Surface Structure of Untreated Parallel and Fishbone Carbon Nanofibres: an Infrared Study

Abstract

The surface structure of untreated parallel and fishbone carbon nanofibres has been studied with transmission infrared spectroscopy. From a comparison of the spectra of the nanofibres and two graphites it can be concluded that both parallel and fishbone carbon nanofibres have a defect-rich graphitic surface structure. These defects bring about the presence of CH$_2$/CH$_3$ groups as well as aromatic C-H groups on both types of fibre. Moreover, on the fishbone carbon nanofibres some surface oxides are formed at the defect sites. Not much difference between parallel and fishbone carbon nanofibres is found, suggesting that the surface reactivity of parallel and fishbone carbon nanofibres is about the same.
2.1 Introduction

Carbon nanofibres (CNFs) that are obtained by catalytic decomposition of carbon-containing gases on small metal particles are a promising catalyst support material for liquid-phase reactions. The fibres are mechanically strong and can withstand the forces involved in vigorous agitation of the reaction medium. Furthermore, the skeins of fibres possess a mesoporous macrostructure, which decreases the possibility to encounter diffusion limitation during catalytic reactions in the liquid phase. The structure of the CNFs can be tuned by changing the growth conditions and their hydrophobicity can be controlled by surface oxidation. Moreover, carbon nanofibres are very pure. They contain no other types of carbon, such as carbon onions, fullerenes or amorphous carbon, and no heteroatoms, such as sulphur, are incorporated during synthesis. They are chemically inert and can be used in strongly acidic or basic liquids. When grown in a fluidised bed reactor, carbon nanofibres can be obtained at low cost, making application as a catalyst support material possible. Finally, after deactivation of the catalyst CNFs can be readily combusted to recover the precious metal component of spent catalysts, without leaving ash residues.

The mechanism of growth of CNFs has been studied extensively. By changing the growth conditions or the metal, carbon nanofibres of a different structure can be obtained. Fishbone as well as parallel types of CNFs can be distinguished. With fishbone nanofibres the graphitic planes are oriented at an angle to the fibre axis, whereas with fibres of the parallel type the graphitic layers are oriented parallel to the axis. Due to the different structure, the surface structure of parallel and fishbone carbon nanofibres have to differ as well. With the parallel fibres the surface consists of basal graphitic planes, whereas with fishbone fibres the edges of the graphitic layers are exposed. Consequently, one can assume that with parallel CNFs no hydrogen is present on the surface as it consists of closed graphene layers. With fishbone fibres, on the other hand, the graphitic edges could very well be terminated by hydrogen.

For the use of carbon nanofibres as a catalyst support it is important to be able to modify their surface, for instance, by the introduction of oxygen containing surface groups. A better interaction of the fibres with catalyst precursor complexes can thus be achieved. It is also viable to use these surface oxides as anchoring sites for the immobilisation of larger molecules and metal-ligand systems. Finally, the hydrophobic or hydrophilic character of the carbon nanofibres can be controlled by surface modification. The difference in surface structure of parallel and fishbone carbon nanofibres may induce a different surface reactivity. For instance, it can be expected that fishbone fibres, which terminate with the more reactive graphitic edges, are more liable to surface oxidation than parallel CNFs. As a first step towards an understanding of the surface reactivity and the mechanism of surface modification of carbon
nanofibres, it is, therefore, important to gain knowledge about the surface structure of the fibres.

Teunissen and co-workers\textsuperscript{6} performed Electron Energy Loss Spectroscopy (EELS) measurements and concluded that with parallel carbon nanofibres no hydrogen was present at the edges of the fibres, which indicates that the outer layers consist of closed graphene planes. With fishbone CNFs, on the other hand, the edges of the fibres were terminated with carbon-hydrogen bonds. These bonds were thought to belong to aliphatic CH$_2$ groups, while no conclusions could be drawn concerning the presence or absence of aromatic C-H groups. These findings correlate well with the assumed surface structure of the different fibres.

