation. The Ba/Al ratios within the black claystones do not show the strong correlation with TOC contents that is generally observed for sapropels but rather shows a topped appearance (Fig. 7). This could indicate that variations in preservation rather than productivity controlled the TOC variations within the black claystones. An alternative explanation is that the Ba/Al record has been affected by remobilisation of barite under reducing conditions.

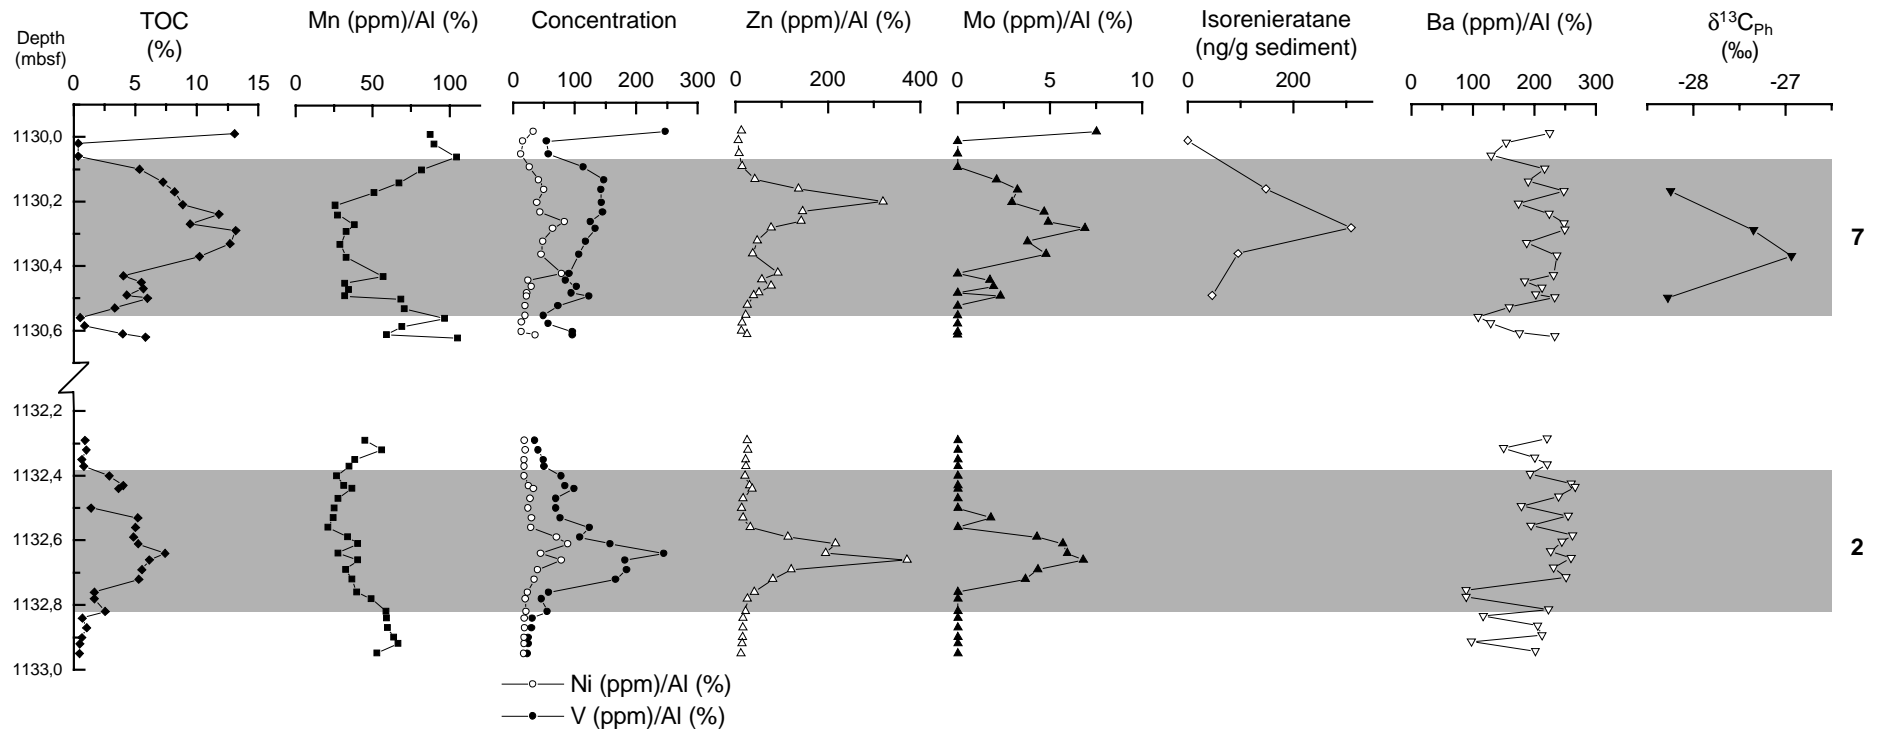

Figure 7. Bulk organic carbon, trace metal and biomarker data of DSDP site 603B. TOC contents of the bulk sediment, concentration profiles of redox sensitive trace metals (Mn, Mo, Zn and V) normalised to Al, concentration profile of the molecular fossil isorenieratane of green sulfur bacteria, concentration profile of the productivity proxy Ba/Al and carbon isotope values (in ‰ vs. VPDB) of S-bound phytane (Ph) derived from phytoplanktonic chlorophyll. The shaded areas show the approximate position of the black claystones BL2 and BL7 (see also Fig. 3). There is no biomarker data (i.e. isorenieratane abundance and $\delta^{13}\text{C}$ values for S-bound Ph) available for BL2 and the adjacent green claystones.

Under suboxic to anoxic diagenetic conditions Ba preservation may be reduced [Dymond *et al.*, 1992] leading to an underestimation of the former Ba levels and thus productivity. Additional evidence for a high primary productivity during the deposition of BL 2 and 7 is provided by the mineralogical composition of the black claystones. The black claystones contain abundant opal CT (Fig. 8a), which is a diagenetic product of biogenic opal, while no opal CT was detected in the green claystones (Fig. 8b). Biogenic opal is predominantly produced by diatoms and radiolarians in highly productive surface waters. Because opal easily dissolves upon sedimentation, special conditions (a high sedimentation rate and a high opal flux) are needed for its preservation. Consequently, the presence of opal proves (but the absence of opal does not exclude) high primary productivity. Opal CT is abundantly present and even strongly dominates the mineralogical composition of some of the investigated samples from the center of the black claystones BL 2 and 7.

Figure 8. Typical XRD patterns of the centre of the black claystone BL7 (a), and of the underlying green claystone (b), of DSDP Site 603B. The patterns have been smoothed by a two points moving average.

An increase in productivity could result from changes in either growth rate or average cell size (i.e. carbon content per cell) of the phytoplanktic community. The degree of photosynthetic carbon fractionation (ϵ_p) for marine phytoplankton shows a strong negative correlation with both growth rate and cell size [Laws *et al.*, 1995; Pancost *et al.*, 1997; Popp *et al.*, 1998; Burkhardt *et*

al., 1999; *Bidigare et al.*, 1999]; therefore an increase in productivity should be reflected in $\delta^{13}\text{C}$ values of phytoplankton-derived organic matter. In accordance with this, variations in $\delta^{13}\text{C}$ values for bulk marine OC and molecular fossils of phytoplanktonic origin have been attributed to changes in ϵ_p resulting from changes in productivity [*Pancost et al.*, 1999; *Krishnamurthy et al.*, 2000; *Murphy et al.*, 2000]. $\delta^{13}\text{C}$ values for inorganic carbon, which are needed to calculate ϵ_p , could not directly be determined due to absence of carbonate carbon at DSDP site 603B. Assuming there was no significant change in the in $\delta^{13}\text{C}$ values for dissolved inorganic carbon during the deposition of BL 7, the increase in $\delta^{13}\text{C}$ values for S-bound phytane at DSDP site 603B (Fig. 7) records a ~1‰ decrease in ϵ_p values. This decrease may have been larger, because shoaling of the chemocline discussed previously could have introduced ^{13}C depleted recycled inorganic carbon into the photic zone. Thus, it seems likely that an increase in productivity accounts for the shift in $\delta^{13}\text{C}$ values for the molecular fossil of phytoplanktonic origin at site 603B. This is entirely consistent with the high Ba and opal CT levels in BL 7.

4.3.4.3 Synthesis of redox and productivity proxies. The co-occurrence of lamination enrichment of redox sensitive trace metals and presence of molecular fossils of pigments from green sulfur bacteria indicates that the northern proto-North Atlantic Ocean water column was occasionally euxinic from the bottom to at least the base of the photic zone (<150 m) during the deposition of the black claystones (Fig. 7). In contrast, the green claystones are bioturbated, are enriched in Mn, do not show enrichments in redox sensitive trace metals and show biomarker distributions indicative of long oxygen exposure times, indicating more oxic water conditions. At the same time there is evidence (e.g. enhanced Ba/Al ratios, abundance of biogenic silica and significant ^{13}C -enrichment for OC of phytoplanktonic origin) for enhanced primary productivity during the deposition of the black claystones.

We propose that enhanced productivity of OM was an important factor in generating and sustaining euxinic conditions during the deposition of the black claystones. Enhanced primary productivity periodically overwhelmed the oxic OM remineralisation potential of the bottom waters leading to the deposition of OM-rich black claystones. A combination of overall sluggish circulation (possibly halothermal instead of thermohaline) and the tectonically isolated nature of the proto-North Atlantic (Fig. 1) likely facilitated the periodic development of anoxic water column conditions [*Poulsen*, 1999; *Bice*, personal communication]. Because the amount of oxygen used for OM remineralisation exceeded the amount supplied by diffusion and deep water circulation, bottom waters became euxinic. These euxinic conditions occasionally even extended into the photic zone of the proto North Atlantic.

4.3.5. Long-term changes as a result of the C/T OAE

During the C/T OAE the average TOC contents at both sites are significantly higher (5-6%) than before (~2%) (Figs. 3 and 4), while average sedimentation rates at both sites remain approximately the same, indicating a large increase in OC accumulation rates during the C/T OAE. An average sedimentation rate of 1.9 cm/ky was calculated for site 603B, assuming an average

duration of ~21 ky for the ~40 cm precession cycles. In a similar approach an average sedimentation rate of 0.9 cm/ky was calculated for DSDP Site 105. Assuming constant sedimentation rates throughout the investigated sections, the average OC accumulation rates before and during the C/T OAE were determined using the TOC contents of the bulk sediments. Prior to the C/T OAE, the OC mass accumulation rates (OC MAR) for sites 105 ($0.2 \text{ gC}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$) and 603B ($0.6 \text{ gC}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$) were significantly smaller than the $9 \text{ gC}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$ and $3 \text{ gC}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$ previously determined for the same interval at site S13 and DSDP site 367, respectively [Kuypers et al., 2000 submitted to *Paleoceanography*]. During the C/T OAE, OC accumulation rates at sites 105 ($0.6 \text{ gC}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$) and 603B ($1.5 \text{ gC}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$) were approximately three times greater than prior to the OAE but still significantly smaller than for the same interval at sites S13 and 367 (9 and $26 \text{ gC}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$, respectively). This increase in OM accumulation rates at sites 105 and 603B is accompanied by a significant increase in HI values from ~150 mg hydrocarbons/g TOC before to ~270 mg hydrocarbons/g TOC during the C/T OAE [Herbin et al., 1987a]. However, these HI values are still significantly lower than for the same interval at sites S13 and 367 (600-700 mg hydrocarbons/g TOC) [Herbin et al., 1986; Kuhnt et al., 1990] indicating a more refractory nature of the sedimentary OM in the northern part than in the southern part of the proto North Atlantic during the C/T OAE. The sediments from site 603B show a significantly lower abundance of redox sensitive trace metals and molecular fossils of green sulfur bacteria than site 367 [Kuypers et al., 2000 submitted to *Paleoceanography*], indicating that the more refractory nature of OM resulted from more oxic conditions in the northern part of the proto North Atlantic during the C/T OAE. Previously we attributed the significant increase in marine OC accumulation rates in the southern part of the proto-North Atlantic (sites S13, 144 and 367) to an increase in primary productivity [Kuypers et al., 2000 submitted to *Paleoceanography*]. As was pointed out by Schlanger et al. [1987]; ‘the widespread distribution of anoxic sediments deposited synchronously during such a short-lived event indicates that such sediments are not simply the product of coincidental local climatic or basinal water mass characteristics’. Therefore, it is tempting to attribute the increase in OM accumulation rates in the northern part of the proto-North Atlantic (sites 105 and 603B) also to an increase in primary productivity. However, there is only a small increase in average Ba/Al ratios from 140 before to 180 during the C/T OAE at site 603B, suggesting only a small increase in productivity. At the same time average Mo/Al (0 to 4), Ni/Al (14 to 50), V/Al (22 to 125) and Zn/Al (19 to 52) ratios as well as the average concentration of isorenieratane (23 to 65 ng/g sediment) are all significantly enhanced during the C/T OAE, indicating more anoxic conditions. This is in good agreement with the strong reduction in the thickness of the green claystones at both sites 105 and 603B during the C/T OAE. It can, however, not be excluded that the Ba/Al record has been affected by diagenesis as indeed seems to be indicated by the constant Ba/Al ratios within the black claystones and that, therefore, the increase in productivity during the C/T OAE is underestimated. Interestingly, the relative contributions of metals of terrestrial origin like Al (8 % to 5 %), Ti (0.45 % to 0.20 %) and Zr (82 p.p.m. to 56 p.p.m.) are all significantly reduced, which could indicate an enhanced dilution by biogenic opal during the C/T OAE. If so, this would indicate enhanced primary productivity. Additional data is needed to clarify this issue.

In any case the periodic increase in productivity seems to have been more pronounced at site 603B than at site 105, resulting in significantly higher OM accumulation rates at the former site

during the deposition of the black claystones. Lower accumulation rates of biogenic components like opal and OM during deposition of the black claystones may also have led to significantly lower sedimentation rates at site 105. However, at both sites the most OC-rich black claystones as well as the thinnest green claystones occur during phase B of the isotope excursion (i.e. plateau with maximum $\delta^{13}\text{C}$ values, Figs. 3 and 4). These long-term trends most likely resulted from global environmental changes that occurred during the C/T OAE possibly related to the formation of a deep water connection between North and South Atlantic basins [Kuypers et al., 2000 submitted to *Paleoceanography*].

4.4. Conclusions

- 1). The high amplitude, short-term cyclic variations in TOC content and HI values of the C/T interval at DSDP sites 105 and 603B most likely resulted from precession controlled changes in productivity.
- 2). Periodically increased primary productivity led to euxinic conditions in the water column of the northwestern proto North Atlantic.
- 3). These anoxic conditions, which sometimes extended to at least the base of the photic zone (<150 m), led to enhanced preservation of marine OM resulting in the deposition of OM-rich black claystones.
- 4). The trends at sites 105 and 603B of continually increasing TOC contents and HI values of the black claystones up section most likely resulted from both enhanced preservation due to increased anoxia and increased production of marine OM as a response to the environmental changes during the C/T OAE.

Chapter 5

Cyanobacterial N₂ fixation fuelled enhanced biological CO₂ pumping during a Cretaceous oceanic anoxic event

Marcel M.M. Kuypers, Stefan Schouten, Jaap S. Sinninghe Damsté

In preparation

Abstract.

The so-called Cenomanian/Turonian oceanic anoxic event (C/T OAE) is characterised by a large global increase in organic matter (OM) burial rates. We investigated the role of N₂-fixing cyanobacteria in this increase at four proto-North Atlantic sites of different palaeobathymetric setting using bulk nitrogen isotope measurements and molecular fossils of cyanobacterial membrane lipids. The organic matter rich sediments (black shales) show ¹⁵N/¹⁴N ratios ($\delta^{15}\text{N} = -2-0$ ‰) typical for newly fixed N₂, indicating that microbial N₂ fixation was the main source of nitrogen for phytoplanktonic growth in the proto-North Atlantic prior to and during the C/T OAE. This agrees well with the abundance of molecular fossils (e.g. 2-methylhopanoids) of cyanobacteria, which are the main N₂-fixers in the modern ocean. Extensive N₂ fixation was essential to sustain productivity in this dysoxic/anoxic basin, where massive loss of nitrate occurred due to extensive denitrification. We propose that increased upwelling of anoxic, phosphorus (P)-loaded, proto-Atlantic deep water, resulting from the formation of a deep water connection between the North and South Atlantic basins, stimulated cyanobacterial productivity, increasing the amount of N₂ fixed by these diazotrophs. This increased nitrogen supply, enhanced phytoplanktonic biomass production and led to a large increase in OM burial during the C/T OAE. The enhanced activity of the 'biological pump' led to a significant drop in atmospheric carbon dioxide concentration during the C/T OAE and, thereby, could have triggered the early Turonian deterioration of the greenhouse climate.

5.1. Introduction

As a result of carbon dioxide exchange between the atmosphere and the ocean, uptake of dissolved inorganic carbon (DIC) during photosynthesis and subsequent export of phytoplanktonic biomass to deeper water and underlying sediment acts as a biological carbon dioxide pump. Organic matter (OM) degradation (i.e. respiration) and ocean circulation will eventually return most of this carbon dioxide back to the atmosphere. However, a small amount of OM escapes degradation and is buried in the sediment. This burial of sedimentary OM largely controls the carbon dioxide content of the atmosphere on geological time scales [Berner, 1991; Berner, 1992].

In addition to DIC, phytoplankton in the ocean surface waters consumes mainly dissolved nitrogen (N) and phosphorus (P). While DIC will normally not be limiting phytoplanktonic growth as it is present in excessive amounts in the upper mixed layer of the ocean, the availability of nutrient N and P limits the production of phytoplanktonic particulate OM (POM). Riverine input is the only significant source of phosphate, the form of dissolved P that is normally used by phytoplankton, to the ocean [Jahnke, 1992; Mackenzie *et al.*, 1993]. Nitrate, nitrite and ammonium are the N compounds (i.e. reactive N) that are generally easily taken up by phytoplankton. An important input of reactive N to the ocean comes via river water, but unlike P, there is also a significant atmospheric input [Mackenzie *et al.*, 1993; Jaffe, 1992]. The atomic ratios of C, N and P of POM are similar throughout the marine realm [Copin-Monteguet and Copin-Monteguet, 1983; Toggweiler, 1993] and on average phytoplanktonic biomass is characterised by a C:N:P ratio of 106:16:1 [Redfield *et al.*, 1963]. In principle C, N and P are released upon remineralisation of POM in similar ratios [Redfield *et al.*, 1963]. These regenerated nutrients can subsequently be used again for the production of POM. To sustain primary productivity the flux of nutrient N and P entering the photic zone needs to be equal to the flux of nutrient N and P exported from it. When photosynthetic production increases relative to remineralisation of POM nutrient N and P will be lost to the sediment and primary productivity will decrease.

In sharp contrast to P, reactive N is not only lost to the sediment but can also be converted to N_2 or N_2O (denitrification) gas, which are much less easily used by phytoplankton. Denitrification is in fact the main sink for reactive N in the marine realm and occurs in suboxic environments, where bacteria use nitrate or nitrite instead of oxygen as an oxidator [Codispoti and Christensen, 1985]. In theory this loss of reactive N as a result of denitrification could lead to an ocean-water N:P ratio significantly smaller than the Redfield (i.e. 15-16) ratio and hence a severe limitation of reactive N for phytoplankton growth. In reality ocean-water N:P ratios are only slightly below Redfield ratio. This discrepancy between theory and reality has been attributed to the activities of N_2 -fixing organisms (mainly cyanobacteria) in the marine realm [Tyrrell, 1999]. These organisms can use the nearly inexhaustible atmospheric reservoir of N_2 as N source but due to the high-energy demand of N_2 fixation they can only outcompete non- N_2 -fixing algae, when reactive N concentrations are low relative to P. According to the model proposed by Tyrrell [Tyrrell, 1999], there is a negative feedback between reactive N versus P concentrations and the abundance of N_2 -fixers. Decreasing N:P ratios as a result of denitrification will lead to an increase in N_2 fixation and subsequent release of reactive N upon remineralisation of their biomass will increase N:P ratios.

Although N₂ fixation can fuel up to half of the new production in oligotrophic ocean gyres [Karl *et al.*, 1997], N₂-fixers make up a relatively small amount of total phytoplanktonic biomass in the modern ocean [Tyrrell, 1999]. However, reduced ocean circulation and extensive denitrification in largely anoxic or suboxic mid and deep waters may have led to N₂-fixing cyanobacteria periodically dominating phytoplankton communities during the early to middle Cretaceous [Rau *et al.*, 1987]. Thinly laminated OM-rich sediments devoid of traces of benthic activity (i.e. black shales) that were globally deposited in a variety of paleo-bathymetric settings [Schlanger and Jenkyns, 1976] indicate that anoxic waters were particularly widespread during the so-called Cenomanian/Turonian oceanic anoxic event (C/T OAE) [Summerhayes, 1987; Bralower and Thierstein, 1987]. Sedimentary derivatives (molecular fossils) of a pigment indicative of anoxygenic photosynthetic bacteria recovered from abyssal and shelf sites indicate that anoxic conditions extended even into the photic zone of the southern proto-North Atlantic during the C/T OAE [Sinninghe Damsté and Köster, 1998]. At the same time a sharp increase in ¹³C/¹²C ratios for marine carbonates and OM provides evidence for a large increase in the global organic carbon (OC) burial rate and a significant drop in atmospheric carbon dioxide concentration during the C/T OAE [Arthur *et al.*, 1988; Freeman and Hayes, 1992; Kuypers *et al.*, 1999].