The EELS study performed by Teunissen \textit{et al.}\textsuperscript{6} has given very valuable information about the surface structure of parallel and fishbone carbon nanofibres. However, the study did not take into account the possible connection between the presence of defects and carbon-hydrogen bonds. Accordingly, their EELS measurements were performed on small, perfectly ordered regions of parallel fibres. The volume of carbon nanofibres analysed was, furthermore, very small.

The presence of defects is very likely since the graphitic ordering within carbon nanofibres is less than in well-crystallised graphite.\textsuperscript{1, 10} The d(002) spacing of the CNFs being larger than that of graphite reflects the lower ordering. Synthetic graphite can be made by decomposition of gaseous hydrocarbons at hot surfaces. Anderson\textsuperscript{11} found that in the early stages of graphitisation the interlayer spacing is higher than the ideal 0.336 nm. Boehm\textsuperscript{12} also noted that the distance between the graphitic layers in microcrystalline carbon is larger than in graphite. The decreased graphitic ordering of CNFs is most probably the origin of defects in their structure. Hydrogen may well be localised at these defect sites. It is, therefore, possible that parallel carbon nanofibres contain carbon-hydrogen species too.

In this investigation, we have studied the surface structure of parallel and fishbone carbon nanofibres with infrared spectroscopy. With IR spectroscopy a larger part of the surface of CNFs is analysed than with EELS. Therefore, it is possible to get an 'overall' impression of the surface structure of carbon nanofibres. Although the strong absorption of light by carbon nanofibres makes infrared spectroscopic analysis very difficult, this study teaches that IR spectroscopy is a suitable technique to investigate carbon nanofibres. A comparison of spectra of graphite and CNFs shows that the carbon nanofibres have a defect-rich structure and that carbon-hydrogen bonds are present on parallel as well as fishbone fibres.
2.2 Experimental

2.2.1 Growth of carbon nanofibres

Carbon nanofibres of the parallel and the fishbone type were produced by catalytic decomposition of CO/H\textsubscript{2} or CH\textsubscript{4} on Ni/Al\textsubscript{2}O\textsubscript{3} catalysts, respectively.\textsuperscript{3-6}

The Ni/Al\textsubscript{2}O\textsubscript{3} catalysts with 20 or 30 wt% nickel metal loading were synthesised by the deposition-precipitation technique.\textsuperscript{13} Alumina (Alon-C, Degussa) was suspended in an acidified aqueous solution of nickel nitrate (Acros, 99 %) and diluted ammonia was injected within two hours at room temperature under vigorous stirring until the pH had reached a value of 8.5. After overnight stirring, the suspension was filtered, washed, and dried at 120°C. Finally, the catalyst was calcined at 600°C in stagnant air for three hours.

Parallel carbon nanofibres were synthesised in small quantities in a fully automated micro-flow system. Fishbone carbon nanofibres, on the other hand, were grown on a larger scale in a manually operated set-up. Therefore, somewhat different synthesis conditions were employed.

For the growth of parallel carbon nanofibres, 100 mg of the 20 wt% Ni/Al\textsubscript{2}O\textsubscript{3} catalyst was reduced at 700°C in 20 % H\textsubscript{2}/Ar (flow rate 100 ml/min) in the micro-flow reactor for two hours. After reduction, the temperature was decreased to 600°C and synthesis gas (20 % CO and 7 % H\textsubscript{2} in Ar, flow rate 100 ml/min) was passed through the reactor during 10 hrs. After reaction, about 0.5 g of parallel CNFs were collected.

For the production of fishbone CNFs, 0.5 g of the 30 wt% Ni/Al\textsubscript{2}O\textsubscript{3} catalyst was reduced at 600°C in 14 % H\textsubscript{2}/N\textsubscript{2} (flow rate 350 ml/min) in a vertical tubular reactor (diameter 3 cm) for two hours. After having decreased the temperature to 570°C, methane (50 % in N\textsubscript{2}, flow rate 450 ml/min) was passed through the catalyst bed for 6.5 hours. The yield of fibres amounted to approximately 12 g.

2.2.2 Characterisation of carbon nanofibres

The parallel and fishbone carbon nanofibres were characterised by transmission electron microscopy (TEM), nitrogen physisorption, X-ray diffraction (XRD), thermogravimetric analysis (TGA), and infrared spectroscopy (IR).

TEM samples were prepared by dispersing ground nanofibres in ethanol by ultrasound and drying a drop on a copper grid covered by a holey carbon film. They were imaged in a Philips CM-200 electron microscope operating at 200 kV.

CNF samples were de-gassed at 120°C in vacuum for at least 16 hours and nitrogen adsorption-desorption isotherms were measured at −196°C on a Micromeretics ASAP 2400 apparatus. Specific surface areas and pore volumes were calculated from the data obtained.
Powder XRD measurements were performed using an ENRAF-NONIUS X-ray diffraction system equipped with a curved position-sensitive INEL detector operating up to a width of 120°2θ. The applied radiation was Co Kα (λ = 1.78897 Å).

TGA analyses were carried out on a Netzsch STA-429 thermobalance. The gases evolved during analysis were monitored by a Fisons Thermolab quadropole mass spectrometer, using a capillary situated directly above the sample cup. Samples of 20-100 mg were heated in 60 ml/min Ar at a rate of 300°C/h to 850°C.

Diffuse reflectance infrared (DRIFT) was executed on a Perkin Elmer 1600 spectrometer equipped with a Spectra-Tech DRIFT accessory. Two hundred and fifty-six scans were co-added at a resolution of 2 cm\(^{-1}\) and a strong apodisation. Dilutions of 1 % (m/m) powdered sample in KBr were used. Transmission infrared spectra were recorded on a Perkin Elmer 2000 spectrometer equipped with an air dryer for removal of water vapour and carbon dioxide. One hundred scans were co-added at a resolution of 8 cm\(^{-1}\) and a boxcar apodisation. Samples were prepared by thoroughly mixing a small amount of ground nanofibres with pre-dried KBr. Tablets were pressed at 4 tons/cm\(^2\) in vacuum for two minutes. The concentration of the nanofibres ranged from 0.1 to 1 ‰ (m/m). All transmission spectra were baseline corrected.

2.3 Results

*Transmission electron microscopy*

Figure 2.1 shows high resolution TEM micrographs of a parallel and a fishbone nanofibre. The graphitic layers are clearly visible. The images show that parallel and fishbone CNFs had been synthesised indeed. With the parallel fibres, perfect graphitic regions are alternated with defect regions. In Figure 2.1A some defects can be distinguished. Other images demonstrate that regions exist where the planes are bend, broken or interrupted. The micrograph of the fishbone fibre (Figure 2.1B) shows that the graphitic layers are oriented at an angle to the outer surface of the fibre (i.e., the axis of the fibre). Many planes are bend and careful examination establishes that planes merge, split and end. Moreover, the angle of the planes with respect to the fibre axis varies from almost parallel to more than 45°. From an image of fishbone fibres at lower magnification (see Figure 2.2), it can be made out that the fibres themselves are bend as well.

*Macrostructure*

The growth of parallel carbon nanofibres from CO/H\(_2\) at 600°C results in a relatively open macroscopic structure of a low mechanical strength and density. The aggregates appear powdery and can easily be broken. The results of the analysis of the N\(_2\)-physisorption data and the observed fibre diameters with TEM are presented in Table 2.1. A specific surface area of 158 m\(^2\)/g and a pore volume
of 1.16 ml/g are obtained. No micropores are present. The diameter of the fibres varies between 15 and 20 nm. The fishbone carbon nanofibres, grown from CH₄ at 570°C, exhibit a strongly interwoven structure. This results in mechanically strong macroscopic bodies of a higher density than that of parallel nanofibres. A specific surface area of 103 m²/g and a pore volume of 0.31 ml/g are found, again

Figure 2.2  Transmission electron microscopy image of fishbone carbon nanofibres.
with no micropores present (see Table 2.1). The diameter of the fishbone fibres ranges from 20 to 90 nm. For both types of fibre a d(002) spacing of 0.344 nm is found with XRD. The width of the XRD peak is large compared to that of graphite.