One of the main sites of carbon burial during the C/T OAE was the proto-North Atlantic Ocean, where up to 80 m thick black shales [Kuhnt *et al.*, 1990], which can contain more than 40% organic carbon [Herbin *et al.*, 1986], were deposited basin-wide. Recently, we reported an increase in marine OC accumulation rates at three sites in the southern part of the proto-North Atlantic (Fig. 1; site S13, and DSDP sites 144 and 367), which we attributed to an increase in primary productivity during the C/T OAE [Kuypers *et al.*, 2000 submitted to *Paleoceanography*]. This increase in primary productivity was accompanied by a significant rise of the chemocline, with euxinic conditions periodically occurring at very shallow water depths of 15 m or less, while bottom water redox conditions did not markedly change (i.e. remained euxinic). An increase in OM accumulation rates, albeit smaller, also occurred at the northern proto-North Atlantic site 603B during the C/T OAE [Kuypers *et al.*, in prep]. Globally enhanced OM burial and thus enhanced burial of organic nitrogen would have increased the phytoplanktonic reactive N demand, while reactive N losses would have been especially high due to extensive denitrification during the C/T OAE. N₂-fixing cyanobacteria could have supplied the additional reactive N required to sustain or even increase marine productivity during the C/T OAE.

Here we determine the role and significance of N₂-fixing cyanobacteria in the increase of OM burial at four proto-North Atlantic sites (Fig. 1) of different palaeobathymetric settings using nitrogen isotope measurements and cyanobacterial membrane lipids. In addition we discuss the consequences of our findings for the mid-Cretaceous global biogeochemical cycles.

Figure 1. Palaeogeographical map of mid Cretaceous (~94 Ma) North Atlantic showing the position of the four studied cores. Light grey shaded regions represent flooded continental plates (from GEOMAR map generator; www.odsn.de/odsn/services/paleomap/paleomap.html). Dark grey shaded regions represent land [Scotese and Golonka, 1992].

5.2. Material and Methods

5.2.1 Material. The sediment samples used in this study were obtained from the Shell exploration well S13 of the Tarfaya area (Morocco), the Deep Sea Drilling Project (DSDP) sites 144 off the coast of French Guyana (leg 14), 367 off the coast of Senegal (leg 41) and 603B off the coast of North America (leg 93). Two to five cm thick sediment slices were taken from the cores. Sub-samples were taken from these slices and subsequently freeze-dried and powdered in an agate mortar.

5.2.2 Stable nitrogen isotopes. The $\delta^{15}\text{N}$ values were measured for bulk sediments. The $\delta^{15}\text{N}$ measurements were performed using an automated on-line combustion system (Carlo Erba CN analyser 1502 series) followed by conventional isotope ratio-mass spectrometry (Fisons Optima). The $\delta^{15}\text{N}$ values for bulk sediments are expressed relative to atmospheric N_2 and have a precision better than 0.2 ‰.

5.2.3 Organic matter analyses. Analyses of soluble and insoluble organic matter were performed as described previously by Kuypers et al. [2000; submitted to *Paleoceanography*]. Briefly, Total Organic Carbon (TOC) contents were determined using a CN analyser. The $\delta^{13}\text{C}$ values ($\pm 0.1\%$ versus Vienna Pee Dee belemnite (VPDB)) were measured on bulk sediments, after removal of the inorganic carbonates with diluted HCl, using automated on-line combustion followed by conventional isotope ratio-mass spectrometry. For analyses of the soluble OM powdered samples (15 to 30 g) were Soxhlet extracted for *c.* 24 h to obtain the total extract. An aliquot (*c.* 250 mg) of the total extract was separated into an apolar and a polar fraction using column chromatography. The hydrocarbons that were released from the polar fraction by Raney Nickel desulfurisation and subsequent hydrogenation [*Sinninghe Damsté et al.*, 1990a] were isolated using column chromatography. Samples were analysed by gas chromatography-mass spectrometry (GC-MS) for compound identification. Compound-specific $\delta^{13}\text{C}$ analyses were performed using a Finnigan Delta C GC-isotope-ratio-monitoring MS. The $\delta^{13}\text{C}$ values for individual compounds are the means of duplicate runs ($\sigma = \pm 0.3$ to 0.6) expressed versus VPDB.

5.2.4 Determination of the relative abundance of sulfur-bound 2-methylhopanes. 17 β ,21 β (H)-Trishomohopane (C₃₃; **I**) and 17 β ,21 β (H)-pentakishomohopane (C₃₅; **II**) are coeluting with 2 β -methyl-17 β ,21 β (H)-trishomohopane (C₃₄; **III**) and 2 β -methyl-17 β ,21 β (H)-pentakishomohopane (C₃₆; **IV**), respectively. For calculating the abundance of **III** and **IV** relative to the abundance of the coeluting **I** and **II**, respectively, the following equation was used:

$$\% \text{ 2-methylhopane } C_n = 100 \cdot x / (x + y) \quad [1]$$

were $x =$ peak area of **III** and $y =$ peak area of **I** for $n = 33$, and $x =$ peak area of **IV** and $y =$ peak area of **II** for $n = 35$. The peak areas were obtained by mass chromatography of m/z 369 and 383 for 17 β ,21 β (H)-hopanes (i.e. **I** and **II**) and 2 β -methyl-17 β ,21 β (H)-hopanes (i.e. **III** and **IV**), respectively. This method was used to determine the relative abundance of 2-methylhopanoids in the C/T sediments analysed in this study as well as a suite of GC-MS analyses from other thermally immature Phanerozoic sediments present in the archive of our laboratory.

5.3. Stratigraphy, palaeosetting and organic carbon accumulation rates

Our study concentrates on the C/T interval between 95 and 93 My before present [*Obradovich*, 1993; *Gradstein et al.*, 1994; *Gradstein et al.*, 1995], roughly coinciding with the late Cenomanian *Rotalipora cushmani* zone and the latest Cenomanian to early Turonian *Whiteinella archaeocretacea* zone. This interval reaches a thickness of ~150 m at well S13 of the Tarfaya basin in the southeastern part of the proto North Atlantic Ocean (Fig. 2). The C/T sequence at site S13 consists of an alternation of dark laminated carbonaceous chalks and lighter coloured homogeneous limestones, deposited in an open shelf sea at a palaeo-water depth of 200-300 m [*Einsele and Wiedmann*, 1982; *Thurrow and Kuhnt*, 1986; *Kuhnt et al.*, 1990]. The late Cenomanian to early

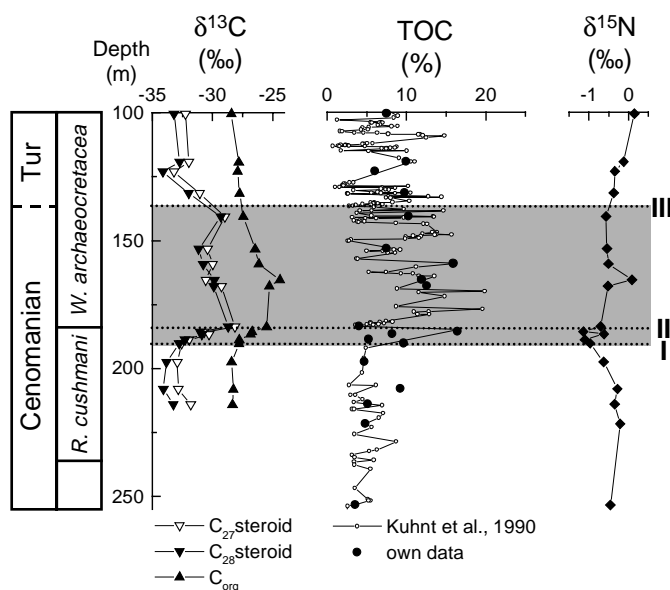

Figure 2. Stratigraphy [Kuhnt *et al.*, 1997], biomarker, bulk organic carbon and nitrogen data of site S13 (Tarfaya basin). Carbon isotope values (in ‰ vs. VPDB) of bulk organic carbon (C_{org}) and free steranes [C_{27} sterane (5α -cholestane) and C_{28} sterane (5α -24-methyl-cholestane)] derived from marine algae, TOC content of the bulk sediment (own data and data previously reported by Kuhnt *et al.* [Kuhnt *et al.*, 1990]), and nitrogen isotope values (in ‰ vs. atmospheric N_2) of the bulk sediment. The dashed lines with Roman numbers show the approximate position of the boundaries between the different phases (i.e. rapid positive shift in $\delta^{13}C$ values, plateau with maximum $\delta^{13}C$ values and return to pre-excursion $\delta^{13}C$ values) of the carbon isotope excursion.

Turonian sediments of site S13 contain high amounts of marine OC [Kuhnt *et al.*, 1990] with maximum total organic carbon (TOC) values of ~16% (Fig. 2).

At DSDP Site 144, the late Cenomanian deposits consist of dark laminated carbonaceous cemented limestones and zeolitic calcareous clay [Hayes *and et al.*, 1972] containing up to 8% (Fig. 3) marine OC [Kuypers *et al.*, 2000 submitted to *Paleoceanography*]. These hemipelagic sediments were deposited at a water depth of ~1300 m [Berger *and von Rad*, 1972].

The black shales that make up the late Cenomanian sequence at DSDP Site 367 (off the coast of north-west Africa) consist of a mixture of terrigenous silicates and clay minerals [Mélières, 1978] and high amounts of marine [Herbin *et al.*, 1987; Kuypers *et al.*, 2000 submitted to *Paleoceanography*] organic carbon (total organic carbon (TOC) contents up to 46 wt. %; Fig. 4). These sediments contain only minor amounts of biogenic carbonate due to deposition below the carbonate compensation depth (CCD). A water depth of 3700 m has been estimated for this time interval at DSDP Site 367 [Chénet *and Francheteau*, 1979].

The late Cenomanian sequence at DSDP site 603B consists of an alternation of OM poor green claystones and OM-rich (TOC 1-21%) black claystones [Herbin *et al.*, 1987]. Carbonate contents are very low (<10%), which suggests that deposition took place below CCD. These hemipelagic sediments were deposited at a water depth of ~4000 m [Chénet *and Francheteau*, 1979]. Rock Eval indices are generally low (HI < 100 mg hydrocarbons/g TOC) for the OM-lean green claystones, which has been attributed to a terrestrial source for the OC [Herbin *et al.*, 1987].

In sharp contrast, high Rock Eval hydrogen indices (HI) [Herbin *et al.*, 1987; Kuhnt *et al.*, 1990] and the low abundance of lignin pyrolysis products generated from the kerogen [Sinninghe Damsté *et al.*, unpublished data] indicate a marine origin for the thermally immature OM for the OC-rich black claystones. This is supported by the low abundance of molecular fossils of unambiguous terrestrial origin (e.g. leaf-wax lipids and oleananes) in the extractable OM [Kuypers *et al.*, unpublished data]. The high amplitude short-term cyclic variations in TOC content of these sediments have been attributed to fluctuations in redox conditions of the bottom waters [Herbin *et al.*, 1987].

In sharp contrast to the shelf section from site S13 [Kuhnt *et al.*, 1990], biostratigraphically significant species are largely absent from the middle Cretaceous sediments from DSDP sites 144, 367 and 603B. Instead, the investigated sections of these abyssal sites were correlated with the C/T section of site S13 by stable carbon isotope stratigraphy using the characteristic ^{13}C excursion in both bulk OM and molecular fossils of algal chlorophyll and steroids (Figs. 2-5). For a more thorough discussion of this method see Kuypers *et al.* [2000]. The horizontal dotted lines with Roman numbers (I-III) in the various plots (Figs. 2-5) indicate the boundaries between the pre-excursion conditions (i.e. pre-excursion $\delta^{13}C$ values) and the three main phases of the isotope excursion (i.e. rapid positive shift in $\delta^{13}C$ values, plateau with maximum $\delta^{13}C$ values and return to pre-excursion $\delta^{13}C$ values). Of particular stratigraphic significance is boundary II that nearly coincides with the last occurrence of *R. cushmani* [Kuhnt *et al.*, 1990] and boundary III, which approximately coincides with the C/T boundary [Gale *et al.*, 1993]. The C/T OAE is coeval with the interval between boundaries III and I (indicated as a grey shaded area in Fig. 2). Coring gaps obscure the later part of the first phase of the carbon isotope excursion (rapid positive shift in $\delta^{13}C$ values) and whole of the second phase (plateau with maximum $\delta^{13}C$ values) at DSDP Site 144, while coring gaps obscure the later part of the second phase at DSDP Sites 367 and 603B. Hence the grey shaded areas (Figs. 3-5) most likely represent only a part of the total C/T OAE interval present at DSDP Sites 144, 367 and 603B. However, the beginning of the rapid shift in $\delta^{13}C$ values was recovered at all sites (Figs. 2-5) allowing a direct comparison of the changes in OC accumulation rates that occurred during the onset of the C/T OAE.

Prior to the C/T OAE, OC mass accumulation rates were significantly larger for the southern part of the proto-North Atlantic (~ 9 and $3 \text{ gC}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$ for S13 and DSDP site 367, respectively), than for the northern part ($\sim 0.6 \text{ gC}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$ for site 603B) [Kuypers *et al.*, 2000 submitted to *Paleoceanography*; Kuypers *et al.*, in prep.]. There is a significant increase in marine OC accumulation rates at all sites during the C/T OAE. At the southern proto-North Atlantic site S13 and DSDP Site 367 this increase in OC accumulation rates could have been as large as 17 and $6 \text{ gC}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$, respectively [Kuypers *et al.*, 2000 submitted to *Paleoceanography*], while it was significantly smaller ($\sim 1 \text{ gC}\cdot\text{m}^{-2}\cdot\text{y}^{-1}$) at the northern proto-North Atlantic site 603B [Kuypers *et al.*, in prep].

5.4. Results and discussion

5.4.1 Proxy records for N₂-fixing cyanobacteria

Unlike certain algae such as dinoflagellates, diatoms and calcareous algae, pelagic cyanobacteria do not leave behind microscopically identifiable fossilised remains. Instead, specific cyanobacterial biomarkers, such as the 2-methyl-bacteriohopanepolyol membrane lipids and the pigment zeaxanthin or molecular fossils of these compounds formed upon diagenesis, can provide information about their relative abundance in ancient marine phytoplankton communities [Summons *et al.*, 1999; Bianchi *et al.*, 2000]. The stable nitrogen isotopic composition of sedimentary OM or the sediment itself can provide information about the significance of cyanobacterial N₂ fixation in the biogeochemical cycle of ancient marine environments [Rau *et al.*, 1987; Haug *et al.*, 1998; Sachs and Repeta, 1999; Bianchi *et al.*, 2000]. Especially a combined biomarker and nitrogen isotopic study can provide important insights in the ecological role of N₂-fixing cyanobacteria in ancient marine settings. In addition the stable carbon isotopic composition of phytoplanktic biomarkers can provide important insight into environmental conditions under which photosynthetic carbon fixation occurred. Thus we investigated the abundance of cyanobacterial biomarkers and their stable carbon isotopic composition and the stable nitrogen isotopic composition of the North Atlantic C/T sediments.

5.4.1.1 Stable nitrogen isotopes. The late Cenomanian to early Turonian sediments of site S13 (Tarfaya basin) are ¹⁵N-depleted relative to atmospheric N₂ with minimum δ¹⁵N values of -1.1‰ (Fig. 2). During the C/T OAE the average δ¹⁵N value is slightly more depleted in ¹⁵N (~ -0.7‰) than before (~ -0.4‰) or after (~ -0.2‰) (Fig. 2). At DSDP Site 144 the δ¹⁵N values for the bulk sediment (~ -1.7‰) are on average even more depleted in ¹⁵N than at site S13 (Fig. 3). A similar ¹⁵N depletion is also observed for the sediments of DSDP Site 367 (i.e. δ¹⁵N_{average} ~ -1.5‰; Fig. 4). During the C/T OAE δ¹⁵N values (~ -1.7‰) are on average slightly more depleted in ¹⁵N than before (~ -1.3‰). At DSDP site 603B we measured δ¹⁵N values for two intervals containing an OM-rich/OM-lean cycle (Fig. 5). While the OM-rich intervals of site 603B show similar negative δ¹⁵N values (~ -1.5‰) as sites S13, 144 and 367, the OM-lean intervals are significantly more enriched in ¹⁵N (δ¹⁵N ~ 1.7‰). At site 603B there is a strong negative correlation between δ¹⁵N values and TOC content of the bulk sediment (R² = 0.96). In sharp contrast, there is no correlation or only a minor correlation (R² = 0.5) between the δ¹⁵N values and the TOC contents of the sediment at sites S13, 144 and 367.

It is generally assumed that sedimentary N predominantly derives from organic N compounds (i.e. ON) like proteins. This is supported by the fact that the stable nitrogen isotopic composition of sedimentary N is similar to that of insoluble OM (i.e. kerogen) isolated from the sediment [Peters *et al.*, 1978]. However, degradation can substantially influence the N-isotopic composition of sedimentary OM. Heterotrophic bacteria play a key role in the degradation of phytoplanktonic OM [Cole *et al.*, 1988]. These organisms that use organic carbon as their sole carbon source can use ammonium as reactive N source and as a consequence of their abundance a large fraction of total ammonium uptake in the marine environment has been attributed to bacteria [Wheeler and Kirchman, 1986]. Since heterotrophic bacteria grown at high concentrations of NH₄⁺ can exhibit

Figure 3. Stratigraphy, biomarker, bulk organic carbon and nitrogen data of DSDP Site 144. Carbon isotope values (in ‰ vs. VPDB) of C_{org} , S-bound phytane (Ph) derived from phytoplanktonic chlorophyll, TOC content of the bulk sediment, nitrogen isotope values (in ‰ vs. atmospheric N_2) of the bulk sediment, the relative abundance of molecular fossils (i.e. S-bound 2-methyl-hopanes) of membrane lipids of cyanobacteria, and the stable carbon isotopic composition of molecular fossils of membrane lipids predominantly of cyanobacterial origin. The dashed lines with Roman numbers show the approximate position of the boundaries between the different phases (i.e. rapid positive shift in $\delta^{13}C$ values, plateau with maximum $\delta^{13}C$ values and return to pre-excursion $\delta^{13}C$ values) of the carbon isotope excursion.

large (up to 27‰) isotopic effects during nitrogen fixation [Hoch *et al.*, 1992] incorporation of large quantities of bacterial biomass could result in ^{15}N depleted sedimentary OM. Protein hydrolyses and subsequent bacterial utilisation of released amino acids or short-chain peptides on the other hand may lead to a significant ^{15}N enrichment of sedimentary OM [Macko *et al.*, 1994 and references therein]. Increases as well as decreases in $\delta^{15}N$ values with water depth have been observed for POM settling through the water column [Calvert *et al.*, 1992 and references therein]. Surface sediments, however, are generally more or less enriched in ^{15}N relative to phytoplankton [Altabet *et al.*, 1999; Holmes *et al.*, 1999]. When bottom waters are well oxygenated or suboxic, sediments are enriched in ^{15}N by 4-6‰ or 2-4‰, respectively, while $\delta^{15}N$ values for recent as well as ancient sediments deposited under anoxic bottom water conditions are within 2‰ of phytoplankton biomass [Sachs and Repeta, 1999]. At site 603B bottom water redox conditions may have fluctuated, with OM-poor and OM-rich sediments representing more or less oxic and anoxic conditions, respectively [Herbin *et al.*, 1987; Kuypers *et al.*, in prep.]. While the OM-rich sediments probably preserve the phytoplanktonic nitrogen isotope signature, diagenetic ^{15}N enrichment of decomposing OM in the presence of oxygen could have severely affected the $\delta^{15}N$ values for the OM-poor sediments of site 603B (Fig. 4). In sharp contrast, bottom waters were constantly anoxic in the southern part of the proto-North Atlantic during the entire deposition of the investigated sections (sites S13, 144 and 367), before as well as during the C/T OAE [Brumsack, 1986; Sinninghe Damsté and Köster, 1998; Kuypers *et al.*, 2000 submitted to *Paleoceanography*]. Hence the black shales of sites S13, 144 and

367 and the OM-rich intervals of site 603B are expected to preserve the original stable nitrogen isotopic ratios of phytoplanktonic POM.