**Figure 2.3**  DRIFT spectra of parallel carbon nanofibres (CNF) and a DARCO KBB activated carbon (AC).

It must be noted that \( \text{Al}_2\text{O}_3 \), originating from the growth catalyst, is still present in the nanofibre samples. It was ascertained that the presence of \( \text{Al}_2\text{O}_3 \) did not interfere with the infrared study of the CNFs. The \( \text{Al}_2\text{O}_3 \) was not
removed, since the prolonged treatment with concentrated acids, needed for removal of the Al₂O₃, would modify the surface of the nanofibres as well.

**Infrared nanofibres**

In Figure 2.3 DRIFT spectra of parallel CNFs and a Darco KBB activated carbon are displayed. Whereas the activated carbon exhibits clearly distinguishable infrared bands, the spectrum of the parallel fibres shows only one straight line. These findings illustrate that although DRIFT spectroscopy is a surface-sensitive technique, it is not suitable for obtaining spectra of carbon nanofibres. Remarkable is the difference between the CNFs and the activated carbon. It is clear that the former absorbs much more infrared light than the latter. In other words, carbon nanofibres are highly opaque.

![Image of Figure 2.4](attachment:image.png)

**Figure 2.4** IR spectra of untreated parallel and fishbone carbon nanofibres. 2000-500 cm⁻¹ range.

In order to get better infrared spectra of carbon nanofibres, transmission IR was applied. The strong IR absorbance of the fibres necessitated a very low sample concentration. To allow comparison, transmission levels of all spectra were kept approximately the same. It was established that, within the transmission window used, the intensity of the bands did not depend upon the transmission level of the spectra. Figure 2.4 shows spectra of parallel and fishbone nanofibres in the 2000-500 cm⁻¹ range. Table 2.2 summarises all infrared band assignments. As a significant water contamination due to the low
sample concentrations was likely, the band at 1633 cm\(^{-1}\) can be discounted as being due to adsorbed water.\(^{14,15}\) This is supported by the observation that the band disappeared when the KBr-fibre mixture was dried at 80°C for several days before the tablet was pressed. The water is most probably exclusively adsorbed onto the KBr as the fibres are hydrophobic and no \(\text{H}_2\text{O}\) evolved during TGA analysis with a fibre sample. The sharp peak at 1384 cm\(^{-1}\) can also be discounted as being due to traces of nitrate, formed from \(\text{NO}_x\) taken up from the air.\(^{16,17}\) Both the 1384 and the 1633 cm\(^{-1}\) band are present in the KBr backgrounds too.

The bands at about 1580 and 1200 cm\(^{-1}\) can be assigned to carbon skeleton vibrations.\(^{14,15,18,19}\) The higher wavenumber absorption is associated with an aromatic ring stretching mode, found at slightly higher wavenumbers in carbon blacks by Prest \textit{et al.}\(^{14}\) (1595 cm\(^{-1}\)) and in coal samples by Painter \textit{et al.}\(^{18}\) (1600 cm\(^{-1}\)). For parallel carbon nanofibres, however, Shaffer \textit{et al.}\(^{15}\) observed this band at 1550 cm\(^{-1}\) while Mawhinney and co-authors\(^{19}\) detected this band at 1581 cm\(^{-1}\) for single-walled carbon nanotubes. The lower wavenumber absorption at about 1200 cm\(^{-1}\) is related to C-C stretching vibrations.\(^{14}\) Prest\(^{14}\) and Shaffer\(^{15}\) observed this band at 1245 cm\(^{-1}\) and at about 1200 cm\(^{-1}\), respectively.

The band at 880-870 cm\(^{-1}\), present in both types of fibre, can be assigned to isolated aromatic C-H out-of-plane bending vibrations.\(^{18}\) Painter \textit{et al.} found that after deconvolution two bands at 888 and 854 cm\(^{-1}\) resulted that could be ascribed to lone aromatic C-H groups in different local environment. The very weak band at 1717 cm\(^{-1}\), present in the spectrum of the fishbone nanofibres, is attributed to the \(\text{C}=\text{O}\) stretching vibration of carbonyl or carboxylic acid groups.\(^{14,18,20,21}\)
TGA-MS analysis showed that a small weight loss is accompanied with the evolution of CO with the parallel nanofibres and the release of CO and CO$_2$ with the fishbone CNFs. Apparently, some oxygen is already present on untreated nanofibres. Considering the finding that only fishbone CNFs lose CO$_2$ when heated in Ar, the 1717 cm$^{-1}$ band may be associated with the C=O vibration of carboxyl groups. Finally, the additional band at 1454 cm$^{-1}$ in the spectrum of the parallel fibres is assigned to CH$_2$ and CH$_3$ bending vibrations. Painter et al. and Gómez-Serrano and co-workers observed this vibration at 1450 cm$^{-1}$ and 1460 cm$^{-1}$, respectively.

The 3200-2700 cm$^{-1}$ range of the spectra provides more insight into the presence of carbon-hydrogen groups on the fibres (see Figure 2.5). Four minima can be distinguished at 3012, 2947, 2917 and 2846 cm$^{-1}$, respectively. The peak at 3012 cm$^{-1}$ can be assigned to aromatic C-H stretching vibrations, whereas the other three absorptions are associated with CH$_2$ and CH$_3$ stretching vibrations. Painter and co-workers observed these bands at about 2950, 2920 and 2850 cm$^{-1}$. On the basis of the assignments most often made in this region of the spectrum, it is tempting to attribute the peak at 2947 cm$^{-1}$ to antisymmetric stretching modes of CH$_3$ groups and the minima at 2917 and 2846 cm$^{-1}$ to the antisymmetric and symmetric vibrations of CH$_2$ groups. Unfortunately, with carbonaceous materials these bands must be considered a composite of various
overlapping contributions. Infrared studies of hydroaromatic model compounds have shown that the position of the vibrational bands of both methyl and methylene groups is dependent upon the structure of those compounds. Only the absorption at about 2850 cm\(^{-1}\) is not very sensitive to the structure and thus can point to the presence of CH\(_2\) groups. In summary, the three modes between 3000 and 2800 cm\(^{-1}\) give information about the CH\(_2\)/CH\(_3\) content in carbonaceous materials, but a distinction between CH\(_2\) and CH\(_3\) groups cannot easily be made.

**Figure 2.6** IR spectra of graphite with a low surface area (Fluka) and a high surfac area (HSAG300). 2000-800 cm\(^{-1}\) range.

Infrared graphite

Spectra were recorded of graphite with a low surface area (Fluka, <10 m\(^2\)/g) and a high surface area (TIMCAL, TIMREX HSAG300, 300 m\(^2\)/g). Figure 2.6 represents the 2000-800 cm\(^{-1}\) range of both graphites. The Fluka graphite only shows a weak band at 1578 cm\(^{-1}\), attributed to aromatic ring vibration. The HSAG300 graphite, in contrast, shows four additional absorptions at 1712, 1455, 1188, and 895 cm\(^{-1}\). Furthermore, the intensity of the 1578 cm\(^{-1}\) band is enhanced considerably. Figure 2.7 shows the 3100-2700 cm\(^{-1}\) range of the spectra of both graphites. It is clear that the Fluka graphite does not possess any CH\(_2\)/CH\(_3\) groups, whereas the carbon-hydrogen stretching vibrations are clearly visible in the spectrum of the HSAG300 graphite. A weak band at 3008 cm\(^{-1}\) can also be distinguished.
Chapter 2

2.4 Discussion

The electron microscopy and XRD data indicate that defects are present in the graphitic structure of the carbon nanofibres. With high resolution TEM the defects can be imaged. The bending of the fibres themselves has to result from defects in the graphitic structure. The d(002) value of 0.344 nm found with XRD is significantly larger than the d(002) spacing of graphite of 0.336 nm. Together with the relatively large width of the d(002) peak this implies less graphitic ordering than in graphite and thus a defect-rich structure.