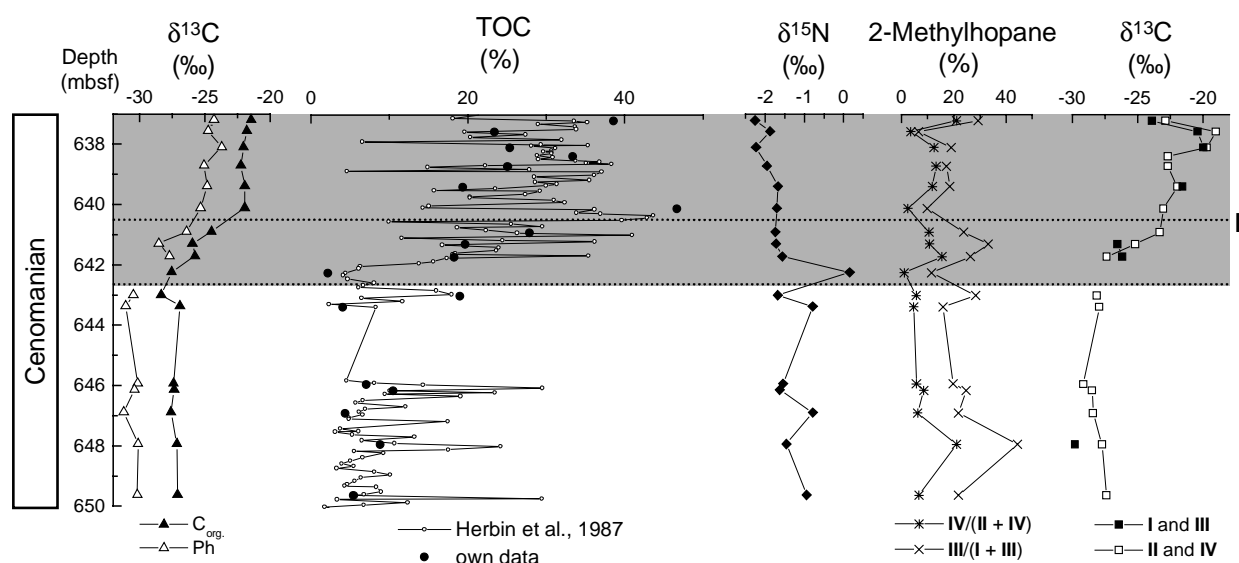

Figure 4. Stratigraphy, biomarker, bulk organic carbon and nitrogen data of DSDP Site 367. Carbon isotope values (in ‰ vs. VPDB) of C_{org} , S-bound phytane (Ph) derived from phytoplanktonic chlorophyll, TOC content of the bulk sediment (own data and data previously reported by Herbin et al. [Herbin et al., 1986]), nitrogen isotope values (in ‰ vs. atmospheric N_2) of the bulk sediment, the relative abundance of molecular fossils (i.e. S-bound 2-methyl-hopanes) of membrane lipids of cyanobacteria, and the stable carbon isotopic composition of molecular fossils of membrane lipids predominantly of cyanobacterial origin. The dashed lines with Roman numbers show the approximate position of the boundaries between the different phases (i.e. rapid positive shift in $\delta^{13}C$ values, plateau with maximum $\delta^{13}C$ values and return to pre-excursion $\delta^{13}C$ values) of the carbon isotope excursion.

The stable nitrogen isotopic composition of POM is a function of the $\delta^{15}N$ value of the nitrogen substrate and the isotopic effect associated with nitrogen fixation [Altabet and Deuser, 1985; Francois et al., 1992]. In the modern ocean nitrate formed upon remineralization of POM below the photic zone plays a key role in sustaining primary productivity (=new production). The preferred uptake of ^{14}N by phytoplankton causes a decrease ($\sim 5\%$) in POM $\delta^{15}N$ values relative to the nitrogen substrate at high nitrate concentrations, while under nitrate-limiting conditions the $\delta^{15}N$ values of source and POM are roughly equal. Hence variations in the $^{15}N/^{14}N$ ratios of sedimentary marine OM have been used to track past changes in relative supply of nitrate to the photic zone [Altabet et al., 1991; Calvert et al., 1992; Farrell et al., 1995]. Since the mean $\delta^{15}N$ value for global deep-water nitrate is 5-6‰ [Farrell et al., 1995], the $\delta^{15}N$ values for extant marine phytoplankton are normally above 0‰. The stable N-isotopic composition of nitrate entering the photic zone is influenced by regional differences in the degree of microbial reduction of nitrate to N_2 and/or N_2O gas under suboxic conditions (i.e. denitrification) [Altabet et al., 1995; Altabet et al., 1999]. Water column denitrification is accompanied by a significant isotopic fractionation (20-40‰) resulting in a substantial enrichment in ^{15}N for the residual nitrate in regions with suboxic intermediate waters (~ 100 -1500 m), such as the Arabian Sea and the Peru upwelling zone [Altabet et al., 1999 and

references therein]. By analogy, substrate nitrate should have been substantially enriched in ^{15}N during the C/T OAE due to overall enhanced oceanic denitrification rates resulting from a significant increase in the ocean area with suboxic to anoxic intermediate waters. Because this would lead to ^{15}N enrichment rather than ^{15}N depletion of the C/T sediments, the negative $\delta^{15}N$ values observed for the OM-rich sediments of sites S13, 144, 367 and the OM-rich sections of site 603B point to a N source other than upwelled nitrate for most of the C/T marine phytoplankton.

Figure 5. Stratigraphy, biomarker, bulk organic carbon and nitrogen data of DSDP Site 603B. Carbon isotope values (in ‰ vs. VPDB) of C_{org} , S-bound phytane (Ph) derived from phytoplanktonic chlorophyll, TOC content of the bulk sediment (own data and data previously reported by Herbin et al. [Herbin et al., 1987]), nitrogen isotope values (in ‰ vs. atmospheric N_2) of the bulk sediment, the relative abundance of molecular fossils (i.e. S-bound 2-methyl-hopanes) of membrane lipids of cyanobacteria, and the stable carbon isotopic composition of molecular fossils of membrane lipids predominantly of cyanobacterial origin. The dashed lines with Roman numbers show the approximate position of the boundaries between the different phases (i.e. rapid positive shift in $\delta^{13}C$ values, plateau with maximum $\delta^{13}C$ values and return to pre-excursion $\delta^{13}C$ values) of the carbon isotope excursion.

Although nitrate is generally the main source for new production in the modern ocean, in some systems such as estuaries [Waser et al., 1998a] and anoxic basins [Velinsky et al., 1991; Velinsky and Fogel, 1999] ammonium could be the main source of new nitrogen. This is because ammonium, if present in sufficient amounts, will always be the preferred nitrogen source for phytoplankton [Waser et al., 1998b]. Like the anoxic waters of the Black Sea, Saanich Inlet, and the Nordic Framvaren fjord [Velinsky et al., 1991; Velinsky and Fogel, 1999], the euxinic waters of the proto-North Atlantic ocean could have contained large amounts of ammonium. It has been shown that algae grown at high concentrations of ammonium under well-constrained laboratory conditions can exhibit large (up to 25‰) isotopic effects during nitrogen fixation [Pennock et al., 1996; Waser et al., 1998a; Waser et al., 1998b]. In accordance with this, $\delta^{15}N$ values of ~1‰ observed for the POM maximum within the euxinic waters of the Nordic Framvaren fjord were attributed to the isotope effect associated with ammonium uptake by photosynthetic anaerobic purple and green

sulfur bacteria [Velinsky and Fogel, 1999]. In the oxic part of the fjords water column $\delta^{15}\text{N}$ values for phytoplanktonic PN were significantly more ^{15}N -enriched ($\sim 4\text{‰}$), which they attributed to the use of nitrate instead of ammonium. The extremely low ammonium concentrations in the oxic part of the water column were attributed to a combination of intense utilisation by anoxygenic photosynthetic bacteria and extensive microbial ammonium oxidation. Extensive anaerobic photosynthesis by green sulfur bacteria could in principle explain the negative $\delta^{15}\text{N}$ values for the C/T sediments from the North Atlantic since molecular fossils of their pigments are abundantly present [Sinninghe Damsté and Köster, 1998; Kuypers *et al.*, 2000 submitted to *Paleoceanography*]. Carbon fixation in green sulfur bacteria occurs via a non-Calvin cycle pathway which results in a strong (10-15‰) enrichment in ^{13}C of their biomass relative to algae or cyanobacteria [Sirevåg *et al.*, 1977; Van der Meer *et al.*, 1998]. Hence a significant contribution of green sulfur bacterial OM to the sediment should also be reflected in the $\delta^{13}\text{C}$ values for sedimentary OM. However, $\delta^{13}\text{C}$ values for OC are relatively depleted in ^{13}C before as well as during the C/T OAE (Figs. 2-5) indicating that green sulfur bacteria did not significantly contribute to the sedimentary OM.

An alternative and in our view more plausible explanation for the ^{15}N depletion of the OM-rich sediments of sites S13, 144, 367 and in the OM-rich sections of site 603B, is microbial N_2 fixation. N_2 fixation was also invoked by Rigby and Batts [1986] and Rau *et al.* [1987] to explain the ^{15}N depletion of Cretaceous OM-rich deposits from Australia and the North and South Atlantic, respectively. A $\delta^{15}\text{N}$ value of 0‰ for atmospheric N_2 and minor isotopic fractionation during N_2 -fixation results in $\delta^{15}\text{N}$ values of -3 to 1‰ for OM from extant marine N_2 -fixing cyanobacteria [Minagawa and Wada, 1986; Carpenter *et al.*, 1997]. This characteristic ^{15}N -depletion of fixed N has been used to determine the contribution of N_2 fixation to the reactive N pool in ancient environments [Rau *et al.*, 1987; Haug *et al.*, 1998; Sachs and Repeta, 1999]. $\delta^{15}\text{N}$ values are more or less constantly negative throughout the investigated sections of the southern proto-North Atlantic, indicating that N_2 fixation contributed substantially to the reactive N pool before as well as during the C/T OAE [Figs. 1-3].

5.4.1.2 Molecular Fossils of Cyanobacterial Membrane Lipids. Bacteriohopanepolyols (BHPs) are membrane lipids exclusively produced by bacteria. They have been recovered from numerous taxa including cyanobacteria [Rohmer *et al.*, 1992]. Like sterols in eukaryotic membranes, they serve a regulating and rigidifying function and as such BHPs are major constituents of bacterial membranes with concentrations varying between 0.1-3 mg/g cell material (dry weight) [Rohmer *et al.*, 1992]. A high proportion of cultured cyanobacteria and recent microbial mats dominated by cyanobacteria contain in addition to 'regular' BHPs, BHPs methylated at the C2 position (i.e. 2-methyl-BHPs), which are absent or only present in relatively low amounts in other bacteria [Summons *et al.*, 1999]. Both BHPs without a methyl group at the C2 position (i.e. 2-desmethyl BHPs) and 2-methyl-BHPs are rapidly transformed in sediments by a variety of diagenetic reactions like oxidation, dehydration, and subsequent hydrogenation, and/or side chain cleavage [Köster *et al.*, 1997]. Their diagenetic derivatives (i.e. C_{31} to C_{36} hopanoids), however, have been recovered from OC-rich sediments as old as 2,500 My [Summons *et al.*, 1999]. These extended hopanoids are especially abundant in anoxic sediments, as a result of the reaction of BHPs with reduced inorganic

sulfur species [Sinninghe Damsté *et al.*, 1995; Köster *et al.*, 1997] during early diagenesis [Kok *et al.*, 2000; Werne *et al.*, 2000]. This natural sulfurisation reaction often preserves taxon-specific carbon-skeletons (i.e. biomarkers) in the geological record [De Leeuw and Sinninghe Damsté, 1989]. In thermally immature euxinic sediments more than 50% of the extractable extended hopanoids are present as sulfur-bound hopanoids, often preserving the biological $17\beta,21\beta(H)$ -conformation [Sinninghe Damsté *et al.*, 1995].

Selective chemical degradation of sulfur-carbon bonds (i.e. desulfurisation) released considerable amounts of extended hopanes from the extractable OM of the C/T sediments from DSDP sites 144, 367 and 603B. These hopanes are typically dominated by the C_{33} and C_{35} 2-desmethyl- $17\beta,21\beta(H)$ -hopanes **I** and **II** and their coeluting 2 β -methyl- $17\beta,21\beta(H)$ -isomers **III** and **IV** (Fig. 6). On average **I-IV** together make up 60 to 80% of the extended hopanes present at the various sites. Desulfurisation of the polar fractions did not release any significant amounts of extended hopanes at the shelf site S13.

Summons *et al.* [Summons *et al.*, 1999] used the relative abundance of 2-methylhopanes, expressed as the so-called ‘2-methylhopane index’, versus the coeluting 2-desmethylhopanes to determine the ecological importance of cyanobacteria in ancient environments. Similarly, we determined the 2-methylhopane indices for sites 144, 367 and 603B from the relative intensities of coeluting 2-desmethylhopanoids and 2-methylhopanoids. In the remainder of this paper the terms ‘ C_{33} hopanoids’ and ‘ C_{35} hopanoids’ will be used for the coeluting pairs of 2-desmethylhopanoids and 2-methylhopanoids **I+III** and **II+IV** (see TIC in Fig. 6), respectively. At DSDP site 144 average index values are 8% and 23% for C_{35} -hopanoids and C_{33} -hopanoids, respectively, with maximum values of 40% for C_{33} -hopanoids (Fig. 3). Similar average values [10% (C_{35} hopanoids) to 22% (C_{33} hopanoids)] are found at site 367, where maximum index values are slightly higher (44%; Fig. 4). At site 603B the average index value for C_{33} hopanoids is slightly lower (13%) while the average index value for C_{35} hopanoids is comparable (10%) to sites 144 and 367 (Fig. 5). In general, the C_{33} hopanoids released upon desulfurisation contain a significantly higher contribution of 2 β -methylhopanoid than the C_{35} -hopanoids. The relatively high quantities of C_{33} hopanoids are remarkable since in most cases the hopanoids released upon desulfurisation are dominated by C_{35} hopanoids only [e.g. De Leeuw and Sinninghe Damsté, 1990; Sinninghe Damsté *et al.*, 1990b; Köster *et al.*, 1997].

Less than 50% of the investigated cyanobacteria and microbial mats dominated by cyanobacteria contain 2 β -methyl-BHPs, while all produce significant quantities of ‘regular’ 2-desmethyl-BHPs [Summons *et al.*, 1999]. On average 2 β -methyl-BHPs make up less than 23% of the total amount of BHPs present in cyanobacteria. Ancient marine environments like their modern analogous probably contained communities consisting of several cyanobacterial taxa. In addition, other bacteria, such as heterotrophic bacteria exclusively producing regular 2-desmethyl-BHPs, will have been abundantly present in the proto-North Atlantic. Therefore, the high average relative abundances (exceeding 20%) of 2 β -methylhopanoids at sites 144, 367 and 603B are remarkable. In fact, they exceed nearly all values reported by Summons *et al.* [1999] for a variety of Phanerozoic settings. The relative abundance of 2 β -methylhopanoids for the C/T sediments of DSDP sites 144, 367 and 603B also exceeds nearly all thermally immature euxinic sediments from a variety of up to

Figure 6. Mass chromatograms of m/z 369 and 383 for $17\beta,21\beta$ (H)-hopanes (i.e. **I** and **II**) and 2β -methyl- $17\beta,21\beta$ (H)-hopanes (i.e. **III** and **IV**), respectively, and reconstructed total mass chromatogram [i.e. total ion count (TIC)]. The Roman numbers in the TIC indicate the two coeluting pairs of 2-methyl and 2-desmethyl extended hopanes **I+III** (C₃₃ hopanoids) and **II+IV** (C₃₅ hopanoids), respectively. 2β -Methyl- $17\beta,21\beta$ (H)-trishomohopane (C₃₄; **III**) and 2β -methyl- $17\beta,21\beta$ (H)-pentakishomohopane (C₃₆; **IV**), respectively, were identified on basis of relative retention time [Summons and Jahnke, 1992]. The stereochemistry of the methyl group at the C2 position in **III** and **IV** is only tentatively identified because 2α - and 2β -methylhopanes have similar retention times in contrast to 3β -methylhopanes [Summons and Jahnke, 1992] and can not be distinguished by mass spectrometry. The sulfur-bound hopanoids present in these sediments all still possess the biological $17\beta,21\beta$ (H)-configuration. The stereochemistry at the C17 and C21 positions is much more prone to isomerisation than the stereochemistry of the methyl substituent at the C2 position [Summons and Jahnke, 1992; Van Duin *et al.*, 1997]. Since 2β is the biological configuration for 2-methylhopanoids [Summons *et al.*, 1999], we infer that **III** and **IV** are 2β -methyl-hopanes.

200 My old settings that have been investigated in our laboratory (Table 1). In most of these sediments the percentage of 2-methylhopanoids is well below the minimum values for the

bathyal/abyssal proto-North Atlantic C/T sediments. The only noteworthy exception is the Jurassic Calcaires en Plaquettes Formation, where paleoenvironmental reconstructions demonstrated a major contribution of cyanobacteria [Tribovillard *et al.*, 1992; van Kaam-Peters and Sinninghe Damsté, 1997]. The high contributions of 2 β -methylhopanoids to the C₃₃- and C₃₅-hopanoids from sites 144, 367 and 603B indicate that cyanobacteria were very abundant in the C/T North Atlantic. They were also most likely the main source of regular 2-desmethyl extended hopanes, which are normally believed to derive from a range of bacterial sources [Rohmer *et al.*, 1992] within the marine environment, since the percentage of 2-methylhopanoids is close to the average value of ~23% for a suite of extant cyanobacteria [Summons *et al.*, 1999]. The relatively high abundance of C₃₃ hopanoids released upon desulfurisation could indicate that certain cyanobacteria biosynthesise(d) BHPs by carbon-carbon linkage of a D-triose instead of a D-pentose [Rohmer *et al.*, 1992] to the pentacyclic triterpenoid. If so, these C₃ extended hopanoids may prove to be biomarkers that are highly specific for certain (N₂-fixing?) cyanobacteria.

Samples origin	n	Age	Setting	2-Methyl %	
				C ₃₃ hopanoids	C ₃₅ hopanoids
C/T sites

Table 1. Age, paleosetting including water depth (where available) and average 2-methylhopane indices (2-methyl %) of C₃₃- and C₃₅-hopanoids of DSDP Sites 144, 367, 603B and a selection of [Brumsack and Thurow, 1986; Bralower and Thierstein, 1987] Tertiary, Cretaceous and Jurassic sites. Abbreviations are NA, North Atlantic; SA, South Atlantic; Fm, formation; My, million years before present; n.a., not applicable.

The extremely low abundance of sulfur-bound (S-bound) extended hopanoids at site S13 can be attributed to a significantly higher thermal maturity of the sedimentary OM at this shelf site than at the abyssal sites 144, 367 and 603B [Sinninghe Damsté and Köster, 1998]. Extended unsaturated

hopanoids (i.e. hopenes) released upon thermal degradation of S-bound hopanoids [Köster *et al.*, 1997], are abundantly present in the apolar fractions of site S13. Although no significant amounts of 2-methyl-hopenes were detected at site S13, a substantial cyanobacterial input of hopanoids can not be excluded because only half of the studied cyanobacterial cultures produce 2-methyl-BHPs [Summons *et al.*, 1999].

Since both 2-methyl and 2-desmethyl extended hopanoids coelute upon gas chromatographic analysis only the stable carbon isotopic composition of the pairs of 2-desmethylhopanoids and 2-methylhopanoids **I+III** (i.e. C₃₃ hopanoids) and **II+IV** (i.e. C₃₅ hopanoids) could be determined. The $\delta^{13}\text{C}$ values of C₃₃ and C₃₅ hopanoids are similar at the bathyal/abyssal sites and only at site 144 there is a minor offset of $\sim 1.5\%$ (Figs. 3-5). In addition, the $\delta^{13}\text{C}$ values of C₃₃ and C₃₅ hopanoids co-vary at sites 144, 367 and 603B, which suggests a common source for these hopanoids. There is no correlation between the percentage of 2 β -methylhopanoids and the stable carbon isotopic composition of the C₃₃ and C₃₅ hopanoids (Figs. 3-5). This suggests that the carbon isotopic composition of regular 2-desmethyl and 2-methyl extended hopanoids is similar and co-varies, which is in good agreement with a predominantly cyanobacterial origin of both regular and 2-methyl extended hopanes.