The infrared data show that aromatic C-H as well as CH$_2$/CH$_3$ groups are present on the CNFs. These groups must be localised at defect sites and, for the fishbone fibres, at the edges of the planes. The presence of the 1200 cm$^{-1}$ C-C stretching vibration also points to the existence of defects. Both the 1580 cm$^{-1}$ and the 1200 cm$^{-1}$ bands are present in the spectrum of a heat-treated carbon black. However, single-walled carbon nanotubes, heated to 800°C in vacuum, show only the vibration at 1580 cm$^{-1}$. The band at 1200 cm$^{-1}$, therefore, has to be associated with defects in carbonaceous materials.

In order to get further information about which bands can be associated with defects in graphitic materials, spectra were recorded of a low and a high surface area graphite. Because of the high surface area of the HSAG300 graphite, it is assumed that the graphitic domains are small and that defects are present in the

---

**Figure 2.7** IR spectra of graphite with a low surface area (Fluka) and a high surface area (HSAG300). 3100-2700 cm$^{-1}$ range.
structure, in contrast to the Fluka graphite, which has a low surface area. This assumption is supported by the larger width of the XRD d(002) peak measured for the HSAG300 graphite. The Fluka graphite, which supposedly has perfectly ordered graphitic domains, shows only a weak aromatic ring vibration at 1578 cm\(^{-1}\). In contrast to the Fluka graphite, the HSAG300 graphite shows a clear, broad absorption at 1188 cm\(^{-1}\). These results clearly indicate that the absorption at 1200 cm\(^{-1}\) in graphitic materials is related to the presence of defects in the structure. Along with the defects in the structure other bands appear in the infrared spectrum as well. First, the peaks at 1455, 2846, 2915, and 2948 cm\(^{-1}\) show that CH\(_2\)/CH\(_3\) groups are present. The absorptions at 895 and 3008 cm\(^{-1}\) point out that the presence of defects leads to aromatic C-H groups and the 1712 cm\(^{-1}\) band indicates the appearance of some oxygen containing surface groups. Finally, the decrease of the size of the graphitic domains results in an increase of the intensity of the 1578 cm\(^{-1}\) absorption, because symmetry restrictions are relieved for more aromatic rings.

The infrared results obtained with the two graphites enable us to interpret the spectra of the parallel and the fishbone carbon nanofibres in more detail. We conclude that the graphitic structure of both types of fibres is rich in defects as their spectra show the C-C stretching vibration at 1200 cm\(^{-1}\). These defects give rise to the presence of CH\(_2\)/CH\(_3\) groups as well as aromatic C-H groups on both types of fibres. Moreover, on the fishbone CNFs some surface oxides were formed at the defect sites. For the parallel fibres, the presence of aromatic C-H groups is clearly shown by bands at 872 and 3012 cm\(^{-1}\). The fishbone fibres, on the other hand, show only a band at 882 cm\(^{-1}\). The difference in position of the isolated aromatic C-H out-of-plane bending vibration at 882 cm\(^{-1}\) for the fishbone CNFs and at 872 cm\(^{-1}\) for the parallel fibres points to differences in local environment. For the presence of CH\(_2\)/CH\(_3\) groups, the same trend is visible. CH\(_2\)/CH\(_3\) groups are clearly present on the parallel CNFs (minima at 1454, 2846, 2917, and 2947 cm\(^{-1}\)), whereas for the fishbone fibres only weak absorptions in the 3000-2800 cm\(^{-1}\) range can be distinguished.