Little is known about the isotopic fractionation by cyanobacteria and all our current knowledge is restricted to one taxon, the unicellular *Synechococcus* [Popp *et al.*, 1998]. Assuming that the factors that control the stable carbon isotopic composition of *Synechococcus* were more or less the same for mid-Cretaceous cyanobacteria, the isotopic composition of cyanobacterial hopanoids prior to and during the C/T OAE can be estimated. It has been shown that, in sharp contrast to algae investigated up to now, the stable isotopic composition of *Synechococcus* is relatively independent of CO₂ concentration and growth rate [Popp *et al.*, 1998]. This has been attributed either to the high cell area to volume ratio for these small organisms [Popp *et al.*, 1998] or to active bicarbonate uptake [Keller and Morel, 1999]. The degree of isotope fractionation during carbon fixation (ϵ_p) for *Synechococcus* is 16-18‰ [Popp *et al.*, 1998]. Dissolved inorganic carbon (DIC) was enriched in ¹³C by 2-3‰ relative to modern values [Arthur *et al.*, 1985; Hayes *et al.*, 1999] during most of the mid-Cretaceous. Assuming ϵ_p for mid-Cretaceous cyanobacteria was also 16-18‰, $\delta^{13}\text{C}$ values of cyanobacterial biomass should be -21 to -24% before the C/T OAE. If we assume that like the hopanoids of *Synechococcus* cyanobacterial BHPs were depleted by 6-8‰ relative to biomass [Sakata *et al.*, 1997], $\delta^{13}\text{C}$ values of cyanobacterial hopanes should be between -27 and -32% during the mid-Cretaceous. These theoretical values agree well with the observed $\delta^{13}\text{C}$ values of the hopanes prior to the C/T OAE. $\delta^{13}\text{C}$ values of DIC increased by 2.5‰ during the C/T OAE [Jenkyns *et al.*, 1994] and a similar increase would be expected for cyanobacteria. However, the hopanes from the C/T OAE interval show a considerably larger increase in ¹³C/¹²C ratios at sites 367 and 603B during the C/T OAE (Figs. 3-5). This suggests a change in the cyanobacterial community with taxa characterised by a significantly smaller fractionation becoming dominant during the C/T OAE. Intriguingly the extant filamentous N₂-fixing cyanobacterium *Trichodesmium* is significantly more ($\delta^{13}\text{C}_{\text{biomass}} \sim -13\%$) ¹³C-enriched [Carpenter *et al.*, 1997] than would be expected from the results of Popp *et al.* [1998] for *Synechococcus*. Since *Trichodesmium* was collected from oligotrophic ocean surface waters it seems likely that this ¹³C-enrichment

resulted from a smaller ϵ_p for this species rather than 'heavier' DIC values. Thus other cyanobacteria may have an ϵ_p significantly different from the 16-18‰ determined for *Synechococcus*. The minor shift in $\delta^{13}\text{C}$ values of the hopanes could indicate that a change in cyanobacterial community did not occur at DSDP Site 144 but as a result of the general lack of data for the C/T OAE interval a change can also not be excluded.

5.4.2 The proto-North Atlantic N cycle and its implications for the mid-Cretaceous carbon cycle.

There is abundant evidence (i.e. ¹⁵N-depletion of OM-rich marine sediments typical for newly fixed N₂ and the abundance of cyanobacterial membrane lipids) that N₂-fixing cyanobacteria played an important role in the N-cycle of the proto-North Atlantic during the C/T. This is in good agreement with the model proposed by Rau et al. [1987], where reduced ocean circulation and extensive denitrification in largely anoxic or suboxic mid and deep waters may have led to N₂ fixation periodically providing an alternate N source for phytoplankton communities during the early to middle Cretaceous. Cyanobacteria are the main N₂-fixers in the marine realm and the abundance of their membrane lipids (e.g. 2-methylhopanoids) in these black shales agrees well with N₂ fixation being the main source of nutrient N for phytoplanktonic growth in the proto-North Atlantic Ocean during this time.

Denitrification in a largely anoxic water column would have removed large quantities of reactive N, decreasing N:P ratios of the seawater. Regeneration of P from sedimenting algal POM is favoured under anoxic conditions and could have further decreased N:P ratios [Ingall and Jahnke, 1997; Van Cappellen and Ingall, 1994]. Preferential P regeneration relative to OC oxidation is indicated by the extremely high atomic C/P ratios for the OC-rich sediments of sites 367 and 603B [Kuypers et al., in prep.]. Average atomic C/P ratios exceed 400 at both sites, while C/P ratios for fresh marine OM is ~ 106 [Redfield et al., 1963]. Hence, seawater supplied to the photic zone would most likely have contained low concentrations of reactive N relative to P (N/P < Redfield) giving N₂-fixing cyanobacteria a competitive advantage over algae [Tyrrell, 1999]. In addition to P the availability of the micronutrient iron (Fe) limits growth of N₂-fixing cyanobacteria as a result of the high dissolved Fe demand of the N₂ fixation mechanism [Falkowski et al., 1998]. Dissolved Fe was probably not biolimiting in the small Atlantic basins where sufficient Fe could be supplied by riverine or aeolian input from the surrounding land [Sinton and Duncan, 1997]. Like in the modern Black Sea reduction of iron oxides in the suboxic/anoxic waters even could have led to high dissolved Fe concentrations [Lewis and Landing, 1991] in the near-surface waters of the proto-North Atlantic basin. Excretion of N during N₂ fixation and remineralisation of cyanobacterial biomass in the upper part of the water column could have released reactive N for algal growth (Fig. 7). Therefore, even though N₂ fixation by cyanobacteria was the primary source of reactive N for phytoplanktonic growth in the proto-North Atlantic, algae could have contributed significant amounts of OM to the C/T sediments (see below).

5.4.2.1 The significance of N₂-fixing cyanobacteria as a source of sedimentary OM. Based upon the extreme ¹⁵N-depletion of the sediment and the amorphous nature of the sedimentary OM, Rau et

al. [1987] suggested that biomass of N₂-fixing cyanobacteria could make up a significant part of early and middle Cretaceous insoluble sedimentary OM. The amorphous nature of the C/T sedimentary OM of sites S13, 144, 367 and 603B in itself does neither support nor exclude a cyanobacterial origin and generally only indicates a marine origin. Although the strong ¹⁵N-depletion of the C/T sediments could indicate an important input of cyanobacterial OM, this depletion could also be explained by other processes involving incorporation of newly fixed N₂ in algal biomass. The most direct way of incorporation of newly fixed N₂ in algal biomass occurs in several species of mat-forming pelagic diatoms that harbor the N₂-fixing endosymbiont *Richelia intracellularis*, which provides them with reactive N [Carpenter *et al.*, 1999]. The combined biomass of algal host and cyanobacterial symbiont shows a ¹⁵N-depletion typical for newly fixed N₂ ($\delta^{15}\text{N} \sim -1.5\text{‰}$) [Carpenter *et al.*, 1999]. Blooms of some of these mat-forming diatoms could significantly contribute new N to regions of the ocean that are poor in reactive N [Carpenter *et al.*, 1999]. It has been suggested that these mats could also contribute significant amounts of OM to the sediment [Kemp *et al.*, 1999]. In fact the high OC content of the sapropels of the Mediterranean Sea may be entirely accounted for by sedimenting mat-forming diatoms and their N₂-fixing endosymbionts [Kemp *et al.*, 1999; Sachs and Repeta, 1999]. Like the mats itself these sapropels show the ¹⁵N depletion typical for newly fixed nitrogen ($\delta^{15}\text{N} \sim -0.1\text{‰}$) [Sachs and Repeta, 1999]. Kemp *et al.* [1999] proposed that these mat-forming diatoms also contributed significantly to the black shale deposits of the Cretaceous.

An alternative and less direct way of incorporation of newly fixed N₂ in algal biomass is the utilisation of N excreted by living N₂-fixing cyanobacteria. For instance the extant filamentous genus *Trichodesmium*, which is thought to be the most significant N₂-fixer in present-day open-ocean waters [Carpenter *et al.*, 1999 and references therein], releases up to 50% of the fixed N₂ as dissolved N [Glibert and Bronk, 1994]. Additional reactive N is released upon degradation of *Trichodesmium* in the upper part of the water column and both processes are a significant source of N for other phytoplankton in some oligotrophic marine settings [Letelier and Karl, 1996]. This significantly affects the stable nitrogen isotopic composition of the total phytoplanktonic community in areas where *Trichodesmium* is common [Minagawa and Wada, 1986; Carpenter *et al.*, 1997; Capone *et al.*, 1998]. Similar observations were made for the Baltic Sea, where the nitrogen isotopic composition of all size-classes of plankton were strongly affected by the direct or indirect incorporation of ¹⁵N-depleted fixed N₂ during blooms of the N₂-fixing *Aphanizomenon sp.* and *Nodularia spumigena* [Rolff, 2000]. Therefore, although the sedimentary $\delta^{15}\text{N}$ signature is strongly affected by cyanobacterial N₂ fixation, algae could still have contributed significantly to the C/T sedimentary OM.

The abundance of molecular fossils of cyanobacterial membrane lipids relative to typical algal biomarkers such as steroids could provide insight into the significance of cyanobacteria as a source of sedimentary OM during the C/T. The extractable OM of the C/T sediments from site S13 contains much more steroids than hopanoids. At DSDP site 144 steroids are also more abundant than hopanoids. However, the extractable OM of the C/T sediments from DSDP site 367 contains much more hopanoids than steroids. There are large differences between sediment samples at DSDP site 603B. Some sediments contain significantly more hopanoids than steroids while other samples are dominated by steroids. The concentration of BHPs in bacterial cells is in the same order of

magnitude as sterols in eukaryotes (e.g. algae) [Rohmer *et al.*, 1992]. Assuming the preservation potential of both membrane components is similar, it seems that at site 367 and for some parts of the C/T sequence of site 603B, cyanobacteria could have significantly contributed to the sedimentary OM. The significant co-variation between the carbon isotopic composition of the extended hopanoids, sulfur-bound Ph and bulk OM also suggests a significant cyanobacterial contribution to the OM at site 367 (Fig. 4). In contrast at sites S13 and 144 and throughout most of the C/T sequence of site 603B, algal-derived OM seems to dominate the sedimentary OM. Here processes involving repackaging of newly fixed N₂ in algal biomass must be implied to explain the strong ¹⁵N-depletion of the C/T sediments. Interesting in this respect is the fact that some of the C/T black claystones of DSDP site 603B contain large amounts of biogenic silica [Kuypers *et al.*, unpublished results]. Although no recognisable remains were found, diatoms and more specifically mat-forming diatoms containing N₂-fixing endosymbionts could be the source of biogenic silica and perhaps a significant part of the OM at this site.

5.4.2.2 Cyanobacterial N₂ fixation and the enhanced biological CO₂ pumping during the C/T OAE. Both shelf (S13) and abyssal marine sediments (144, 367 and 603B) show a ¹⁵N-depletion typical for newly fixed N₂ already well before the C/T OAE (Figs. 2-5). We attribute the important role of N₂-fixers in the nitrogen cycle of the proto-North Atlantic Ocean prior to the C/T OAE to basin-wide stagnation and anoxia (Fig. 7). Previously we have shown that the southern part of the proto-North Atlantic was euxinic well before the C/T OAE [Kuypers *et al.*, 2000 submitted to *Paleoceanography*]. The co-occurrence of lamination, enrichment of trace metals and abundance of molecular fossils of pigments from green sulfur bacteria at different palaeo-water depths indicates that the southern proto-North Atlantic Ocean water column was periodically euxinic from the bottom to at least the base of the photic (<150 m) zone prior to as well as during the C/T OAE. Similar conditions may have periodically occurred in the northern part of the proto-North Atlantic as well [Herbin *et al.*, 1987; Kuypers *et al.*, unpublished results].

During the C/T OAE there is a significant increase in marine OC accumulation rates at the sites in the southern part of the proto-North Atlantic (sites S13, 144 and 367), which we have attributed to an increase in primary productivity [Kuypers *et al.*, 2000 submitted to *Paleoceanography*]. An increase in OM accumulation rates also occurred in the northern proto-North Atlantic (site 603B) during the C/T OAE [Kuypers *et al.*, unpublished results]. In the modern ocean enhanced primary productivity is closely linked with intensified upwelling of intermediate waters into the photic zone. Enhanced upwelling in the proto-North Atlantic has been attributed to the initiation of a deep connection between the proto-North and South Atlantic basins [Tucholke and Vogt, 1979; Summerhayes, 1981; Summerhayes, 1987]. The influx into the proto-North Atlantic of large amounts of highly saline, old, oxygen deficient water from the northern South Atlantic would have displaced deep water towards the surface [Tucholke and Vogt, 1979; Summerhayes, 1981; Summerhayes, 1987]. As a more or less stagnant anoxic basin possibly with a partly estuarine-like circulation [Arthur *et al.*, 1987; Thierstein and Berger, 1979], the proto-North Atlantic could have acted as a nutrient trap [Summerhayes, 1987] comparable to the Holocene Black Sea and Cariaco Trench that contain relatively high levels of dissolved reactive N and especially P below the chemocline [Sarmiento *et al.*, 1988; Velinsky *et al.*, 1991; Fry *et al.*, 1991].

Figure 7. Simplified representation of the nitrogen, phosphorus and carbon cycle in the mid-Cretaceous North Atlantic Ocean before and during the C/T OAE. Abbreviations are R, Redfield ratio for N/P ~ 16 ; OM, organic matter; NO_3^{2-} , reactive N (mainly nitrate); PO_4^{3-} , phosphate. The arrows indicate fluxes of major nutrients N and P, and phytoplanktonic OM. Increased fluxes of major nutrients N, P and phytoplanktonic OM during the C/T OAE are indicated by the thick black arrows. Enhanced nutrient N and P levels, increased N_2 -fixation and increased algal biomass during the C/T OAE are indicated by the larger text font size. The thick dotted line mark the relative depth of the oxycline, which is inferred from the occurrence of specific biomarkers of photosynthetic anoxygenic green sulfur bacteria [Kuypers et al., 2000 submitted to *Paleoceanography*].

Thus, water brought to the surface as a consequence of the influx of South Atlantic dense water was likely extremely nutrient-rich but had a deficit of N relative to P (Fig. 7). Neither $\delta^{15}\text{N}$ values of the bulk sediments nor the relative abundance of 2-methyl-hopanoids shows a significant change indicating that N₂-fixing cyanobacteria remained the main source of nutrient N during the C/T OAE. However, the shift in $\delta^{13}\text{C}$ values for cyanobacterial hopanoids could indicate that there was a change in the composition of the cyanobacterial community. Changes in the composition of the cyanobacterial community have also been observed for modern marine settings like the Baltic Sea, where the blooming filamentous cyanobacterium *Aphanizomenon flos-aquae* is replaced by the shallower dwelling filamentous *Nodularia spumigena* as a response to the shallowing of the upper mixed layer [Kononen *et al.*, 1996]. The increase in primary productivity during the C/T OAE was accompanied by a significant rise of the chemocline, with euxinic conditions in the southern proto-North Atlantic periodically occurring at very shallow water depths of 15 m or less, while bottom water redox conditions did not markedly change (i.e. remained euxinic) [Kuypers *et al.*, 2000 submitted to *Paleoceanography*]. This shallowing of the chemocline could have resulted in a competitive advantage for cyanobacteria like the extant *Nodularia* with a tolerance for higher temperatures, higher light intensity as a result of better protective mechanisms against photo-oxidation and/or higher phosphate affinity [Kononen *et al.*, 1996]. Increased upwelling of anoxic, P-loaded waters would have increased the amount of N₂ fixed by these cyanobacteria fuelling a larger production of phytoplanktonic biomass leading to the observed increase in OC burial. This enhanced activity of the biological pump led to a significant drop in atmospheric carbon dioxide concentration during the C/T OAE [Freeman and Hayes, 1992; Arthur *et al.*, 1988; Kuypers *et al.*, 1999] and, thereby, could have triggered the early Turonian deterioration of the greenhouse climate.

Chapter 6

Massive expansion of marine Archaea during a mid-Cretaceous oceanic anoxic event

Published in *Science*, 293, 92-94, 2001

Abstract

Biogeochemical and stable carbon isotopic analysis of black shale sequences deposited during an Albian oceanic anoxic event (~112 Myr) indicate that up to 80 wt. % of sedimentary organic carbon is derived from marine, non-thermophilic archaea. The ^{13}C content of archaeal molecular fossils indicates that these archaea were living chemoautotrophically. Their massive expansion may have been a response to the strong stratification of the ocean during this anoxic event. In fact, the sedimentary record of archaeal membrane lipids suggests that this anoxic event actually marks a moment in Earth history at which certain hyperthermophilic archaea adapted to low-temperature environment.

6.1 Introduction

The mid-Cretaceous was a period of exceptional oceanic volcanic activity. Evidence of this igneous activity is provided by the presence of large oceanic plateau, including the Ontong Java, Kerguelen and Caribbean Plateau, which have been dated at 125-88 Myr (1). Enhanced volcanic outgassing of CO₂ could have caused the mid-Cretaceous ‘greenhouse’ climate (2), with its minimal equator-to-pole temperature difference. In contrast, episodic oceanic anoxic events (OAEs) may have effectively reduced CO₂ concentrations during brief periods by sequestering carbon in the subsurface (3, 4). The widespread deposition of black-shales during the OAEs has been attributed either to decreased organic matter (OM) remineralisation resulting from a decreased oxygen flux (5) or to increased primary productivity overwhelming the oxic OM remineralisation potential of the water column (6). The increase in organic carbon (OC) accumulation rates during the OAEs in these two basically different models is attributed to enhanced burial of marine OM, which is typically of phytoplanktonic origin. Here we determined the source for both soluble and insoluble OM of the early Albian OAE 1b black shales of the Ocean Drilling Program site 1049C (North Atlantic Ocean off the coast of Florida: 30°08’N, 76°06’W) and the Ravel section of the Southeast France Basin (44°06’N, 6°28’E) using optical, chemical, and stable carbon isotopic analyses, and show that the sources of OM for this OAE are fundamentally different from other OAEs.

6.2 Results and discussion

The upper Aptian-lower Albian sequence of site 1049C consists of marls and calcareous marls characterised by a low (< 0.1 wt%) OC content interrupted by an OC-rich (up to 6 wt%; Fig. 1A) black shale interval. This black shale interval (grey shaded area; Fig. 1) has been identified as the local expression of OAE 1b (7). The bulk OC shows a sharp increase in its ¹³C-content during the OAE1b (Fig. 1B). Similar increases in δ¹³C values observed for marine carbonates and OM from other mid Cretaceous OAEs have been attributed to an increase in the ¹³C content of the oceanic/atmospheric pool of inorganic carbon as a result of globally enhanced OC burial rates (3). However, the stable carbon isotopic composition of picked planktonic and benthic foraminifers (7) indicate that there was no significant increase in δ¹³C values for inorganic carbon during the OAE1b at site 1049C.

To resolve the origin of the increase in δ¹³C values for bulk OC (δ¹³C_{org.}) we first analysed the extractable OM. The saturated hydrocarbon fractions of the black shales contain long-chain (C₂₅-C₃₁) *n*-alkanes that are largely derived from leaf waxes of terrestrial plants, some bacterial hopanoids and acyclic isoprenoids. Remarkably, the acyclic isoprenoid, 2,6,15,19-tetramethylcosane [TMI (**I**), Fig. 1] is the most abundant component of the saturated hydrocarbon fraction. So far, TMI has only been found in the contemporaneous (7) OAE1b black shale of the Ravel section in France (8). TMI (**I**) is structurally closely related to 2,6,10,15,19-pentamethylcosane (PMI) (**II**), a compound of known archaeal origin (9), which was also present in the saturated hydrocarbon fraction. Further evidence for archaeal compounds was found on

treating the polar fraction from the black shale interval with HI/LiAlH_4 to cleave ether bonds. The released fractions were dominated by acyclic (**a**), monocyclic (**b**), bicyclic (**c**) and tricyclic (**d**)

Figure 1 Stratigraphy, bulk and biomarker data of Ocean Drilling Project site 1049C. TOC content (A), and carbon isotope values (in ‰ vs. VPDB) of bulk OC (B), bi- ($\text{C}_{40:2\text{cy}}$) and tricyclic ($\text{C}_{40:3\text{cy}}$) biphytanes, PMI (II) and TMI (I) derived from archaea (C), oxygen-bound steranes [cholestane (VII) and 24-ethyl-cholestane (VIII)] mainly derived from marine algae (D), and oxygen-bound phytane (IX) derived either from the isotopically ‘light’ (^{12}C -rich) phytol side-chain (VI) of algal and cyanobacterial chlorophyll or the isotopically ‘heavy’ (^{13}C -rich) archaeal membrane lipids (E), and concentrations ($\mu\text{g}/\text{gTOC}$) of GDGT VI and TMI derived from archaea (F) of late Aptian/early Albian abyssal sediments from site 1049C (28). In all graphs the centre of the bullet corresponds to the top of the ~2 cm thick sediment samples. The OAE1b black shale interval has been indicated as a grey shaded area in the graphs. Dotted lines in graph (B) indicate estimated contributions (in %) of archaeal derived insoluble OM to TOC as discussed in text. Relevant structures are indicated.

biphytanes (C_{40} isoprenoids), which are also exclusively found in archaea (10, 11). In addition, a recently developed HPLC/MS technique (12) revealed the presence of four (III–VI) intact isoprenoid glycerol dialkyl glycerol tetraethers (GDGTs) in the black shale interval. GDGTs are the main constituents of archaeal membranes (11) and IV–V are characteristic of the archaeal lineage Crenarchaeota (10, 13), which includes the hyperthermophilic archaea which thrive at temperatures $>60^\circ\text{C}$. In contrast, VI is highly diagnostic for their non-thermophilic relatives (11, 14–16), and the dominance of this compound (representing 60% of total GDGTs) indicates an important input of non-thermophilic crenarchaeota. To the best of our knowledge this is the earliest fossil evidence for marine non-hyperthermophilic crenarchaeota, extending their geological record by more than 60 million years (14).

The $\delta^{13}\text{C}$ values of components of unambiguous archaeal origin such as II, c and d and the related I are significantly enriched in ^{13}C relative to algal steroids VII–VIII (Fig. 1C–D), bacterial derived hopanes and the leaf-wax *n*-alkanes *n*- C_{29} and *n*- C_{31} from higher plants (17). Cholestane

(**VII**) and 24-ethyl-cholestane (**VIII**), released after HI/LiAlH₄ treatment, derive from C₂₇ and C₂₉ sterols, predominantly biosynthesised by marine algae (18). Their $\delta^{13}\text{C}$ values record changes in the stable carbon isotopic composition of algae (Fig. 1C). The offset of >10‰ between the $\delta^{13}\text{C}$ values for TMI/PMI and the algal biomarkers (Figs. 1C-D) is in agreement with our earlier observations for the OAE1b black shales of the Ravel section in France (8).

While archaeal lipids are abundant in the OC-rich OAE1b black shales, they are largely absent in the adjacent sediments (Fig. 1F). This suggests a significantly increased archaeal contribution to the sedimentary OM during OAE1b. Evidence for an increase in the relative contribution of archaeal biomass is also provided by the ~12‰ shift in $\delta^{13}\text{C}$ values for the isoprenoid phytane (**IX**) released from the polar fractions upon HI/LiAlH₄ treatment (Fig. 1E). Phytane (**IX**) derives either from the isotopically ‘light’ (¹²C-rich) phytol side-chain of algal and cyanobacterial chlorophyll or the isotopically ‘heavy’ (¹³C-rich) archaeal membrane lipids such as archaeol. Before and after the black shale interval, $\delta^{13}\text{C}$ values for phytane (**IX**) are comparable to those of steranes, consistent with an algal origin, whereas in the black shale interval it is enriched by up to 12‰, indicating a predominant archaeal origin. There is no coinciding positive shift in $\delta^{13}\text{C}$ values for the algal steranes (Fig. 1D). Therefore, the sharp increase in $\delta^{13}\text{C}$ values for phytane (**IX**) indicates a change in the relative contribution from algal and archaeal OM sources during the OAE1b. An increase in the relative contribution of ¹³C enriched archaeal biomass to the OM deposited during OAE1b could thus also explain the shift in $\delta^{13}\text{C}$ values for bulk OC (Fig. 1B).

To determine the archaeal contribution to the bulk OM, the insoluble OM, representing >95% of the bulk OM, was also investigated. Thin laminae of amorphous OM (as revealed by scanning electron microscopy) that occur throughout the black shale make up a significant part of the OM. This OM cannot be hydrolysed either by strong acid or base, and shows the enrichment in ¹³C ($\delta^{13}\text{C} = -15.5\text{‰}$) typical of archaeal lipids. Both thermal (flash pyrolysis) and chemical degradation (RuO₄ oxidation) of this amorphous OM almost exclusively (>95%) releases molecules with acyclic isoprenoidal carbon skeleton. These isoprenoids were also abundant in the flash pyrolysates of the OAE1b black shale of the Ravel section (8, 19). The weighted average of the $\delta^{13}\text{C}$ values of the chemically released isoprenoids ($\delta^{13}\text{C} = -14\text{‰}$) from the black shale is in good agreement with the bulk isotopic composition of the OC from the laminae, indicating that these are the main components of this polymeric OM. The distribution of chemical degradation products indicates that the polymer consists of monomers with essentially two different carbon skeletons: TMI (**I**) and PMI (**II**) linked together by ether-bonds [Kuypers et al., unpublished results]. This strongly suggests that the positive shift in $\delta^{13}\text{C}_{\text{org}}$ (Fig. 1B) indeed results from an increased contribution of ¹³C enriched archaeal-derived OC during OAE1b.

The relative contribution of archaeal polymer to the OC can be estimated from $\delta^{13}\text{C}_{\text{org}}$ using a two end-member mixing model and assuming that the $\delta^{13}\text{C}$ value (~ -24‰) for bulk sedimentary OC before the OAE1b represents the non-archaeal endmember and $\delta^{13}\text{C} = -15.5\text{‰}$ for the archaeal endmember. There is on average a very large (~50 wt%) and sometimes even a predominant (~80 wt%) contribution of archaeal OC in the black shale interval (Fig. 1B). A significant contribution (up to 40 wt%) of archaeal OC is also found for the OAE1b black shales in France using the stable carbon isotopic composition of *n*-alkanes and isoprenoids obtained after off-line pyrolysis of the

bulk OM (19) as algal and archaeal endmembers, respectively. Although prokaryotes can constitute more than 70 wt% of carbon biomass in the upper ocean (20) and their biomarkers are abundantly present in the sediment (21), evidence for a substantial (>10 %) prokaryotic contribution to Phanerozoic OC-rich sediments is generally lacking (22). Therefore, the domination of OM derived from archaea during OAE1b is both unexpected and unprecedented, indicating that this was a unique time in Earth history. Certainly, it reveals that enhanced OM deposition during OAE1b was caused by a different mechanism than has been invoked for other OAEs.

The diversity of archaeal lipids recovered from the OAE1b black shales suggests that they derive from a multitude of archaeal species. However, the specific ^{13}C enrichment of these lipids indicates a common 'heavy' (^{13}C -rich) carbon source for the archaea and/or a common pathway of carbon-fixation with a reduced ^{13}C fractionation effect compared to the Calvin cycle used by algae, cyanobacteria and higher plants. The large enrichment (up to 12 ‰) in $^{13}\text{C}/^{12}\text{C}$ ratios between the algal biomarkers and the archaeal molecular fossils suggest that archaea were not living heterotrophically on photoautotrophic biomass. Hence it seems likely that the archaea present during OAE1b were autotrophs and used a chemical energy source for carbon fixation. The ecological niche of these chemoautotrophic archaea in the mid-Cretaceous ocean is not clear.

The abundance of GDGT **VI** in the OAE1b black shales can be interpreted, however, to suggest that at least some of these archaea were thriving in the marine water column. In the present-day ocean GDGT **VI** is abundantly present in marine particulate OM and surface sediments (11, 16), which is consistent with the fact that planktonic representatives of the marine crenarchaeota comprise as much as 20% of the picoplankton (23). Compound-specific radiocarbon analyses of biphytanes **c** and **d** derived from **VI** indicate that these archaea are not feeding on phytoplanktonic biomass but rather use 'old' ^{14}C -depleted dissolved inorganic carbon from well below the photic zone in the water column (24). Furthermore, these components show a significant ^{13}C enrichment (4-5‰) relative to algal steroids (14), indicating that planktonic crenarchaeota, like related hyperthermophiles (25), may use a non-Calvin cycle pathway of carbon assimilation with a smaller degree of carbon-isotope fractionation during carbon assimilation. The offset between $\delta^{13}\text{C}$ values for the biphytane **d** derived from **VI** in present-day marine particulate OM (-20 to -23‰) (14) and in OAE1b sediments (-17 to -18‰) can be explained by the enrichment of dissolved inorganic carbon in ^{13}C by 2-3‰ relative to modern values during the mid-Cretaceous (2). The remainder of the larger (3-7‰) enrichment of biphytane **d** relative to algal steroids can probably be accounted for by enhanced carbon isotope fractionation by algae during the mid-Cretaceous due to enhanced CO_2 availability (26). Carbon isotopic evidence thus suggests that the mid-Cretaceous crenarchaeota producing GDGT **VI** used similar biochemical pathways as their present-day representatives.

The massive expansion of marine, non-thermophilic archaea during the mid-Cretaceous OAE1b is unprecedented and could actually mark a moment in geological history at which certain hyperthermophilic archaea adapted to low-temperature environments. Older sediments of comparable thermal maturity do not contain the characteristic GDGT **VI**, whereas this GDGT is commonly found in black shales younger than Albian (11, 14). On the other hand, TMI (**I**) and macromolecular OM composed thereof has so far only been reported for this time interval. This suggests that at least two distinct groups of marine, non-thermophilic archaea existed, of which one has thrived for the past 112 Myr, whereas the other (TMI-producing) group seems to become

extinct after OAE1b when environmental conditions became less favourable. Prolonged (millions of years) periods of enhanced hydrothermal activity (1) would have significantly altered the ocean chemistry during the mid-Cretaceous, providing the necessary reduced compounds to sustain a large community of chemoautotrophic archaea. In fact, the Cretaceous strontium isotope record indicates maximum ocean-ridge crustal production during the Aptian-early Albian stages (27). In addition, the pronounced water column stratification and anoxic conditions that are characteristic for OAE1b (7) may have assisted in the development of a diverse community of marine, chemoautotrophic, non-thermophilic archaea.

28. Total Organic Carbon (TOC) contents were determined using a CN analyser. The $\delta^{13}\text{C}$ values ($\pm 0.1\text{‰}$) ($\delta^{13}\text{C} = [(\text{R}_{\text{sample}}/\text{R}_{\text{standard}} - 1) \cdot 1,000]$, where R is $^{13}\text{C}/^{12}\text{C}$ and the standard the Vienna Pee Dee belemnite) were measured

on bulk sediments after removal of the inorganic carbonates with diluted HCl using automated on-line combustion followed by conventional isotope ratio-mass spectrometry. The powdered samples (15 to 30 g) were Soxhlet extracted for *c.* 24 h to obtain the total lipid fraction. The total extracts were separated into apolar and polar fractions using column chromatography. The hydrocarbons that were released from the polar fraction by HI/LiAlH₄ and subsequent hydrogenation were isolated using column chromatography. Samples were analysed by GC-mass spectrometry (GC-MS) for identification. Compound-specific $\delta^{13}\text{C}$ analyses were performed using GC-isotope-ratio-monitoring MS. The $\delta^{13}\text{C}$ values for individual compounds are the means of duplicate runs ($\delta^{13}\text{C} = \pm 0.3$ to 0.6) expressed versus VPDB. HPLC/MS analyses were performed as previously described (12). Macromolecular material was isolated from the decalcified and extracted sediments by density centrifugation (at 3700 r.p.m. for 5 min) using pure dichloromethane (floating fraction). Fourier transform infrared spectroscopy (frequency range of 400 cm⁻¹ to 4000 cm⁻¹) was performed on 2 mg of dry macromolecular material pressed into KBr pellets. The extract obtained after RuO₄ degradation of ~5 mg of isolated macromolecular material was derivatised with BF₃/methanol prior to analysis. Curie-point flash pyrolysis (10 s; 610°C) was performed with a pyrolysis unit connected to a gas chromatograph.

Archaeal remains dominate marine organic matter from the early Albian oceanic anoxic event 1b

Submitted to *Palaeogeography, Palaeoclimatology, Palaeoecology* August 2, 2001

Abstract

The sources for both soluble and insoluble organic matter of the so-called early Albian (~112 Myr) 'oceanic anoxic event (OAE) 1b' black shales of the Ocean Drilling Program (ODP) site 1049C (North Atlantic Ocean off the coast of Florida) and the Ravel section of the Southeast France Basin (SEFB) were determined using optical, chemical, stable carbon and nitrogen isotopic analyses. Archaea-derived isoprenoidal tetraether membrane lipids and free and macromolecularly bound isoprenoid alkanes are abundant in these black shales. More specifically, the presence of certain ether lipids (bi/tricyclic biphytane tetraethers) indicates an important contribution of representatives of marine planktonic archaea. The large difference (up to 12 ‰) in $^{13}\text{C}/^{12}\text{C}$ ratios between algal biomarkers and the much more abundant planktonic archaea-derived biomarkers indicates that the latter were living chemoautotrophically, possibly using ammonium as an energy source. This offset in $^{13}\text{C}/^{12}\text{C}$ ratios was used to estimate that up to ~40% of the organic matter of the SEFB and up to ~80% of the organic matter of ODP site 1049C preserved in the black shales is derived from archaea. Furthermore, it is shown that, even though there are apparent similarities (high OC content, distinct lamination, ^{13}C -enrichment of organic carbon) between the black shales of OAE1b and the Cenomanian/Turonian (C/T ~ 94 Myr) OAE, the origin of the organic matter (archaeal versus phytoplanktonic) and causes for ^{13}C -enrichment of OC are completely different.

7.1. Introduction

Extensive oceanic volcanism is thought to have led to 3 to 12 times higher atmospheric levels of carbon dioxide during the mid-Cretaceous (~125-88My) than at present [Arthur *et al.*, 1985a; Larson, 1991; Berner, 1992]. This could have caused the mid-Cretaceous ‘greenhouse’ climate with its warm temperatures and small equator-to-pole temperature gradient [Barron, 1983]. Oceanic anoxic events (OAEs), episodes of globally enhanced organic carbon (OC) burial rates, may have effectively reduced CO₂ concentrations of the mid-Cretaceous ‘greenhouse’ atmosphere by sequestering carbon in the subsurface.

Originally the term OAE was introduced to describe the episodic expansion and intensification of the Oxygen Minimum Zone (OMZ), which was proposed to explain the seemingly global distribution of laminated OC-rich (> 1%) sediments (black shales) in pelagic sequences of Aptian-Albian and Cenomanian/Turonian (C/T) age [Schlanger and Jenkyns, 1976]. Since then several other time-bounded envelopes of particularly, perhaps more globally, widespread black shale deposition in marine environments have been identified [Arthur *et al.*, 1987] and a total of five OAEs have been recognised for the mid-Cretaceous. In most cases the OAE black shales are devoid of or strongly impoverished in benthic faunas indicating that these sediments were deposited under oxygen-deficient bottom-water conditions [Summerhayes, 1987]. The most intensely studied OAEs occurred near the Barremian/Aptian (OAE1a) and C/T (C/T OAE or OAE2) transition. Both OAEs are accompanied by a significant increase in ¹³C/¹²C ratios for marine carbonates (up to 2.5‰) and organic matter (up to 6‰). These positive excursions in δ¹³C values reflect changes in the global atmospheric-oceanic pool of inorganic carbon resulting from a global increase in the burial rate of ¹³C-depleted OC [Arthur *et al.*, 1988]. Positive shifts in δ¹³C values of marine carbonate, albeit it significantly smaller, may also have been associated with other mid-Cretaceous OAEs [Erbacher and Thurow, 1997].

There are apparent similarities between OAE black shales such as enrichment in OC, lamination, absence of or impoverished benthic faunas, ¹³C-enrichment of inorganic and/or organic carbon. To investigate if this also implies that organic matter (OM) in various OAE black shales has a similar origin, we studied early Albian (~112 My) OAE1b black shales and compared the results with our earlier findings for the C/T OAE [Kuypers *et al.*, submitted]. So far, knowledge about the community of organisms contributing OM to these black shales is mainly restricted to visual identification of microfossils such as pollen or dinoflagellate cysts and ignores organisms that do not leave behind microscopically readily identifiable fossilised remains such as bacteria. In fact, the visually identifiable fraction generally makes up only a small part of the total OM present and most OM in these OC-rich sediments is amorphous. Lipids and pigments or their fossilised remains (biomarkers) and their stable carbon isotopic composition [e.g. Freeman *et al.*, 1990] can give important information on the sources of the extractable OM. In a similar way, the analyses of products released upon thermal and chemical degradation can reveal important insights into the sources of insoluble OM [e.g. Blokker *et al.*, 2000].

Here we use detailed molecular and compound-specific carbon isotope measurements, thermal (flash pyrolysis), and chemical degradation (RuO₄ oxidation) techniques to determine the sources of both soluble and insoluble OM of OAE1b black shales from the Ravel section of the Southeast

France Basin (SEFB) and Ocean Drilling Program (ODP) site 1049C (North Atlantic Ocean off the coast of Florida) (Fig.1) and show that the sources of OM for this OAE are fundamentally different from the C/T OAE.

Figure 1. Palaeogeographic reconstruction for the late Aptian (120 Myr ago) showing the position of the two studied sections. Modified after Erbacher et al. [2001].

7.2. Material and Methods

7.2.1 Geological setting. The upper Aptian-lower Albian at the SEFB consists of a monotonous sequence of dark, fine-grained, marly sediments. The laminated black shales of the Niveau Paquier (the local expression of the OAE1b) consist of a mixture of biogenic carbonate, clay minerals, silt-sized quarts and abundant OM [Tribovillard and Gorin, 1991].

The upper Aptian-lower Albian sequence of ODP site 1049C consists of marls and calcareous marls characterised by a low OC content interrupted by an OC-rich black shale interval [Shipboard Scientific Party, 1998]. This black shale interval (indicated as a grey shaded/black area in Fig. 2) has been identified as the local expression of OAE 1b [Erbacher et al., 1999; Erbacher et al., 2001].

7.2.2 Samples. The samples used in this study were taken from the Ravel section of the Southeast France Basin (SEFB) and Ocean Drilling Program (ODP) Hole 1049C off the coast of northern Florida (leg 171B). Two to three cm thick sediment slices were taken from core 12 section 3 recovered from 142.3-143.8 meters below seafloor at ODP Site 1049C. Sub-samples were taken from the slices and subsequently freeze-dried and powdered in an agate mortar. Five samples were analysed from the Ravel section of the SEFB [Vink et al., 1998].

7.2.3 Bulk Analyses. Total Organic Carbon (TOC) and Total Nitrogen (N_{tot}) contents were determined with a Carlo Erba CN analyser 1502 series. The $\delta^{15}\text{N}$ measurements were performed using an automated on-line combustion system (Carlo Erba CN analyser 1502 series) followed by conventional isotope ratio-mass spectrometry (Fisons optima; [Fry *et al.*, 1992]). The $\delta^{15}\text{N}$ values for bulk sediments are expressed relative to atmospheric N_2 , with a precision better than 0.2 ‰. To measure the $\delta^{13}\text{C}$ values ($\delta^{13}\text{C} = [({}^{13}\text{C}/{}^{12}\text{C})_{\text{sample}}/({}^{13}\text{C}/{}^{12}\text{C})_{\text{standard}}] - 1$) of OC, inorganic carbon was removed from the bulk sediments with 2 M HCl (12 h at 60°C). Subsequently, the sediments were rinsed three times with demineralised water to remove CaCl_2 and dried in a stove (12 h at 60°C). The $\delta^{13}\text{C}$ measurements were performed using an automated on-line combustion system (Carlo Erba CN analyser 1502 series) followed by conventional isotope ratio-mass spectrometry (Fisons optima). The $\delta^{13}\text{C}$ values for OC are expressed versus the VPDB standard, with a standard deviation for duplicate runs of $\pm 0.1\%$.

Small sub-samples were decalcified with 2 M HCl and subsequently sieved (10 μm mesh) for microscopic screening.

7.2.4 Extraction and fractionation of extractable organic matter. The powdered samples (10 to 20 g) of ODP Site 1049C were Soxhlet extracted with a dichloromethane (DCM)/methanol (7.5:1, v/v) mixture for 24 h to obtain the total lipid fraction. Total lipid fractions, to which a mixture of four standards was added for quantitative analyses [Kohnen *et al.*, 1990], were separated into apolar and polar fractions using a column (20 x 2 cm; column volume (V_0) = 35 ml) packed with alumina (activated for 2.5 h at 150 °C) eluted with hexane/DCM (9:1, v/v; 150 ml) and methanol/DCM (1:1, v/v; 150 ml), respectively. The apolar fractions were further separated by column chromatography on AgNO_3 -impregnated silica, with hexane as eluent (to remove unsaturated compounds) to obtain relatively simple fractions for isotope-ratio-monitoring gas chromatography-mass spectrometry (irm-GC-MS). Portions of the polar fractions were silylated using bis(trimethyl-silyl)trifluoroacetamide (BSTFA)/pyridine and analysed by gas chromatography (GC) and GC-mass spectrometry (GC-MS).

Aliquots of the polar fractions were treated with HI/ LiAlH_4 as described previously [Hoefs *et al.*, 1997]. Briefly, the fractions were refluxed in a solution of 56 wt% HI in water for 1 h and the released alkyl iodides were isolated using column chromatography (alumina as stationary phase, hexane/DCM (9:1, v/v) as eluent). Subsequently, the alkyl iodides were treated with LiAlH_4 in 1,4-dioxane for 1 h to convert them into hydrocarbons. The hydrocarbons were hydrogenated under a hydrogen-atmosphere for 1 h using PtO_2 as a catalyst to convert unsaturated compounds into saturated hydrocarbons. The released compounds were analysed by GC and GC-MS [see Hoefs *et al.*, 1997 for details].

Aliquots of the polar fractions spiked with a thiophene standard [2,3-dimethyl-5-(1,1- d_2 -hexadecyl)thiophene] were also desulfurised with Raney Nickel and subsequently hydrogenated as described by Sinninghe Damsté *et al.* [Sinninghe Damsté *et al.*, 1990]. The released hydrocarbons were isolated by column chromatography with alumina and analysed by GC and GC-MS. Subsequently, AgNO_3 column chromatography was used to obtain relatively simple fractions for irm-GC-MS.

7.2.5 Isolation of macromolecular material. The residues obtained after Soxhlet extraction of the sediments of the SEFB and ODP Site 1049C were decalcified by treatment with 2 M HCl (12 h at 60°C). Subsequently, the decalcified sediments were rinsed with demineralised water (3x) to remove CaCl₂ and ultrasonically re-extracted with methanol (3X) and DCM/hexane (1:1) to remove extractable OM. Macromolecular material was isolated from the decalcified and extracted sediments by density centrifugation (at 3700 r.p.m. for 5 min.) using pure DCM (floating fraction).