Since with parallel fibres the CH\(_2\)/CH\(_3\) bands are more intense in the 3000-2800 cm\(^{-1}\) region and a peak at 1454 cm\(^{-1}\) is visible, it seems that the concentration of these groups is higher with the parallel than with the fishbone fibres. However, other factors may also influence the intensity of these bands. Because of the very high absorption of the CNFs, it is likely that the penetration dept of the IR radiation is smaller than the diameter of the fibres. Therefore, most of the radiation is blocked by the nanofibres. Only at the edges of the fibres the light passes through. This explains the very low sample concentrations needed to obtain a signal. Consequently, the diameter of the fibres and thus their external surface area influences the intensity of the IR signal. The external surface area of parallel fibres is higher than that of fishbone CNFs and as a result more intense CH\(_2\)/CH\(_3\) bands are detected. This explanation is supported by the finding that parallel fibres with an external surface area of 300 m\(^{2}\)/g
(grown out of supported Fe particles) exhibited even more intense \( \text{CH}_2/\text{CH}_3 \) bands. Another factor that can play a role is the macroscopic density of the carbon nanofibre bodies. Bodies of parallel fibres are much less dense than those of fishbone CNFs. Therefore, more infrared light can pass through a particle of parallel carbon nanofibres.

Thus, the higher intensity of the \( \text{CH}_2/\text{CH}_3 \) bands in parallel carbon nanofibres cannot be unambiguously associated with a higher concentration of those groups. Therefore, we conclude that, overall, there is not much difference between parallel and fishbone carbon nanofibres.

At first sight, the present results obtained with infrared and the findings of Teunissen et al. with EELS® seem partly contradictory. Teunissen found that with the parallel carbon nanofibres no carbon-hydrogen bonds could be detected. For the fishbone CNFs, aliphatic \( \text{CH}_2 \) groups were detected and no conclusion could be drawn concerning the presence or absence of aromatic C-H groups. However, the EELS results were obtained by analysing a perfectly ordered region of a parallel CNF. The findings described above have made clear that the presence of \( \text{CH}_2/\text{CH}_3 \) groups is related to defects in the graphitic structure. In view of this, both observations are complementary. The infrared results obtained with fishbone nanofibres have led to the conclusion that these fibres contain \( \text{CH}_2/\text{CH}_3 \) groups. Unfortunately, no distinction between these groups can be made. These findings are in accordance with the conclusions drawn by Teunissen. The presence of aromatic C-H was not observed by EELS, but IR has been able to detect these groups on both types of fibres. Considering the structure of the fishbone CNFs, it is very likely that the carbon edges end in \( \text{CH}_2/\text{CH}_3 \) or aromatic C-H groups.

Because of the defect-rich graphitic structure of both parallel and fishbone carbon nanofibres, there does not seem to be much difference in their surface composition. It is, therefore, also very well possible that the surface reactivity of parallel and fishbone fibres does not differ significantly. The surface reactivity of carbon nanofibres towards oxidising agents will be dealt with in Chapter 3. It should be noted that from a practical point of view fishbone CNFs are more favourable as catalyst support than parallel fibres. Fishbone fibres have a higher cluster density and are mechanically stronger. Furthermore, they can be grown in higher yields.
2.5 Conclusions

Untreated parallel and fishbone carbon nanofibres were studied with transmission infrared spectroscopy. With DRIFT spectroscopy no useful spectra of CNFs could be obtained. From a comparison of the spectra of the nanofibres and two graphites, we conclude that both parallel and fishbone carbon nanofibres have a defect-rich graphitic surface structure. These defects lead to the presence of CH₂/CH₃ groups as well as aromatic C-H groups on both types of fibre. Moreover, on the fishbone CNFs some surface oxides form at the defect sites. Not much difference between parallel and fishbone carbon nanofibres is found, suggesting that the surface reactivity of parallel and fishbone carbon nanofibres is about the same.

Acknowledgements

We wish to acknowledge prof. dr. J.H. van der Maas of the Department of Vibrational Spectroscopy, Utrecht University, for the discussions about the IR data.