7.2.6 Ruthenium tetroxide treatment. This treatment was modified from a procedure reported previously [Blokker *et al.*, 1998]. Briefly, c. 5 mg of isolated macromolecular material of the SEFB or ODP Site 1049C was ultrasonically suspended in a mixture of 1 ml chloroform, 1 ml acetonitrile and 2 ml of an aqueous solution of NaIO₄ (0.2 M, pH 3-4). After addition of 6 mg Ru(III)Cl₃, the two phase system was allowed to react in an ultrasonic bath. After 4 h, 3 ml water and 2 ml hexane were added. The organic layer was removed and quenched with methanol (MeOH) (0.5 ml). The aqueous layer was extracted with 2 ml hexane (1x) and 2 ml dichloromethane (2x) and these organic layers were transferred to the first organic extract. The black Ru-salts were precipitated from the organic layer by centrifugation. The remaining supernatant was washed with 0.5 ml Na₂S₂O₃ solution (5% in H₂O). The extract was dried over Na₂SO₄, evaporated to dryness under a nitrogen flow and derivatised with BF₃/methanol prior to analysis.

7.2.7 Gas chromatography. GC was performed using a Hewlett-Packard 5890 instrument, equipped with an on-column injector. A fused silica capillary column (25 m x 0.32 mm) coated with CP-Sil 5 (film thickness 0.12 µm) was used with helium as carrier gas. Both a flame ionization detector (FID) and a sulfur-selective flame photometric detector (FPD) were used, applying a stream-splitter with a split ratio of FID:FPD = c. 1:2. The samples were dissolved in ethyl acetate and injected at 70 °C. Subsequently, the oven was programmed to 130 °C at 20 °C/min and then at 4 °C/min to 320 °C at which it was maintained for 20 min.

7.2.8 Curie-point pyrolysis gas chromatography. Pyrolysis (Py)-GC was conducted on a Hewlett Packard 5890 series II gas chromatograph fitted with a 25 m x 0.32 mm CP-Sil 5 (film thickness 0.45 µm) fused silica capillary column and equipped with a FID. Samples of ODP Site 1049C were pressed on flattened ferromagnetic wires with a Curie temperature of 610°C. The wire was inserted into a glass liner, subsequently introduced into a FOM-4LX pyrolysis unit and inductively heated for 10 s. The desorbed fragments were flushed into the capillary column using helium as the carrier gas. The gas chromatograph was equipped with a cryogenic unit and programmed from 0°C (5 min) to 320°C (hold time 10 min) at 3°C/min. Helium was used as a carrier gas and the temperature of the flame ionisation detector (FID) was 320°C.

7.2.9 Gas chromatography-mass spectrometry. GC-MS was performed using a Hewlett-Packard 5890 gas chromatograph interfaced to a VG Autospec Ultima Q mass spectrometer operated at 70 eV with a mass range m/z 50-800 and a cycle time of 1.8 s (resolution 1000). The column

conditions and temperature program were the same as described above for GC and Py-GC analyses, respectively.

7.2.10 Isotope-ratio-monitoring gas chromatography-mass spectrometry. Compound-specific $\delta^{13}\text{C}$ analyses were performed for the samples of ODP Site 1049C using an isotope-ratio-monitoring GC-MS (irmGC-MS) system that is in principal similar to the DELTA-S system described by *Hayes et al.* [1990]. A Hewlett-Packard 5890 gas chromatograph was used. The column conditions and temperature program were the same as described above for GC analyses. The $\delta^{13}\text{C}$ values for individual compounds are reported in the standard delta notation against VPDB standard and are the means of duplicate runs with a precision of ± 0.3 to 0.6% .

7.2.11 High performance liquid chromatography/atmospheric pressure positive ion chemical ionization mass spectrometry. Intact isoprenoid glycerol dialkyl glycerol tetraethers (GDGTs) in the polar fractions of ODP site 1049C were determined according to Hopmans *et al.* [2000]. Briefly, aliquots of the polar fractions were redissolved in hexane:propanol (99:1) and filtered through $0.45\ \mu\text{m}$ PTFE filters. Analyses were performed using an HP (Palo-Alto, CA, USA) 1100 series LC-MS equipped with an auto-injector and Chemstation chromatography manager software. Separation was achieved on an Econosphere NH_2 column ($4.6 \times 250\ \text{mm}$, $5\ \mu\text{m}$; Alltech, Deerfield, IL, USA), maintained at 30°C . GDGTs were eluted with 99% A and 1% B for 5 min, followed by a linear gradient to 1.8% B in 45 min, where A = hexane and B = propanol at a flow rate of 1 ml/min. Detection was achieved using atmospheric pressure positive ion chemical ionization mass spectrometry (APCI-MS) of the eluent. Positive ion spectra were generated by scanning m/z 950-1450 in 1.9 s. GDGTs were quantified by comparing their combined $[\text{M}+\text{H}]^+$ and $[\text{M}+\text{H}]^++1$ ion intensities to the combined $[\text{M}+\text{H}]^+$ and $[\text{M}+\text{H}]^++1$ ion intensity of known amounts of caldarcheol, isolated from Arabian Sea sediments according to Sinninghe Damsté *et al.* [2000].

7.2.12 Fourier transform infrared spectroscopy. Fourier transform infrared spectroscopy was performed for the isolated macromolecular material of ODP Site 1049C on a Bruker IFS28 instrument scanning over a frequency range of $400\ \text{cm}^{-1}$ to $4000\ \text{cm}^{-1}$ using KBr pellets containing 2 mg of dry macromolecular material.

7.3. Results and discussion

7.3.1 Abundance and stable carbon isotopic composition of organic carbon

While the upper Aptian-lower Albian marls and calcareous marls of ODP site 1049C are characterised by a low ($< 0.1\ \text{wt}\%$) TOC content, the black shale interval contains up to $6\ \text{wt}\%$ TOC (Fig. 2a). The sixty-fold increase in TOC content is accompanied by a sharp increase in the $^{13}\text{C}/^{12}\text{C}$ ratio for bulk OC of approximately $4\text{-}5\%$ during OAE1b (Fig. 2b). The uppermost sample of the black shale is characterised by the most ^{13}C -enriched OC. Similar increases in $\delta^{13}\text{C}$ values have

been observed for marine carbonates and organic matter from other mid Cretaceous OAEs and have been attributed to globally enhanced carbon burial rates [Arthur *et al.*, 1988]. The isotope effect associated with carbon fixation (ϵ_p) by primary producers causes OC to be enriched in ^{12}C relative to the inorganic carbon source. Therefore, burial of large quantities of OC into black shales could lead to an increase in the ^{13}C content of the remaining oceanic-atmospheric pool of inorganic carbon. However, results obtained from selected specimens of planktic and benthic foraminifers [Erbacher *et al.*, 1999; Erbacher *et al.*, 2001] indicate that there was no significant increase in $\delta^{13}\text{C}$ values for inorganic carbon during the OAE1b at ODP site 1049C. Hence the increase in $\delta^{13}\text{C}$ values for bulk OC cannot be attributed to globally enhanced OC burial rates.

In order to resolve the origin of the increase in $\delta^{13}\text{C}$ values for bulk OC ($\delta^{13}\text{C}_{\text{org}}$), both the extractable and insoluble OM was investigated in detail.

Figure 2. Stratigraphy and bulk sediment data of ODP Site 1049C. TOC content (a), carbon isotope values (in ‰ vs. VPDB) of bulk OC (b), nitrogen isotope values (in ‰ vs. atmospheric N_2) of bulk sediment (c), and atomic $\text{C}_{\text{org}}/\text{N}_{\text{total}}$ ratios (d) of late Aptian/early Albian abyssal sediments from ODP Site 1049C. In all graphs the centre of the bullet corresponds to the top of the ~2 cm thick sediment samples. The OAE1b black shale interval has been indicated as a grey shaded area in the graphs.

7.3.2 Extractable OM

7.3.2.1 Composition of the extractable OM. Only small amounts of total extracts were recovered from the OM-lean sediments outside the black shale interval (below quantification limit), while higher amounts (1.0 to 2.0 mg/g dry sediment) were recovered from the black shales. The extractable OM was separated into apolar and polar fractions. There is approximately 50 times more

polar than apolar material within the black shale interval, which probably indicates a low thermal maturity of the OM. The apolar hydrocarbon fractions within the black shale interval consist mainly of short-chain *n*-alkanes (C₁₆-C₂₂) with no odd-over-even predominance, long-chain (C₂₅-C₃₁) *n*-alkanes with a moderate odd-over-even carbon number predominance (CPI = 2), hopanoids, and acyclic isoprenoids (Fig. 3a). The polar fraction from the black shale interval typically contains sterols, a compound that has tentatively been identified as the ketone of 2,6,15,19-tetramethylcosane (TMI; **I**, see Appendix), biphytane diols [Schouten *et al.*, 1998], and diphytanylglycerol diether (archaeol; **III**, see Appendix) [Koga *et al.*, 1993] and is strongly dominated by an unresolved hump. In addition, HPLC/MS revealed abundant intact isoprenoid glycerol dialkyl glycerol tetraethers (GDGTs) in the polar fraction. Since GDGTs are not GC amenable and relatively simple fractions are needed for irm-GC-MS, the polar fractions were treated with HI/LiAlH₄ and subsequently hydrogenated to convert the sterols, archaeol and biphytane diols/GDGTs into steranes, phytane and biphytanes, respectively. HI/LiAlH₄ treatment of the polar fractions from the black shale released fractions containing *n*-alkanes with an even-over-odd carbon number predominance, phytane, cholestane, 24-methylcholestane and 24-ethylcholestane, but which are dominated by acyclic (**a**), monocyclic (**b**), bicyclic (**c**) and tricyclic (**d**) biphytanes (C₄₀ isoprenoids) (Fig. 3b). HI/LiAlH₄ treatment of the polar fractions of the marls mainly released *n*-alkanes with an even-over-odd carbon number predominance of unknown origin, phytane, cholestane and 24-ethylcholestane, while biphytanes are absent.

Since functionalised lipids and carotenoids may become sulfurised during early diagenesis in anoxic, sulfide-rich sediments [Kok *et al.*, 2000], three polar fractions from the black shale interval were also desulfurised. The apolar fractions (Fig. 3c) obtained after desulfurisation of the polar fractions are mainly dominated by phytane and two isomers of a C₂₀ monocyclic isoprenoid (**V**, Appendix).

In the following sub-paragraphs the relative abundances and stable carbon isotopic compositions of the various classes of biomarkers encountered in the sediments from site 1049C are discussed.

7.3.2.2 *n*-Alkanes. The apolar fractions from the OAE1b black shales contain short-chain *n*-alkanes (C₁₆-C₂₂) with no odd-over-even carbon number predominance and long-chain (C₂₅-C₃₃) *n*-alkanes with a moderate odd-over-even carbon number predominance (Fig. 3a). The odd-over-even predominance (CPI ~ 2) of the *n*-C₂₅ to *n*-C₃₃ suggests that leaf waxes of terrestrial plants are a significant source [Eglinton and Hamilton, 1967]. A major mode of transport of leaf wax *n*-alkanes is *via* wind, as indicated by the high relative amounts of leaf wax components in aeolian dust collected at remote ocean sites [Gagosian *et al.*, 1981]; consequently, they are common constituents of extractable OM of recent and ancient abyssal plane sediments [Farrington and Tripp, 1977]. Taking into account the prevailing wind direction [Poulsen, 1999], the most likely candidate for the origin of these aeolian transported terrestrial *n*-alkanes is the nearby North American continent (Fig. 1).

The concentration of leaf-wax *n*-alkanes (normalised to TOC) is enhanced in the faintly laminated dark shale interval and in the less OM-rich black shales (up to ~20 µg/gTOC, Fig. 4b) compared to the underlying marls (5 to 10 µg/gTOC). Concentrations decrease again to well below

Figure 3. Typical gas chromatograms of apolar fraction (a), and hydrocarbon fractions released after HI-LiAlH₄ treatment (b), and desulfurisation (c), of the polar fraction from sediment extracts of the OAE1b black shales of ODP Site 1049C. Filled circles, open squares and filled triangles indicate *n*-alkanes, hopanes and saturated acyclic isoprenoids, respectively. Abbreviations are: is, internal standard; 23, *n*-C₂₃; 29, *n*-C₂₉; C, contaminant; α, 5α isomers of steranes; β, 5β isomers of steranes; ?, compound of unknown structure. Other letters and roman numbers refer to structures shown in the Appendix.

10 μg/gTOC in the overlying more OM-rich black shales. These trends can not be attributed to changes in redox state of the bottom-waters because *n*-alkanes and bulk marine OM have a similar preservation potential under oxic conditions [Sinninghe Damsté et al., 1997a; Hoefs et al., in prep]. The increase in *n*-alkane concentrations could point to a relatively enhanced terrestrial contribution

to the sediment during the onset of black shale deposition, while the decrease can probably fully be attributed to dilution by marine OM.

Figure 4. Stratigraphy, bulk and biomarker data of ODP Site 1049C. TOC content (a), and concentrations ($\mu\text{g/gTOC}$) of *n*-alkanes (*n*- C_{27} and C_{31}) mainly derived from leaf-waxes (b), hopanoids (i.e. C_{27} and C_{29} hopanoids) mainly derived from bacteria (c), GDGTs **XI**, **XIII** and **XIV** derived from archaea (d), and TMI derived from archaea (e) of late Aptian/early Albian abyssal sediments from ODP Site 1049C. In all graphs the centre of the bullet corresponds to the top of the ~2 cm thick sediment samples. Roman numbers refer to structures shown in the Appendix. The OAE1b black shale interval has been indicated as a grey shaded area in the graphs. Lithology as in Fig.2.

The $\delta^{13}\text{C}$ values of the *n*- C_{27} and *n*- C_{31} range from -28 to -29‰ (Fig. 5b), which is slightly more enriched than the -30 to -37‰ typically observed for extant plants using a C_3 metabolism [Collister *et al.*, 1994; Lockheart *et al.*, 1997]. Since this small offset can fully be attributed to a ^{13}C -enrichment of the inorganic carbon (e.g. CO_2) pool (2-3‰) during the mid-Cretaceous [Arthur *et al.*, 1985b], it seems likely that the *n*-alkanes derive predominantly from a C_3 -type vegetation. This fits well with models that predict C_3 domination, even of low-latitude terrestrial vegetation, as a result of the high p_{CO_2} levels during the mid-Cretaceous [Cerling *et al.*, 1997].

7.3.2.3 Steroids. Treatment of the polar fractions of extracts from the black shale interval with HI/LiAlH_4 to cleave ether bonds and subsequent hydrogenation released significant amounts of steranes (Fig. 3b). Remarkably, some of the samples from the OAE1b black shales contain significantly more 5β than the more commonly occurring 5α isomers of cholestane (**VI**), 24-methylcholestane (**VII**) and 24-ethylcholestane (**VIII**) (Fig. 3b). The polar fractions from the black shale interval are strongly dominated by an unresolved hump, but also contain abundant intact sterols; mainly cholesterol, 24-methylcholesterol and 24-ethylcholesterol. Since HI/LiAlH_4 treatment also defunctionalises alcohols, the 5α and 5β steranes are expected to derive predominantly from cholesterol, 24-methylcholesterol and 24-ethylcholesterol, which are predominately biosynthesized by marine algae [Volkman, 1986]. 24-Ethylcholestane (**VIII**) may,

however, also have a terrestrial contribution [Volkman, 1986]. Cholesterol and other C₂₇ sterols are also indirectly formed by dealkylation of ingested C₂₈ and C₂₉ sterols [Goad, 1981] by zooplankton heterotrophically living on algal biomass. The stable carbon isotopic fractionation resulting from such heterotrophy has been shown to be negligible for steroids [Grice *et al.*, 1998] and hence δ¹³C values of cholestane released after HI/LiAlH₄ should reflect the average stable carbon isotopic composition of algal sterols. Similarly, 24-methylcholestane (δ¹³C = -27 to -29‰) and, to a lesser extent, 24-ethylcholestane (Fig. 5c) record changes in the carbon isotopic composition of algae.

Figure 5. Stratigraphy, bulk and biomarker data of ODP Site 1049C. Carbon isotope values (in ‰ vs. VPDB) of bulk OC (a), *n*-alkanes (*n*-C₂₇ and C₃₁) mainly derived from leaf-waxes (b), oxygen-bound steranes [C₂₇ steroid (cholestane) and C₂₉ steroid (24-ethyl-cholestane)] mainly derived from marine algae (c), hopanoids (i.e. C₂₇ and C₂₉ hopanoids) mainly derived from bacteria (d), bi- (C_{40:2cy}) and tricyclic (C_{40:3cy}) biphytanes, PMI and TMI derived from archaea (e), and oxygen-bound phytane (Ph) derived either from the isotopically ‘light’ (¹²C-rich) phytol side-chain (XVI) of algal and cyanobacterial chlorophyll or the isotopically ‘heavy’ (¹³C-rich) archaeal membrane lipids (III) (f) of late Aptian/early Albian abyssal sediments from ODP Site 1049C. In all graphs the centre of the bullet corresponds to the top of the ~2 cm thick sediment samples. The OAE1b black shale interval has been indicated as a grey shaded area in the graphs. Dotted lines in graph (b) indicate estimated contributions (in %) of archaeal derived insoluble OM to TOC as discussed in text. Lithology as in Fig.2.

The δ¹³C values of both C₂₇ and C₂₉ steranes show significant fluctuations throughout the investigated interval, but there is no clear trend across the black shale interval (Fig. 5c). Since δ¹³C values of picked planktonic foraminifers indicate that there is no significant shift in isotopic composition of inorganic carbon [Erbacher *et al.*, 2001], the observed fluctuations for steranes may result from changes in atmospheric CO₂ concentrations and/or algal growth rates/cell sizes [e.g. Rau *et al.*, 1989; Laws *et al.*, 1995; Pancost *et al.*, 1997; Popp *et al.*, 1998; Burkhardt *et al.*, 1999; Bidigare *et al.*, 1999].

7.3.2.4 Hopanes. Considerable amounts of C₂₇-C₃₁ hopanes (up to ~30 µg/gTOC for the sum of the stereoisomers of the C₂₉-hopane) were detected in the apolar fractions of samples from the OAE1b black shale interval (Figs. 3a, 4c). Hopanoids were also detected outside the black and dark shale interval, albeit in significantly lower concentrations (below 5 µg/gTOC, Fig. 4c). Sedimentary hopanes are likely diagenetic products of hopanols such as bacteriohopanopolyol derivatives (C₃₅) or diplopterol (hopanes < C₃₀) and may derive from numerous bacterial taxa such as cyanobacteria, heterotrophic bacteria and methanotrophic bacteria [Rohmer *et al.*, 1992]. The lower hopane concentrations in the marls could have partly resulted from selective oxic degradation of the hopanol precursors relative to bulk OM. Rates of oxic degradation exceeding those for bulk OM (up to 5 times as fast) have been reported for another triterpenoid [i.e. tetrahymanol, *Sinninghe Damsté et al.*, 1997a; Hoefs *et al.*, in prep]. Part of the observed increase in the black shale could, however, also have resulted from an increase in bacterial production.

Hopanes containing a methyl group at the C2 position are considered reliable biomarkers for cyanobacteria because 2-methylbacteriohopanepolyols occur in a high proportion of cultured cyanobacteria and environments dominated by cyanobacteria [Summons *et al.*, 1999]. No detectable amounts of 2-methyl hopanes were found in the black shale sediments of ODP site 1049C. In fact, only trace amounts of hopanes >C₃₁ are present and are restricted to the desulfurised polar fractions. However, a cyanobacterial source for the hopanes from ODP site 1049C cannot be fully excluded because not all cyanobacteria produce 2-methylbacteriohopanepolyols. The strong predominance of the 17β,21β(H)-isomers indicates a low thermal maturity [(ββ)/(αβ+βα+ββ)] C₃₁ hopane ratio = 0.6] of the organic matter [Seifert and Moldowan, 1986] for these sediments.

The stable carbon isotopic composition (δ¹³C = -24 to -27‰) of the hopanes (Fig. 5d) extracted from the OAE1b black shales excludes an important contribution of methanotrophic bacteria. δ¹³C values for these biomarkers should be significantly more negative if methanotrophs were substantial sources because their lipids are strongly ¹³C-depleted (up to -120‰) as a result of both the generally strong depletion in ¹³C of methane and large degree of isotope fractionation associated with the assimilation of methane [Summons *et al.*, 1994; Pancost *et al.*, 2000; Freeman *et al.*, 1990; Spooner *et al.*, 1994].

7.3.2.5 Isorenieratene derivatives. Previous studies have shown that while bottom-waters were well oxygenated before and after OAE 1b, anoxic conditions prevailed at this bathyal sites during the deposition of the black shales [Erbacher *et al.*, 1999]. To investigate whether this anoxia extended into the photic zone, the samples from the black shale interval of hole 1049C were checked for specific pigments (isorenieratene and its derivatives) of the brown coloured strain of green sulfur bacteria (Chlorobiaceae). These photosynthetic bacteria require both light and H₂S for carbon fixation and are, therefore, indicators for photic zone anoxia. At the present day the habitat for green sulfur bacteria is restricted to a few euxinic basins such as the Black Sea [Repeta *et al.*, 1989; Sinninghe Damsté *et al.*, 1993; van Gemerden and Mas, 1995]. Sinninghe Damsté and Köster [1998] showed that during the mid Cretaceous C/T OAE these organisms were also present in the proto North Atlantic Ocean. However, no isorenieratene derivatives were found in the black shales

from site 1049C, indicating that, in contrast to the C/T OAE, the specific conditions of overlapping photic and anoxic zone were not present during the lower Albian OAE1b.

7.3.2.6 Isoprenoid glycerol dialkyl glycerol tetraethers. A recently developed technique using HPLC/APCI-MS [Hopmans *et al.*, 2000] revealed abundant intact isoprenoid glycerol dialkyl glycerol tetraethers (GDGTs) in the polar fraction. GDGTs are the main constituents of archaeal membranes [Koga *et al.*, 1993; De Rosa and Gambacorta, 1988]. Four different GDGTs (**XI-XIV**) were identified in the extracts from the black shale interval (Fig. 6a).

Figure 6. Base peak mass chromatograms of sediment extracts of the OAE1b black shales of ODP Site 1049C (a), and the Arabian Sea (Holocene) [from Sinninghe Damsté *et al.*, in prep.] (b). Asterisks indicate isomers of GDGT **XIV**. Roman numbers refer to structures shown in the Appendix.

These GDGTs have recently also been identified in a wide variety of marine sediment extracts (Schouten *et al.*, 2000) (e.g. Fig. 6b). GDGTs **XI**, **XIII** and **XIV** are the most abundant biomarkers in the extractable OM of the black shale interval, with concentrations of **XIV** of up to 300 $\mu\text{g/gTOC}$ (Fig. 4d). In sharp contrast, both above and below the black shale interval only small amounts of **XI** were detected, while **XII-XIV** are absent. The absence of these GDGTs in the marls can not be attributed to preferential loss of the GDGTs under oxic conditions, because GDGTs have a similar oxic degradation rate as other marine biomarkers such as sterols [Sinninghe Damsté *et al.*, in prep.]. Therefore, the increase in GDGT concentrations indicates a sharp increase in archaeal production. GDGTs **XII-XIII** are characteristic of the archaeal lineage Crenarchaeota containing hyperthermophilic archaea [De Rosa and Gambacorta, 1988; Stetter, 1998], which thrive at temperatures $>60^\circ\text{C}$. In contrast, **XIV** appears to be highly diagnostic for their non-thermophilic relatives [Hoefs *et al.*, 1997; DeLong *et al.*, 1998], and the dominance of this compound (representing 60% of total GDGTs) indicates an important input of non-thermophilic planktonic

archaea [Schouten *et al.*, 2000; Hoefs *et al.*, 1997]. To the best of our knowledge this is the earliest fossil evidence for marine planktonic archaea, extending their geological record by more than 60 million years [Hoefs *et al.*, 1997].

Treatment of the polar fractions of the extracts of the black shales with HI/LiAlH_4 to cleave ether bonds released fractions dominated by acyclic (**a**), monocyclic (**b**), bicyclic (**c**) and tricyclic (**d**) biphytanes (C_{40} isoprenoids) (Fig. 3b). The GDGTs are the source for these biphytanes released upon ether-bond cleavage. In addition, the released biphytanes may partly originate from biphytane diols, which are also present in the polar fraction. Although the biphytane diols have not yet been identified in organisms, their structural similarities with ether-bound biphytanes and their co-occurrence in sediments led Schouten and co-workers [Schouten *et al.*, 1998] to suggest that they are also biosynthesised by planktonic archaea.

The $\delta^{13}\text{C}$ values of the archaeal biphytanes **a-d** (Fig. 5e) are significantly enriched in ^{13}C relative to algal steroids **VI-VIII** (Fig. 5c), bacterial derived hopanes **IX-X** (Fig. 5d) and the leaf-wax *n*-alkanes *n*- C_{29} and *n*- C_{31} from higher plants (Fig. 5b). This ^{13}C enrichment indicates a ‘heavy’ (^{13}C -rich) carbon source (e.g. bicarbonate) for the archaea and/or the utilisation of a pathway of carbon-fixation with a reduced ^{13}C fractionation compared to the Calvin cycle that is used by algae, cyanobacteria and higher plants. The large differences (up to 12 ‰) in $^{13}\text{C}/^{12}\text{C}$ ratio between the algal steranes and the archaeal biphytanes suggest that the marine planktonic archaea were not living heterotrophically on photoautotrophic biomass, although it has been shown that some extant marine crenarchaeotes can take up amino acids [Ouverney and Fuhrman, 2000]. While photoautotrophy within the domain of the Archaea is restricted to only a few species from hypersaline environments, chemoautotrophy is common. Hence it seems likely that the marine archaea present during OAE1b used a chemical energy source for carbon fixation.

Compound-specific radiocarbon analyses of archaeal biphytanes **c** and **d** and algal sterols isolated from marine sediments from the Santa Monica and Santa Barbara Basins deposited before (pre-bomb) and after (post-bomb) the introduction of large quantities of ‘nuclear bomb’ $^{14}\text{CO}_2$ into the atmosphere also indicates a chemoautotroph ecology for marine planktonic archaea [Pearson, 2000]. Pearson showed that, in sharp contrast to the sterols, the biphytanes do not show a large increase in ^{14}C content during the transition from the pre-bomb to post-bomb sediments. This indicates that marine planktonic archaea are not living on phytoplanktonic biomass but rather are autotrophs using ‘old’ ^{14}C depleted dissolved inorganic carbon from below the photic zone [Pearson, 2000].

Like the mid-Cretaceous biphytanes, lipids of marine planktonic archaea isolated from recent sediments and suspended particles show a significant ^{13}C enrichment relative to algal steroids [Hoefs *et al.*, 1997], albeit smaller (4-5‰) than for the OAE1b sediments (8-11‰). This enrichment indicates that these non-thermophilic archaea, like related hyperthermophiles, may use a non-Calvin cycle pathway of carbon assimilation such as the 3-hydroxypropionate (3-HP) pathway [Menendez *et al.*, 1999] or the reverse TCA cycle [Fuchs *et al.*, 1992]. The degree of carbon-isotope fractionation during carbon assimilation is much smaller for these pathways than for the Calvin cycle such that prokaryotes using these pathways are expected to be depleted in ^{13}C by only 8-14‰ relative to dissolved CO_2 [Holo and Sirevåg, 1986]. Recently, an even smaller ^{13}C -depletion (~3‰) of bulk cell material relative to the inorganic carbon source (bicarbonate) was observed for the

hyperthermophilic crenarchaeon *Metallosphaera sedula*, which uses a 3-HP-like pathway [van der Meer *et al.*, 2001]. The acyclic, mono-, di- and tri-cyclic biphytanes released upon ether bond cleavage from the total lipid fraction of this crenarchaeon were ~2‰ enriched in ^{13}C relative to the bulk cell material. Biphytanes of marine pelagic archaea could be similarly ^{13}C -enriched relative to bulk cell material, if these non-thermophilic archaea also use a 3-HP-like pathway. During the mid-Cretaceous dissolved inorganic carbon (e.g. CO_2) was enriched in ^{13}C by 2-3‰ relative to modern values [Hayes *et al.*, 1999], which could explain the offset between $\delta^{13}\text{C}$ values for the biphytane **d** in Holocene (-20 to -23‰) [Hoefs *et al.*, 1997] and OAE1b (-17 to -18‰) sediments. Enhanced carbon isotope fractionation by algae during the mid-Cretaceous due to enhanced CO_2 availability [Arthur *et al.*, 1985b] may account for the remainder of the larger (3-7‰) enrichment of biphytane **d** relative to algal steroids. This suggests that mid-Cretaceous marine planktonic archaea occupied a similar niche in the marine environment as their present-day representatives.

Compound-specific radiocarbon analyses of recently deposited lipids derived from marine planktonic archaea indicate that these organisms thrive near the maximum concentration of nitrite, which is the initial product formed upon ammonium oxidation (nitrification), suggesting that these chemoautotrophs are nitrifiers [Pearson, 2000]. This is supported by the positive correlation between crenarchaeal rRNA abundance and nitrite observed for marine pelagic sites [Murray *et al.*, 1999]. Ammonium-oxidising planktonic archaea are expected to be strongly depleted in ^{15}N because autotrophic organisms growing at high concentrations of ammonium exhibit large (up to 20‰) isotopic effects during nitrogen fixation [Pennock *et al.*, 1996]. Hence the extreme ^{15}N depletion ($\delta^{15}\text{N}_{\text{average}} = -2.7\text{‰}$ and $\delta^{15}\text{N}_{\text{minimum}} = -4.9\text{‰}$) of the OM of the black shale interval of ODP site 1049C (Fig. 2c) is in good agreement with an important input of biomass of nitrifying planktonic marine archaea during OAE1b.

7.3.2.7 Other acyclic and cyclic isoprenoids. The most abundant compound in the apolar fraction isolated from the black shales (Figs. 3a) is the irregular acyclic isoprenoid, TMI (**I**); in contrast this compound is absent in the overlying and underlying units (Fig. 4e). Since there is no reason to assume that TMI or its functionalised derivatives are significantly more labile than other marine biomarkers, it seems unlikely that the absence in the marls resulted from the preferential loss of TMI. Therefore, the increase in TMI points to a sharp increase in abundance of the organism(s) producing this biomarker during black shale deposition. So far, TMI has only been found in the contemporaneous [Erbacher *et al.*, 1999] OAE1b black shales of the Southeast France Basin (SEFB) [Vink *et al.*, 1998]. TMI (**I**) is structurally similar to 2,6,10,15,19-pentamethylcosane (PMI) (**II**), a compound of known archaeal origin [Brassell *et al.*, 1981; Schouten *et al.*, 1998], which is also present in the saturated hydrocarbon fraction, albeit in relatively low amounts. PMI was also released from the polar fraction after Raney-Nickel desulfurisation; the most likely precursors for these sulfur bound (S-bound) compounds are unsaturated archaeal PMIs [Schouten *et al.*, 1998]. Sulfurisation of compounds containing functional groups such as the double bonds present in unsaturated PMI occurs during early diagenesis in sulfide-containing anoxic surface sediments [Kok *et al.*, 2000; Werne *et al.*, 2000].

In some of the apolar fractions from the OAE1b black shales, squalane (**IV**) is present in considerable amounts (Fig. 3a). In addition to TMI (**I**) and squalane (**IV**), other isoprenoids of unknown origin but structurally related to the archaeal lipids are abundant. Amongst them are two isomers (C₂₀) of a tentatively identified cyclic isoprenoid (**V**), which were released from the polar fraction after Raney-Nickel desulfurisation (Fig. 3c). So far, this C₂₀ cyclic isoprenoid skeleton has also only been found in the OAE1b black shales from the SEFB [Vink *et al.*, 1998].

The carbon isotopic values of the isoprenoids **I** ($\delta^{13}\text{C} = -16$ to -17‰ , Fig. 5e), **IV** ($\delta^{13}\text{C} = -18$ to -23‰) and **V** ($\delta^{13}\text{C} = -15$ to -16‰) is similar to compounds of unambiguous archaeal origin such as **II** ($\delta^{13}\text{C} = -16$ to -21‰ , Fig. 5e), and **a-d** ($\delta^{13}\text{C} = -17$ to -20‰ , Fig. 5e). The offset of $>10\text{‰}$ between $\delta^{13}\text{C}$ profiles for TMI/PMI and the algal biomarkers (Figs. 5c, e) is in agreement with observations for the SEFB [Vink *et al.*, 1998]. The close structural similarity of TMI and PMI and their extreme ¹³C-enrichment indicates an archaeal origin for TMI [Vink *et al.*, 1998]. For similar reasons an archaeal source is suggested for **IV** and **V** as well.

Pristane and phytane are only minor constituents of the apolar fractions. Phytane (Ph, **XV**) released from the polar fractions upon HI/LiAlH₄ treatment (Fig. 3b) derives either from the phytol side-chain (**XVI**) of algal and cyanobacterial chlorophyll or archaeal membrane lipids such as archaeol (**III**). Archaeol, but not phytol, was found in the polar fraction of the black shales, indicating a predominantly archaeal source for the released Ph from the OAE1b sediments. This is also indicated by a similar ¹³C-enrichment relative to algal steroids for Ph (up to 12‰) and archaeal derived compounds such as PMI and biphytanes **a-d** (Figs. 5c, e, f). Before and after the black shale interval $\delta^{13}\text{C}$ values for Ph are similar to those of the steranes, consistent with an algal origin for Ph. Hence it seems likely that the $\sim 12\text{‰}$ positive shift in $\delta^{13}\text{C}$ values for Ph (Fig. 5f) resulted from an increase in the contribution of isotopically ‘heavy’ (¹³C-rich) archaeal derived Ph relative to the isotopically ‘light’ (¹²C-rich) algal or cyanobacterial Ph. The fact that there is no coinciding positive shift in $\delta^{13}\text{C}$ values for the algal steranes (Fig. 5c) supports this.

The Ph that dominates the apolar fractions obtained after desulfurisation of the polar fractions of the black shale interval (Fig. 3c) shows a similar ¹³C-enrichment also indicating an archaeal source.

7.3.3 Insoluble OM

7.3.3.1 Causes for the positive shift in $\delta^{13}\text{C}$ values for bulk OC. The positive shift in stable carbon isotope values for bulk OC (Fig. 5a) could have resulted from a decrease in atmospheric CO₂ concentrations as ϵ_p values for marine phytoplankton show a pronounced dependence on CO₂ concentration [Rau *et al.*, 1989]. In addition, ϵ_p for marine phytoplankton shows a strong negative correlation with both growth rate and cell size [Laws *et al.*, 1995; Pancost *et al.*, 1997; Popp *et al.*, 1998; Burkhardt *et al.*, 1999; Bidigare *et al.*, 1999] and hence increases in growth rate and/or cell size could also have caused the observed positive shift for bulk OM. However, there is no coinciding positive shift for biomarkers that record changes in the carbon isotopic composition of algae such as cholestane and to a lesser extent 24-ethyl-cholestane (Fig. 5c).

Alternatively and in our view more likely, the shift in $\delta^{13}\text{C}$ values for bulk OC could result from a change in the composition of the OM. Similarly as for Ph released from the polar fraction upon

HI/LiAlH₄ treatment, an increase in the relative contribution of ¹³C enriched archaeal biomass to the OM deposited during OAE1b could also explain the shift in δ¹³C values for bulk OC (Fig. 5a).

7.3.3.2 Nature of the OM from OAE1b. The atomic C_{org}/N_{total} ratios show a close correlation (R² = 0.97) with the δ¹³C values for bulk OC. Before and after the OAE1b interval C_{org}/N_{total} ratios are between 3 and 16, while the black shale sediments show significantly higher values of 26 to 69 with the maximum value for the uppermost black shale sample (fig. 2d). C/N ratios are commonly used to differentiate between terrestrial and marine OM [e.g. *Prahl et al.*, 1980; *Meyers*, 1994]. The atomic C_{org}/N_{total} ratios (Fig. 2d) in the OAE1b interval are significantly higher than C/N Redfield ratios for modern marine plankton (6.6). Since, inorganic nitrogen, in addition to organic-bound nitrogen, contributes to the N_{total}, the real C/N ratios for the sedimentary OM (C_{org}/N_{org}) should be even higher. The values are closer to the ratios observed for modern terrestrial [>20, *Meyers*, 1994] than to modern marine organic matter. C/N ratios exceeding Redfield ratios are common for sedimentary OM (C_{org}/N_{org}) and have been attributed to the preferential remineralisation of the more labile nitrogen-rich organic compounds such as proteins, during passage through the water column, and during the early stages of OM burial [*Aller*, 1994]. Alternatively the enhanced contribution of nitrogen-poor, ¹³C-enriched archaeal-derived OM could explain the observed increase in both C_{org}/N_{total} and δ¹³C values for bulk OC during the OAE1b.

While woody debris sporadically occur in the Cretaceous sediments near the black shales, high Rock Eval hydrogen indices (HI) and the extremely low abundance or even absence of vascular plant remains indicate a predominantly marine origin for the OC within the OAE interval [*Shipboard Scientific Party*, 1998]. This is supported by the low abundance of molecular fossils of unambiguous terrestrial origin (e.g. leaf-wax lipids and oleananes) in the extractable OM (Fig. 3a-c).

Products, released upon thermal degradation (flash pyrolysis) can reveal important insights into the sources of insoluble OM [e.g. *Blokker et al.*, 2000]. Pyrolysis of the decalcified black shale sediments predominantly released *n*-alkenes/*n*-alkanes, alkylbenzenes and C₇-C₁₅ isoprenoidal alkenes/alkanes. The extremely low abundance of lignin thermal degradation (pyrolysis) products generated from the kerogen (Fig. 7a) supports a marine origin for the OM. Remarkably, the C₈-C₁₅ isoprenoidal alkenes/alkanes are by far the most abundant compounds released (Fig. 7a). These isoprenoidal compounds are also abundant in the flash pyrolysates of the OAE1b sediments of the SEFB [*Höld et al.*, 1998; *Vink et al.*, 1998]. In sharp contrast pyrolysates from the C/T OAE [*Kuypers et al.*, unpublished results] and from ancient marine kerogens in general [e.g. *Sinninghe Damsté et al.*, 1989; *Eglinton et al.*, 1990; *Larter and Horsfield*, 1993; *Hartgers et al.*, 1994a] are dominated by *n*-alkanes/*n*-alkenes, alkylbenzenes and/or alkylthiophenes, while isoprenoidal compounds are only present in relatively low amounts.

Thin laminae of amorphous OM (as revealed by SEM, Fig. 8) that occur throughout the black shale interval make up a significant part of the OM of the OAE1b sediments. The macromolecular OM of the laminae was isolated from the sediments by density centrifugation using pure DCM (floating fraction). This OM can neither be hydrolysed by strong acid nor base and also shows the strong enrichment in ¹³C (δ¹³C_{TOC} = -15.5‰) typical for the archaeal lipids. Flash pyrolysis of this amorphous OM releases almost exclusively C₈-C₁₅ isoprenoidal alkenes/alkanes

(Fig. 7b). Small amounts of TMI (I) and mono-unsaturated PMI (II:1) were also detected in the pyrolysate (Fig. 7b). Absorption bands at 2929, 1458 and 1378 cm^{-1} in the Fourier transform infrared spectrum of the isolated OM are consistent with the aliphatic isoprenoid nature of the macromolecular material.

Figure 7. Gas chromatograms of the flash pyrolysates (Curie temperature of 610 °C) of decalcified and extracted sediment (a), and macromolecular material isolated by density centrifugation (b), and gas chromatogram of hydrocarbon fraction released after RuO_4 treatment of the isolated macromolecular material (c) from the OAE1b black shales of ODP Site 1049C. Filled triangles, open triangles, open diamonds, filled hexagons and open hexagons indicate

acyclic saturated isoprenoids, mono-unsaturated isoprenoids, isoprenoid ketones, branched mono-acids and branched and straight chain diacids, respectively. Brackets with arabic numbers indicate isoprenoid isomers with the same number of carbon atoms (i.e. C₈ to C₁₅). Roman numbers refer to structures shown in the Appendix.

Figure 8. SEM of laminae of amorphous, macromolecular organic matter from the OAE1b black shales of ODP Site 1049C.

Chemical degradation (i.e. RuO₄ oxidation) has been a useful method in the analyses of aliphatic biomacromolecules because it releases characteristic, GC-amenable fragments from the macromolecules [Blokker *et al.*, 1998; Schouten *et al.*, 1998]. Fragments containing either carbonyl or carboxyl functionalities or both are released from the macromolecules upon RuO₄ oxidation depending upon the original functional group and its position (Fig. 9).

Figure 9. Schematic representation of the main reactions involved in the RuO₄ oxidative degradation of double bonds and alcohols (a), and single and vicinal ether-linkages (b).

RuO₄ oxidation of double bonds and vicinal ether-linkages give similar products; straight-chain compounds yield fragments containing one or more carboxyl groups while some branched compounds yield fragments containing carbonyl groups. Oxidation of alcohols or single ether-bonds

on the other hand releases exclusively compounds containing carbonyl groups [see also *Blokker et al.*, 1999] for a more thorough discussion]. RuO₄ oxidation of the amorphous OM isolated by density centrifugation from the black shales releases almost exclusively compounds with acyclic isoprenoidal carbon skeletons. More specifically, the RuO₄ degradation products (Fig. 7c) are dominated by C₈-C₁₄ isoprenoidal mono-acids/ketones and C₄-C₈ straight chain/branched dicarboxylic acids (**XVII-XXXIII**). The $\delta^{13}\text{C}$ values of the C₈-C₁₄ isoprenoidal mono-acids/ketones are between -12 and -17‰, with a weighted average of -14‰. This weighted average is in good agreement with the bulk isotopic composition of the OC from the laminae, indicating that these degradation products represent the main building blocks of this polymeric OM. RuO₄ oxidation of the amorphous OM of the OAE1b black shales from the SEFB also released mainly compounds with acyclic isoprenoidal carbon skeletons, albeit almost exclusively smaller than C₁₀. Since the isolated organic material of ODP site 1049C is macromolecular, the mono- and dicarboxylic acids and the ketones released upon RuO₄ oxidation can not only derive from hydroxyl-groups and double bonds. Ether-bonds, either vicinal or single, are required to build a macromolecule. The abundance of dicarboxylic acids with both branched and straight-chain carbon skeletons (**XVIII, XIX, XXI-XXIV, XXVI-XXVIII, XXX**) indicates that some of the building blocks contained at least two functional groups; either vicinal ether-linkages or double bonds. In fact the distribution of chemical degradation products is entirely consistent with a polymer consisting of monomers with essentially two different carbon skeletons: TMI (**I**) and PMI (**II**) linked together by vicinal ether-bonds (Fig. 10). The occurrence of compounds containing the TMI and PMI carbon-skeleton in the pyrolysate (i.e **I** and **II:1**, Fig. 7b) of the macromolecular material and their abundance in the extractable OM supports this hypothesis. The lower abundance of dicarboxylic acids relative to monocarboxylic acids in the RuO₄ degradation product mixture could result from either losses of the more water-soluble dicarboxylic acids during the work-up procedure or an incomplete oxidation of the macromolecular material as it is easier to oxidise one than two vicinal bonds. Although no residue was recovered, it can not be excluded that soluble, but non-GC amenable, oligomers were released. This would partly explain the relatively low (~1%) yield of the RuO₄ oxidation as determined by GC. Significant amounts of material may also have been lost by evaporation of volatile short chain products, as highly water-soluble dicarboxylic acids, or as carbon dioxide. In addition, short-chain products formed upon RuO₄ oxidation could remain undetected because they coelute with the solvent peak.

There are no known modern analogues for this TMI/PMI based aliphatic isoprenoidal macromolecular material. In principal this material could either be a biopolymer formed by the archaea themselves, such as a structural component of their cell wall, or a geopolymer formed upon diagenesis after the archaea died. Although aliphatic biopolymers have been identified in cell walls of various organisms such as specific freshwater [e.g. *Blokker et al.*, 1998] and marine [e.g. Gelin et al., 1996], they have never been found in archaea. The absence of a clear cellular structure and the smooth, homogeneous appearance of the thin laminae of macromolecular material are suggestive of a geopolymer rather than a biopolymer. This archaeal-polymer could have formed in a similar way as has been suggested for natural fossil casts of dinoflagellates formed upon polymerisation of unsaturated fatty-acids during early diagenesis [Blokker et al., in prep.]. However, ultralaminae such as those reported in Largeau et al., [1989] and suggestive of cell walls, may have escaped

detection by SEM; thus, based on the available data it is not possible to exclude that the macromolecular OM is actually a biopolymer. On the other hand it is likely that the macromolecular material formed upon cross-linking of PMI and TMI derivatives containing some functional groups such as double bonds. That such functionalities were present in these molecules is indicated by the fact that both a ketone of TMI and sulfur-bound PMI are present in the polar fraction. In any case our data indicate that archaeal macromolecular material is a quantitatively important component of the sedimentary OM of the black shale interval.

Figure 10. Generalised and simplified reconstruction of the proposed TMI/PMI based macromolecular material isolated from the OAE1b black shales of ODP Site 1049C by density centrifugation (floating fraction).

7.3.3.3 Archaeal contribution to the OM. The relative contribution of the archaeal polymer to the OC can be estimated from $\delta^{13}\text{C}_{\text{org}}$ using a two end-member mixing model and assuming that the $\delta^{13}\text{C}$ value ($\sim -24\text{‰}$) for bulk sedimentary OC before the OAE1b represents the non-archaeal endmember and $\delta^{13}\text{C} = -15.5\text{‰}$ the archaeal endmember. Based on this, there is on average a very large (~ 50 wt%) contribution of archaeal OC that even dominates (~ 80 wt%) in some sections of the black shale interval (Fig. 5a). A significant contribution (up to 40 wt%) of archaeal OC is also estimated from the $\delta^{13}\text{C}_{\text{org}}$ values of the black shales of the SEFB using the stable carbon isotopic values of *n*-alkanes and isoprenoids obtained after off-line pyrolysis of the bulk OM [Höld *et al.*, 1998] as algal and archaeal endmembers, respectively (Table 1).

The maximum relative contribution of archaeal OC of ~ 80 wt% for the uppermost part of the black shales of ODP Site 1049C could indicate that environmental conditions were especially favourable for marine pelagic archaea during the latter part of the OAE1b. But this could also be explained by renewed oxygenation of the bottom waters and sediments after OAE1b resulting in the

preferential oxidative removal of labile algal OM relative to the more refractory archaeal polymer from the uppermost part of the black shale interval. Both the observed extreme C_{org}/N_{total} ratios and $\delta^{13}C$ values for bulk OM of the uppermost OAE1b black shale sample could have resulted from such a selective oxidation of OM (Fig.2).

Sample	Thickness (m)	TOC (%)	$\delta^{13}C_{org}$ (‰)	Archaeal OC (%)
3714	0.9	1.7	-24.8	32
3717	1	2.6	-25.0	30
3722	1.25	2.8	-24.6	34
3724	1.37	2.1	-25.2	29
3726	1.42	2.7	-23.9	41

Table 1. Estimated relative archaeal OC contribution to the OAE1b black shales of the Ravel section of the SEFB. TOC content and $\delta^{13}C$ values for bulk OC of these black shales are also indicated. The relative contribution of archaeal OC was estimated from $\delta^{13}C_{org}$ using the $\delta^{13}C$ values of the *n*-alkane ($\delta^{13}C \sim -28‰$) and isoprenoidal ($\delta^{13}C \sim -18‰$) fractions obtained after off line pyrolysis of the bulk OM [Höld *et al.*, 1998] as non-archaeal (e.g. algal) and archaeal endmembers, respectively.

Although prokaryotes can constitute > 70 wt% of carbon biomass in the upper ocean [Fuhrman *et al.*, 1989] and their biomarkers are abundantly present in the sediment [Ourisson and Albrecht, 1992], evidence for a substantial (>10 %) prokaryotic contribution to Phanerozoic sedimentary OC is generally lacking [Hartgers *et al.*, 1994b; Sinninghe Damsté *et al.*, 1997b]. Therefore, the abundance of OM derived from archaea at ODP Site 1049C and the SEFB during OAE1b is unexpected.

7.3.4 Sedimentary OM of the early Albian OAE1b and the C/T OAE black shales: a comparison at the molecular level.

The extractable OM of the OAE1b black shales is clearly dominated by archaeal lipids. In sharp contrast, the extractable OM of the C/T OAE black shales is dominated by molecular fossils (e.g. S-bound 2-methylhopanoids) of cyanobacterial membrane lipids and algal biomarkers such as steroids [Kuypers *et al.*, 1999; Kuypers *et al.*, 2000 submitted to *Paleoceanography*; Kuypers *et al.*, in prep.]. Although archaeal lipids have also been found in the C/T OAE black shales, their contribution to the extractable OM is generally small [Kuypers *et al.*, unpublished data]. While GDGTs **XI-XIV** and PMI have been identified, neither TMI nor the tentatively identified cyclic isoprenoid **V** were found in the C/T black shales. In fact, none of these latter components have so far been reported outside the OAE1b black shale interval.

Archaea-derived C_8 - C_{15} isoprenoidal alkenes/alkanes are by far the most abundant compounds released upon pyrolysis from the OAE1b black shales. The stable carbon isotopic composition of the bulk OC indicates that black shales from OAE1b contain up to 80% of OC derived from archaea. In contrast, isoprenoidal compounds in general are only present in relatively

low amounts in the C/T OAE black shales with the C₁₈ (e.g. pristane, pristene) homologues being most abundant. The C₈-C₁₅ isoprenoidal alkenes/alkanes that characterise the OAE1b interval are extremely rare or absent from the C/T OAE black shales [Kuypers et al., unpublished data]. Instead, *n*-alkanes/*n*-alkenes, alkylbenzenes and/or alkylthiophenes [Kuypers et al., unpublished data], generally dominate the pyrolysates from the C/T OAE. This indicates a non-archaeal, probably phytoplanktonic, source for the OM of the C/T black shales. A predominantly phytoplanktonic origin for the sedimentary OM of the C/T black shales is also suggested by the significant co-variation between the carbon isotopic composition of typical algal (e.g. steroids) and cyanobacterial (e.g. extended hopanoids) biomarkers and bulk OM [Kuypers et al., in prep].

The comparison on the molecular level indicates that not only the sources of the sedimentary OM of the OAE1b and C/T OAE black shales are different, but also that the redox conditions of the water column may have been different during deposition. Molecular fossils (e.g. isorenieratane) of a pigment indicative of anoxygenic photosynthetic bacteria recovered from abyssal and shelf sites indicate that anoxic conditions extended into the photic zone of the southern proto-North Atlantic during the C/T OAE [Sinninghe Damsté et al., 1998]. Isorenieratane was recently also recovered from C/T black shales deposited in the northern proto-North Atlantic, albeit in significantly smaller amounts [Kuypers et al., unpublished data]. In contrast, there were no isorenieratane derivatives found in the OAE1b black shales from the SEFB and ODP Site 1049C, indicating that the specific conditions needed by these bacteria, with overlapping photic and anoxic zone, were not present in the northern-proto North Atlantic/western Tethys during the lower Albian OAE1b.

Although various analysis (e.g. Rock Eval, pyrolysis) indicate that there is only a minor contribution of terrestrial biomass to the insoluble sedimentary OM of both black shales, leaf-wax *n*-alkanes were identified in the saturated hydrocarbon fraction of the OAE1b and the C/T OAE black shales [Kuypers et al., 1999]. In sharp contrast to the C/T OAE [Kuypers et al., 1999] the stable carbon isotopic composition of these leaf-wax lipids does not provide evidence of abundant C₄-type vegetation during OAE1b. This could indicate that atmospheric CO₂ concentrations during the early Albian OAE were significantly higher than during the C/T OAE. Alternatively, abundant C₄-type vegetation did occur during OAE1b but was restricted to the equatorial region (e.g. northern Africa). Compound specific biomarker analyses from early Albian equatorial sites are required to clarify this issue.

7.4 Conclusions

- 1). Archaea-derived isoprenoidal tetraether membrane lipids and free and macromolecularly bound isoprenoid alkanes are abundant in the investigated OAE1b black shales.
- 2). Up to ~40% of the organic matter of the SEFB and up to ~80% of the organic matter of ODP site 1049C preserved in the black shales is derived from archaea.
- 3). The abundance of a GDGT containing a bicyclic and a tricyclic biphytane indicates an important contribution of representatives of the marine planktonic archaea (crenarchaeota).
- 4). To the best of our knowledge this GDGT provides the earliest fossil evidence for marine planktonic archaea, extending their geological record by more than 60 million years.

- 5). The large difference (up to 12 ‰) in $^{13}\text{C}/^{12}\text{C}$ ratio between the algal biomarkers and the much more abundant pelagic archaea-derived biomarkers indicate that the latter were living chemoautotrophically, possibly using ammonium as an energy source.
- 6). There seems to be no unifying mechanism for black shale deposition during the mid-Cretaceous OAEs. Although there are apparent similarities (distinct lamination, low abundance or absence of benthic foraminifers, ^{13}C -enrichment of OC) between the black shales of OAE1b and other OAEs, our detailed molecular work shows that the origin of the OM (prokaryotic versus eukaryotic), redox conditions of the photic zone of the ocean and causes for ^{13}C -enrichment of OC are completely different.

Appendix. Structures of compounds.

Samenvatting

Tussen 130 en 90 miljoen jaar geleden, tijdens het Krijt, was de aarde veel warmer dan zij vandaag de dag is. Deze periode is dan ook niet voor niets bekend als de ‘broeikas wereld’. Dit warme klimaat met veel kleinere temperatuursverschillen tussen de evenaar en de polen dan nu was waarschijnlijk het gevolg van de vulkanische uitstoot van enorme hoeveelheden van het broeikasgas kooldioxide (CO₂).

Tijdens een aantal geologisch gezien korte periodes (elk duurde slechts enkele honderdduizenden jaren) zou echter het gehalte aan broeikasgas tijdelijk kunnen zijn afgenomen als gevolg van de begraving van grote massa's aan organische koolstof in de zeebodem. Zo'n ‘begravings’ episode vond plaats circa 90 miljoen jaar geleden, tijdens een periode van het Krijt die het Cenomaan-Turoon word genoemd. Uit geochemisch onderzoek van chemische fossielen van landplanten blijkt dat er tijdens deze periode een drastische verandering in de Noord-Afrikaanse plantengemeenschappen heeft plaatsgevonden (hoofdstuk 2). In ongeveer 30.000 jaar verdrongen planten, die op een actieve manier de hoeveelheid CO₂ in hun bladeren kunnen verhogen (zgn. C₄-planten), de tot dan toe dominante, maar primitievere planten. Bij deze planten is het de passieve diffusiesnelheid die de hoeveelheid CO₂ in het blad bepaalt. Een dergelijke verandering is hoogst opmerkelijk omdat een actieve, energiekostende manier om CO₂ vast te leggen niet past in het broeikasklimaat van het Krijt. In het Krijt milieu met haar hogere atmosferische kooldioxideconcentraties zijn immers de ‘actieve’ C₄-planten in het nadeel. Wij concluderen dan ook dat de verandering in het Noord-Afrikaanse ecosysteem alleen is te verklaren door een forse (40-80 procent), geologisch gesproken abrupte (in zo'n 60.000 jaar) afname van het broeikasgas.

De oorzaak voor de periodieke begraving van grote hoeveelheden organisch koolstof in de oceaan is nog onduidelijk, maar volgens sommige onderzoekers zijn er aanwijzingen dat veranderingen in oceaanstromingen geleid hebben tot zuurstofloze omstandigheden in bepaalde delen van de zee, waardoor afgestorven algenmateriaal niet werd afgebroken, maar in de bodem begraven werd. Andere onderzoekers denken dat de massale bloei van algen tot de begraving van grote hoeveelheden algenmateriaal heeft geleid onder andere doordat zoveel zuurstof tijdens de bloei aan het oceaانwater onttrokken werd dat minder algenmateriaal kon worden afgebroken. De aanwezigheid van chemische fossielen van fotosynthetische bacteriën die groeien onder zuurstofloze omstandigheden en sporenelementen die aangerijkt worden in het sediment onder dergelijke omstandigheden duiden erop dat ten minste het zuidelijk deel van de Noord Atlantische Oceaan al zuurstofloos was vóór de eigenlijke koolstof-‘begravings’ episode tijdens het Cenomaan-Turoon (hoofdstuk 3). Dit duidt erop dat vermoedelijk een algenbloei tot de verhoogde begraving van algenmateriaal heeft geleid. De onderzochte zeersedimenten uit het Krijt bevatten hiervoor ook directe chemische bewijzen.

Bewijzen voor een algenbloei als oorzaak voor de begraving van grote massa's aan organisch koolstof komen ook van sedimenten uit het Cenomaan-Turoon van het noordelijke deel van de Noord Atlantische Oceaan (hoofdstuk 4). In dit deel van de Noord Atlantische Oceaan was er echter ook in een tijdsbestek van enkele tienduizenden jaren een sterke fluctuatie in de hoeveelheid organisch koolstof die begraven werd. Dit is waarschijnlijk een gevolg van veranderingen in het klimaat van het Krijt. Deze klimaatsschommelingen vonden plaats in

regelmatige periodes van zo'n 20.000 jaar en waren het gevolg van veranderingen in de hoeveelheid zonnestraling die de aarde bereikte door fluctuaties in de baan die de aarde om de zon maakt.

De oorzaak van de algenbloei is nog niet duidelijk. Vast staat echter dat grote hoeveelheden extra voedingsstoffen nodig zijn voor de massale bloei van algen. Twee van de belangrijkste voedingsstoffen voor algen zijn stikstof en fosfor. In hoofdstuk 5 onderzoeken we de rol van bepaalde blauwgroene algen, die in tegenstelling tot andere algen, uit de atmosfeer stikstof kunnen opnemen en dus alleen afhankelijk zijn van de beschikbaarheid van fosfor in de Noord Atlantische Oceaan tijdens het Cenomaan-Turoon. Het blijkt dat deze blauwgroene algen een belangrijk onderdeel waren van de algengemeenschappen en niet alleen organisch koolstof aan het sediment hebben bijgedragen, maar destijds ook extra stikstof aan het zeewater hebben toegevoegd voor de groei van andere algen. Tijdens de 'begravings' episode in het Cenomaan-Turoon zou het omhoogbrengen van fosforrijk water uit de diepere delen van de Noord Atlantische Oceaan, als gevolg van veranderende oceaanstromingen, tot de massale bloei van blauwgroene algen hebben kunnen geleid. Tevens zou dit ook tot de bloei van andere algen, die de extra stikstof konden benutten, kunnen verklaren. De veranderende oceaanstromingen zouden een gevolg kunnen zijn geweest van de vorming van een diepe zeeverbinding tussen de Noord en Zuid Atlantische Oceaan, als gevolg van het uit elkaar drijven van Afrika en Zuid-Amerika.

In hoofdstukken 6 en 7 hebben we de bron voor het organische materiaal van een organische koolstof-begravings episode, circa 110 miljoen jaar geleden, chemisch en microscopisch onderzocht. Hieruit bleek dat niet algen of landplanten de belangrijkste bron van het organisch materiaal zijn, maar archaea die, naast de bacteriën en de organismen met celkern, de derde grote belangrijke onderverdeling van het leven representeren. Dit toont aan dat de organismen die betrokken waren bij de 'begravings' episodes circa 110 en 90 miljoen jaar geleden, totaal verschilden, ondanks het feit dat in vele andere aspecten deze episodes grote overeenkomsten vertonen.

Dankwoord

Een grote groep van mensen heeft geholpen bij het totstandkomen van dit proefschrift. In de acknowledgements van de afzonderlijke hoofdstukken is een aantal van hen al met naam genoemd; hier wil ik het nog eens dunnetjes over doen.

Jürgen Köster, Rikus Kloosterhuis, Sjerry van der Gaast, Michael Böttcher, Jürgen Rullkötter, Michiel Kienhuis, Joe Werne, Elle Hopmans, Patty Slootweg, Marlene Dekker, Wim Pool, Irene Rijpstra, Walter Reints en Marianne Baas wil ik bedanken voor hun hulp bij het genereren en uitwerken van de data. Marianne Baas verdient afzonderlijk nog mijn dank omdat ze mij heeft geïntroduceerd in geochemische labtechnieken. Helaas was ik niet zo'n goede leerling op alle gebieden en bij deze wil ik mij bij haar verontschuldigen voor mijn vrije interpretatie van labtafel-ergonomie.

Met name Richard Pancost, Jochen Erbacher, Ivar Nijenhuis, Stefan Schouten, Peter Blokker, Arnoud Boom, Mark Sephton, Hanno Kinkel en Jaap Sinninghe Damaste dank ik hartelijk voor de stimulerende discussies en hun hulp bij het schrijven van de diverse manuscripten.

Mijn promotor Prof. Dr. Jan de Leeuw, wil ik bedanken voor zijn constructieve opmerkingen op de inhoud van dit proefschrift.

Een woord van dank ook aan mijn co-promotor en begeleider, Jaap Sinninghe Damsté, voor het opzetten en sturen van het onderzoek, en voor de grote mate van vrijheid die ik kreeg tijdens het uitvoeren daarvan, en voor het geduld dat hij heeft opgebracht bij het reviseren van de vele manuscript-versies.

Voor hun steun en het creëren van een prettige werksfeer: dank aan mijn collega's van de afdeling Mariene Biogeochemie en Toxicologie.

Tot slot dank ik ook John Jagt, omdat ik zonder hem nooit aan dit onderzoek begonnen zou zijn, als ook mijn ouders, Pupu Koski, vrienden en familie voor hun steun gedurende de afgelopen jaren.

Curriculum Vitae

Marcel Kuijpers werd op 6 juni 1970 geboren in Hunsel. Na de MAVO en HAVO doorlopen te hebben volgde hij een opleiding organische chemie aan het HLO te Sittard waar hij, na stage te hebben gelopen bij Andeno B.V. te Venlo-Blerick, zijn diploma behaalde in 1992. Vervolgens studeerde hij organische chemie aan de Katholieke Universiteit Nijmegen. Deze studie werd in 1995 afgerond. Na driekwart jaar vrijwilligers werk aan het Natuurhistorisch Museum Maastricht en een zeer kortstondig verblijf in militaire dienst is hij in 1996 in dienst getreden van NWO als onderzoeker-in-opleiding aan het Nederlands Instituut voor het Onderzoek der Zee bij de afdeling Mariene Biogeochemie en Toxicologie. Aansluitend op dit promotieonderzoek is hij als Postdoc gestart bij de afdeling Biogeochemie van het Max-Planck-Institut für Marine Mikrobiologie te Bremen.
